The microscope, on its side, has not been behindhand in the same field, and has told us something more about this organic air dust. It is found to vary in character according to the objects from which it proceeds, and according to the degree of ventilation in an apartment. A microscopist, with his air analyser, would very likely have told Professor Tyndall's audience how they were breathing fragments of each other's clothes, and the scurf skin of each other's hands and faces, besides other matters brought into the Institution by the listeners, or wafted in through the windows; and if a whiff of sewer air had entered the room, living *vibriones* would probably have been among the subjects of the microscopist's demonstration. Chemistry also has been at work in the same direction, and by means at her disposal she has been able to estimate approximately the amount of organic matter in air; and this application of chemical methods is now in common use for determining the state of ventilation in inhabited buildings, as well as the comparative purity of the air in town and country. We are glad that Prof. Tyndall has enlisted optical analysis in the same useful field of inquiry. His lecture, from the perfection of his experiments, was well adapted to impress the advantages of pure air on the minds of his audience and the public at large.

We cannot help feeling, however, that it would have been well if the able lecturer had confined his statement strictly to the scientific aspects of his subject. The germ theory of disease has nothing in common with it, and yet it was referred to as if to show that the fact of organic dust existing in the air rendered the existence of "disease germs," as they are called, more probable than they were before. In scientific subjects we cannot accept mere theories for facts. Let the advocates of disease germs first prove their existence, and then possibly optical and microscopic analysis will throw light on their mode of conveyance.

In imperfect science, as in other imperfect things, the first false step may lead anywhere, as the following extract from Dr. Bryden's singularly interesting report on Indian cholera, one of the supposed germ diseases, will show:—

"The facts of the first European invasion showed that aërial transmission did not account for all the phenomena observed, such as the transmission of cholera by fomites, and the occasional infection of attendants on the sick. Hence there was initiated (*a*) the doctrine that cholera might be propagated by human intercommunication, and, as the latest phase of this doctrine, we find the confident assertion promulgated as a truth, that cholera is always and not occasionally so propagated. To prop up this assertion it was necessary to make a second assumption or theory. And hence arose the doctrine (*b*) that cholera is multiplied in the human economy. But this also must have stood alone and unsupported, unless it could be shown how and where the multiplication took place. And this led on to the starting of the third theory (*c*), which asserts that cholera is multiplied in, and is spread around by, the intestinal evacuations of those already suffering from the disease. But even this, although urged in the most forcible manner, did not meet all difficulties; and there arose the demand that it should be supplemented by a fourth theory. In relation to this demand, the latest theory (*d*) alleges that the evacuations of an individual in whom cholera has not become apparent, and never will appear, may be the means of spreading cholera around."

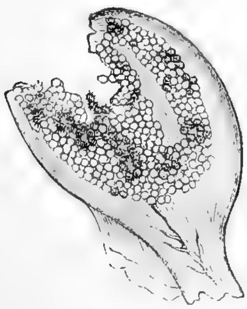
By endeavouring without observation to attain to knowledge which can only be arrived at by observation, theory has, in this instance, walked round in a circle and left science outside. In great questions affecting the health and life of nations, theories are quite out of place. They do no good, cost money, and bar scientific progress.

Practically, so far as health is concerned, Professor Tyndall has given us a scientific account, not only of certain optical properties of impure air, but likewise of the benefit of several popular practices, such, for example, as lighting fires during epidemics to purify the air, the use of gauze curtains in malarious districts as a protection against fever, covering the mouth with a cloth during sleep in fever countries, and the like. He has further given us an additional means of estimating the purity or impurity of the air we breathe. He has shown that heat purifies, more or less, impure air; and that impure air can be deprived of its suspended impurity by filtering it, as is the case with water. On the real proximate aërial cause of disease, if such there be, no new light has been yet thrown either by the optician, the microscopist, or the chemist.

VEGETABLE MONSTROSITIES

Vegetable Teratology: An Account of the Principal Deviations from the usual Construction of Plants. By Maxwell T. Masters, M.D., F.L.S. With numerous illustrations by E. M. Williams. (Published for the Ray Society. 1869.)

IN the volume before us we have the most complete account that has yet been given to the public of the various aberrant forms which are from time to time presented by the different organs of which plants are composed. Such investigations are no mere idle amusement for the leisure hours of naturalists, but have an important scientific bearing. Since botanists have attempted to arrange the vegetable kingdom in a classification possessing a higher claim to the title of "natural" than that proposed by Linnæus, it has been acknowledged that the true, though hidden, relationships of a genus may often be indicated by an abnormal or monstrous variety. A new interest has been given to these inquiries by the theory, now so generally adopted by naturalists, that affinity in structure is but an indication of consanguinity in descent; these exceptional forms or "sports" being regarded as frequently reversions to an ancestral type of structure. Apart, however, from such modifications as are of importance in systematic botany, there are others which are noteworthy as throwing light on controverted points in morphology, and on the relation to one another of the different organs. Among these are the exact morphological character of the carpel, viewed in the light of a metamorphosed leaf; and of the so-called "inferior" ovary, whether its covering is to be considered as a united calyx-tube, or as a modified continuation of the axis. The occasional substitution of one organ for another is carried to a far greater extent in the vegetable than ever appears, even occasionally, in the animal kingdom. As Dr. Masters remarks, the animal physiologist would regard as an incredible monstrosity the replacement of sperm-cells by germ-cells, or the converse; although these are comparable to abnormal growths, of which several are recorded, where ovules are borne by stamens, or pollen is produced inside ovules. The two wood-cuts which we give illustrate these remarkable transformations.



Pollen within Ovule of Passiflora

Ovule-bearing Anther of Cucurbita

De Candolle was the first systematic botanist to draw attention to the importance of Vegetable Teratology: he was followed by Moquin-Tandon, Morren, and others; and the great work of Moquin-Tandon has been followed by Dr. Masters in the main in classifying the phenomena under discussion. This classification of an enormous number of isolated facts presents considerable difficulties. It might at first sight appear as if the most natural arrangement would be to arrange under one head all the known modes of malformation or aberration of each organ: but this plan would involve much repetition, from the frequency with which it happens that similar organs are abnormally affected in the same manner; as when the parts of the calyx and corolla are both unduly increased in number. The plan adopted by Dr. Masters, though very artificial, possesses the advantage of clearness and of easy reference. He divides the phenomena of Teratology into four sections: 1, Deviations from ordinary Arrangement; 2, Deviations from ordinary Form; 3, Deviations from ordinary Number; 4, Deviations from ordinary Size and Consistence; each with several subdivisions. Until we know more of the cause of these variations from ordinary structure, a more scientific classification would appear to be hopeless.

The work is essentially one of reference, a collection of facts rather than a statement of theories. An enormous number of instances, illustrative of every conceivable variation from normal structure, has been collected with unwearied assiduity from English and foreign records, and with that personal knowledge of the subject which few possess to so great a degree as the author. Where Dr. Masters so far strays from his subject as to enter into morphological questions, as when he discusses the irregular monandrous flower of Orchids, we are tempted to wish that he had permitted himself more digressions of the kind.

The text is illustrated by a large number of woodcuts, original and copied, which add greatly to the clearness of the descriptions; and not the least valuable portion of the work is the long list of references at the end of each section to papers and monographs bearing upon it, forming a complete bibliography of the subject. In the lists of plants which are mentioned as peculiarly subject to each description of malformation, we could wish that more care had been taken not to designate the same plant by more than one scientific name, a practice confusing to the student. We also regret that in some instances recognised botanical terminology has been departed from; as in the distinction drawn by Lindley and Oliver between "regularity" and "symmetry." These, however, are but minor defects in a work which we can cordially recommend to all students of botany, who are interested in the real structure of the various organs of plants.

A. W. BENNETT

ATTFIELD'S CHEMISTRY

Chemistry: General, Medical, and Pharmaceutical, including the Chemistry of the British Pharmacopœia. By John Attfield, Ph.D., F.C.S. 1 vol. pp. 624. (London: Van Voorst.)

THIS book is mainly intended to supply the want of a manual more expressly suited to the requirements of students of medicine and of pharmacy. A work of this nature necessarily differs in many particulars from the ordinary run of chemical manuals, and it would be unjust, therefore, to judge of it altogether by the standards generally employed in determining the degree of excellence of such books. It is obviously impossible for the medical student to make himself acquainted with the multitude of organic compounds known, the greater portion of which are simply interesting to the scientific chemist on account of the theoretical opinions based on them; and hence it would manifestly be absurd to censure the author of this book for the fact that much of what constitutes modern organic chemistry is either but cursorily treated, or altogether omitted. Nor, on the other hand, should he be blamed for giving what might otherwise appear undue prominence to the descriptions of substances which are simply interesting from the fact of their application as remedial agents, but of which the chemical constitution is either entirely unknown or but imperfectly understood. In all that concerns the most immediate objects which the author had in view in its compilation, his book is a faithful record of the present state of the science. Thus, on page 353 we notice a very complete description of the method of preparing the newly-discovered alkaloid apomorphia, the remarkable physiological effects of which have lately attracted so much attention. The plan of the work is entirely novel. The author commences with some very pertinent advice to candidates as to the best method of studying the book in order to fit themselves for examination by the various boards. After the usual introduction, the student passes on to the practical study of the general properties of the non-metallic elements, and when he has familiarised himself with the various manipulative processes, and acquired a certain amount of chemical knowledge, he proceeds to the study of the general principles of chemical philosophy. The properties of the various metallic elements, their official preparations, and the tests employed in their detection, next engage his attention; after which he is put through a systematic course of qualitative analysis. The student next occupies himself with the study of the compounds of vegetable and animal origin, with the reactions of the alkaloids and of some other organic principles, and of the various substances which the author distinguishes as Galenical, and which can only fairly be regarded from a pharmaceutist's point of view, many of them being "not yet brought within the grasp of the chemist." The principles of toxicology, and the various methods employed in the examination of morbid urine and calculi, are then explained, and the different classes of official, Galenical, and chemical preparations enumerated. A course of quantitative analysis, sufficiently comprehensive for the student's requirements, and consisting of both gravimetric and volumetric processes, next follows. Several of the gravimetric methods are, however, in our opinion not the best at the disposal of the analyst. Thus, for the estimation of nitric acid Frankland and Armstrong's method of determining the amount of that acid in potable waters, is the only one recommended. This method, although doubtless excellently adapted to the purpose for which it was devised, is not, however, generally applicable. We would recommend the method of Vernon Harcourt to Dr. Attfield's attention. With some slight modifications, this method is pronounced by Professor Bunsen, of Heidelberg, in whose laboratory it is constantly used, to be by far the best of the many processes hitherto proposed for the estimation of nitric acid; and in the laboratory to which the writer is attached it is frequently employed with the most satisfactory results. The account given of the processes for the ultimate analysis of organic substances also appears to be somewhat defective, and the statement that the best combustion-furnace is that known as Hofmann's is open to dispute. The furnaces of Eslenmeyer and of Donny as modified by Glaser are certainly to be preferred; indeed, we understand that the Berlin professor has already renounced the use of the furnace which bears his name. Dr. Attfield is surely in error, also, in recommending (page 460) that the boiling point of a liquid should be determined by inserting the bulb of the thermometer in the heated liquid. Kopp pointed out long ago the errors incidental to this method of procedure. These, however, are defects of but minor importance, and may easily be remedied in future editions. We have derived much satisfaction from the perusal of Dr. Attfield's book: it is eminently practical in its character, and is written with a just appreciation of the small amount of time for the study of chemistry at the disposal of the student in medicine and pharmacy.

OUR BOOK SHELF

Japanese Shells.—*Japanische Meeres-conchylien.* By Dr. C. E. Lischke. (Cassell: 1869.) Quarto, with 14 coloured plates.

JAPAN is not less remarkable for the works of its people than for its natural productions. Its sea-shells are of a mixed character, arctic and tropical. Some species range to the Mediterranean; for *Verticordia granulata* of Seguenza, from the Sicilian tertiaries, which I have now discovered living in the Gulf of Egina at a depth of 130 fathoms, was lately dredged by Mr. A. Adams in the seas of Japan, and is described by him as *V. multicostata.* Another species of *Verticordia*—or perhaps more correctly *Hippagus*—the *H. acuticostatus* of Philippi, a Calabrian and Sicilian fossil (which occurs also in our Coralline Crag, under Sowerby's name of *V. cardiiformis*), is the *V. Deshayesiana* of Fischer, and *V. Japonica* of A. Adams, from China and Japan. The only other known living species of *Hippagus* (*Trigonulina ornata*, D'Orbigny = *H. novemcostatus*, Adams and Reeve) is common to the West Indies and China. Unfortunately we know far too little of the former and present course of those great currents which traverse the ocean in every direction, to be able to explain satisfactorily the geographical distribution of the marine fauna. Nevertheless, although physical data are wanting, zoological facts are accumulating; and Dr. Lischke, as well as Mr. Arthur Adams, have rendered great assistance by their investigation of the Japanese mollusca. The present is not a complete treatise on the subject; but it shows great care and critical acumen, and it is beautifully illustrated. The author is Oberburgomeister of the large manufacturing town of Elberfeld, and finds time not only for his onerous public duties, but also for good scientific work; so that in other countries besides our own, writers on natural history are not confined to the class of paid professors.

J. GWYN JEFFREYS

Chemistry for Schools.—*An Introduction to the Practical Study of Chemistry.* By C. Haughton Gill, Assistant Examiner in Chemistry at the University of London. (London: Walton.) 8vo. pp. xv. and 315. 1869.

DURING the last few years the subject of science teaching in schools has occupied so much attention that a special class of manuals has been originated for the schoolmaster's use. Those which treat of Chemistry have been in some cases experiments, seldom remarkable for true appreciation of their professed purpose, or, perhaps, merely the pecuniary speculation of an ignorant writer. Under such circumstances, it is gratifying to meet with a book of this kind, which really is what it was intended to be—"a sufficient manual of chemistry for schools and junior students, and an aid to teachers wishing to introduce the science into the ordinary course of school study."

Mr. Gill's experience as teacher of chemistry and experimental physics at University College School appears to have been embodied in his book, if we may judge from its decided and perspicuous tone, and an evident intention that the pupil should strive, not only to *know*, but to *reason*. It is, indeed, precisely at this point that the power and merits both of teacher and writer become most apparent; and we have no hesitation in saying that it is in this sphere that the efficacious distinction between one manual and another lies.

After "Directions to the Reader" (as to the most advantageous mode of using the book), a list is given of the chapters into which the subject is divided. An exhaustive series of questions follows each chapter. A great deal of space has been gained by printing many of the necessary comments and descriptions in a smaller type than the more important text; and the illustrations, though generally of diminutive size, are no doubt large enough, and certainly distinct enough, for most readers. It need hardly be said that the province of *Chemistry for Schools* is comprised within the limits of the "metalloids" and their immediate allies. The nomenclature employed is throughout what has been termed "Berzelian," but is, in fact, derived from the hereditary Latin forms, which have been common for centuries to the whole of natural science, and are still the only ones which can be legitimately adapted to the requirements of our own language. The writer terminates with some useful appendices, not the least valuable of them being a list of necessary apparatus and chemicals, with approximate cost.

Mr. Gill has fairly earned the thanks of scientific chemists; nor will the schools be slow to appreciate a manual which has been thus well devised and executed by an author who has himself been a successful school teacher.

The Blow-Fly.—*A Monograph on the Anatomy and Physiology of the Blow-Fly.* By Benjamin Thompson Lowne. (Van Voorst.)

In this little volume, just issued by Van Voorst, Mr. Lowne has treated the subject of his monograph very exhaustively. The text is judiciously divided into two parts, the first comprising a neat popular sketch of the organisation of this familiar and pertinacious little companion of domestic life; and the second containing the more technical and elaborate account of the author's own dissections and investigations, which are illustrated by ten very beautiful plates, engraved by his own hand from his own microscopical demonstrations.

The book is eminently satisfactory, as being a clear and complete statement of what is known of fly-organisation. But it has also, in some degree, the stamp of original research upon it, and represents a remarkable amount of labour and industry. The nature of the all-embracing integuments, and the way in which they are modelled to form the external organs and implements of the creature's active life, are in the first instance dwelt upon. The theme then passes on to the examination of the digestive and assimilative apparatus, the arrangements for circulation and respiration, the nerve structure, and the organs of special sense. It would be possible to pause upon matters of particular moment and interest in each one of these departments of the treatise. But it must, for this occasion, suffice to draw attention to the explanation of the way in which the so-called false tracheæ of the trunk are modelled into an exquisite strainer, to enable the fly to draw off the finer and more nutritious parts of the half rotten pulpy matters that are used as food, and to the manner in which the terminal lip of this sucking trunk is furnished with supplementary rasping teeth and salivary pores, to allow such matters as loaf sugar to be broken down and dissolved into a juice also available for suction. The description of the manner in which the poisers, properly the abortion of the second pair of wings, are turned to account as ears which receive the vibrations of sound upon terminal knobs, instead of within trumpet cavities, is also most worthy of notice. But before all must stand Mr. Lowne's demonstration of the fly brain. He shows that the fly has a sense-centre, or cephalic ganglia, some thirty times larger than that of the most portly beetle, which sufficiently accounts for the energy and vivacity of the insect's life; and that it has also, in common with the bee and the ant, a small rudimentary convoluted brain, attached by a little footstalk to the larger and simpler nerve-mass of the head. Mr. Lowne holds that the fly clearly exhibits some trace of mental faculty, such as memory, in virtue of this shadowing forth of true cerebral organisation.

Terrestrial Physics.—*Ueber die Lehre von den Meeresströmungen.* By Dr. Adolf Mühry. (Göttingen, 1869. London: Williams and Norgate.)

This is a very successful attempt to introduce something like order into the complicated phenomena of oceanic currents. The author sketches first the two well-known main systems, viz. (1) the great west-current which forms a belt of nearly 50° of latitude on both sides of the equator, and to which the earth's rotation, combined with the inertia of the ocean, is assigned as cause; (2) the great thermal circulation from the poles towards the equator, with its compensating current in the opposite direction; both are, according to the author, produced by the difference in density of cold and warm water, and he refutes, with great knowledge and sagacity, the opinions of previous writers, of Maury among others, who seek the cause in differences in the amount of evaporation and rain, the prevailing winds, and the amount of saline matter in the sea.

Then follows an *exposé* of comparatively local systems. Here the author supplants the incompleteness of known facts by his own speculations, which are neither always clear nor above the suspicion that doubtful points have been decided by the author, with a view of confirming his own hypotheses. Thus a very elaborate chapter on the currents in the North Polar Basin rests entirely on his assumption that sea-water behaves like pure water as regards the temperature at which it has the greatest density. He describes some very crude experiments made by him, which prove the fact in his opinion, but are contradicted by the well-known experiments of such a distinguished physicist as Despretz, who found different points of maximum density for different saline solutions.

B. L.

Protozoe Helvetica.—*Mittheilungen aus dem Berner Museum der Naturgeschichte über merkwürdige Thier-und Pflanzenreste der schweizerischen Vorwelt.* Edited by W. A. Ooster and C. von Fischer-Ooster. Part I. Basle and Geneva, 1869. 4to. pp. 14, map and two double plates. (London: Williams and Norgate.)

This is the first fasciculus of a series intended to illustrate the palæontology of Switzerland. The work is intended chiefly as a means of making known by descriptions and drawings a number of interesting fossils from the animal and vegetable kingdom, in part at least new to science. Most of these have been derived from the Swiss Alps, and are now preserved in the Bern Museum of Natural History. It is also intended to serve as the organ for shorter palæontological communications from the whole extent of Swiss territory, the several authors being answerable for their own views. The first part contains a short paper, just completed, "On the Red Limestone of Wimmis and its Fauna;" the next will contain plates and descriptions of various remarkable fossils from the Swiss Alps. Three, or at most four such parts will form a volume, when a title-page and index will be issued.

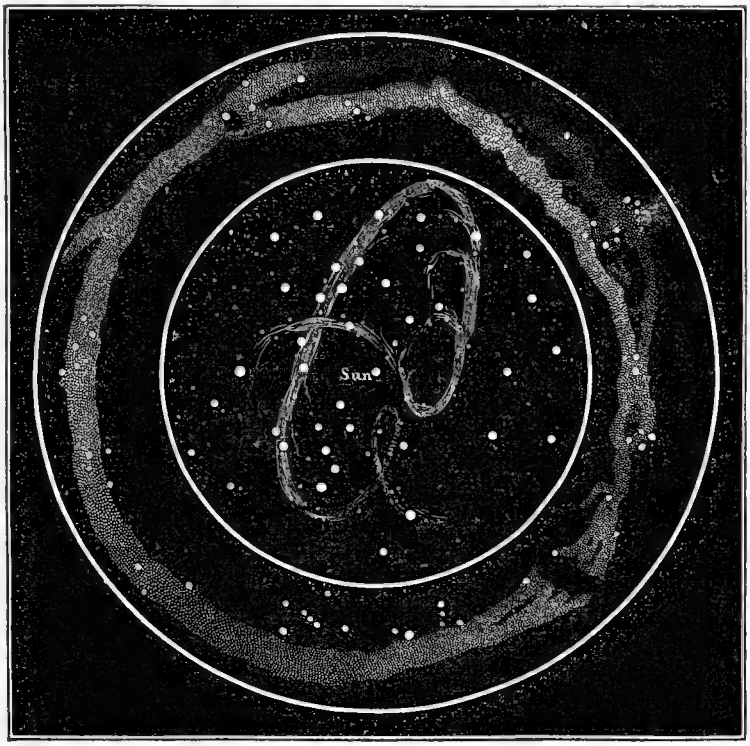
We need only add that the plates before us contain figures of fish-teeth (*Oxyrrhina*, sp.), mollusca (*Inoceramus Brunneri*, and an undetermined species), and echinodermata (*Collyrites Friburgensis* and *C. capistrata*), that the drawings are of large size, and, except for occasional flatness in the shading, well-executed.

H. B. B.

ARE ANY OF THE NEBULÆ STAR-SYSTEMS?

THIS may seem a bold question, for it is commonly believed that Sir William and Sir John Herschel—the Ajax and the Achilles of the astronomical host—have long since proved that many of the nebulæ are star-systems. If we inquire, however, into what the Herschels have done and said, we shall find that not only have they not proved this point, but that the younger Herschel, at any rate, has expressed an opinion rather unfavourable than otherwise to the theory that the nebulæ are galaxies in any sense resembling our own sidereal system.

Sir William Herschel, by his noble plan of star-gauging, proved that the stars aggregate along a certain zone, which in one direction is double. He argued, therefore, that presuming a general equality to exist among the stars and among the distances separating them from each other, the figure of the sidereal system resembles that of a cloven disc. And as the only system from which he could form a probable judgment—I mean the planetary system—presented to him a number of bodies, widely separated from each other and each a globe of considerable importance, he reasoned from analogy that similar relations exist in the sidereal spaces. This being so, his cloven disc theory of the sidereal system seemed satisfactorily established.



Then, of course, those nebulæ which exhibit a multitude of minute points of light very close together, and those other nebulæ which, while not thus resolvable into minute points, yet in other respects resemble those which are, came naturally to be looked upon as distinct from the sidereal system. The analogy of this system, in fact, pointed to them as external star-systems, resembling it in all important respects.

Then there were certain other objects, which seemed to present no analogy either to the sidereal system or to separate stars. These objects Sir Wm. Herschel considered to belong to our sidereal system; for he could not put them outside its range without looking on them as objects *sui generis*, which would have been to abandon the argument from analogy. In order to explain their appearance, he suggested that they might be gaseous bodies, by whose condensation stars would one day be formed.

The value of Sir Wm. Herschel's work is not in the least affected even if science have to reject every one of these opinions. He himself held them with a light hand; he had once held other opinions; and he was gradually modifying these. Had he seen one sound reason for rejecting any or all of them he would have done so instantly. For it belonged to the strength of his character that he was never fettered by his own opinions, as weak men commonly are.

Sir John Herschel did for the southern heavens what his father had done for the northern. He completely surveyed and gauged them. It is commonly believed that the results of his labours fully confirmed the opinions which his father had looked upon as probable.

Let us see if this is so.

Sir W. Herschel thought the Milky Way indicated that the sidereal system has the figure of a cloven disc; Sir John Herschel judges rather that the sidereal system has the figure of a flattened ring. Sir Wm. Herschel thought the stellar nebulæ are probably external galaxies; Sir John gives reasons for believing that they lie within our system, and Whewell considered that these reasons amount to absolute proof.

It has been further believed and stated that the researches of the elder Struve go far to confirm the opinions put forward by Sir W. Herschel as probable.

Let us inquire how far this is true.

Struve found that the numbers of stars of given magnitudes exhibit nearly the same proportion in different directions. Thus supposing that in a given direction there are three times as many stars of a certain magnitude as there are of the next highest magnitude, then in other directions, also, the same relation is observed. This is a very striking law; but to make it serve as a proof of the opinion which Sir William Herschel had put forward as probable, it would be necessary that another law should be exhibited. For clearly, if that opinion were just, it would be easy to calculate what the relation should be between stars of different magnitudes. Had Struve been able to show that the numbers actually seen corresponded to the relations thus calculated, he would have gone far to render that view certain which Herschel always spoke of as merely an assumption.

But Struve found no such law of stellar distribution. On the contrary, he found a law so different, that in order to force the facts into agreement with Sir William Herschel's views about the sidereal system, he had to invent his famous theory of the extinction of light in traversing space. Now, according to this theory, we cannot see to the limits of our sidereal system, even though we could increase the powers of our telescopes a million-fold; so that if the theory is true, the question which heads this paper is at once disposed of. Obviously, we cannot see galaxies beyond the sidereal system if we cannot see to the limits of that system. And I may note in passing that (independently of Struve's theory) the most powerful telescopes cannot render visible the most distant stars of our sidereal scheme; so that if the nebulæ are really external galaxies, the stars we see in them must be enormously greater than those in our galaxies, supposing Herschel was right in thinking these tolerably uniform in magnitude.

Before proceeding to exhibit the evidence which has led me to the conviction that the nebulæ belong to our sidereal system, I may mention some reasons for believing that if Sir William Herschel's labours in the sidereal heavens were to be begun now, not only would he not have been led to adopt as probable the view on which he formed his opinions, but he would have rejected it as opposed to known analogies.

He had argued that because the planetary system exhibits a definite number of bodies separated by wide distances, therefore analogy should lead us to regard the sidereal system as similarly constituted, though on a much larger scale. This was perfectly just. Despite the various differences which no one recognised more clearly than he did, this view was the only one he could safely adopt for his guidance, ninety years ago.

But would not he have been the first to reject that view if he had known what we now know of the solar system? If he had known that besides the primary planets, there are hundreds of minute bodies forming a zone between the orbits of Mars and Jupiter; that the rings of Saturn are formed of a multitude of minute satellites; that innumerable meteor-systems circle in orbits of every conceivable degree of eccentricity; that near the sun these systems grow denser and denser; that the comets of the solar system must be counted by millions on millions; that, in fine, every conceivable form of matter, every conceivable degree of aggregation, and every conceivable variety of size, exists within the limits of the solar system,—would he, then, have been led by analogy to recognise in the sidereal system only discrete stars and masses forming into stars?

From a careful study of all that Sir William Herschel has written, I feel certain, that in the case I have imagined, he would have been prepared, even before commencing his labours, to expect precisely that variety of matter, size, and aggregation, which modern observations, rightly understood, prove actually to exist within the range of the sidereal system.

The Herschels, father and son, discovered about 4,500 nebulæ. Other observers have brought up the number to about 5,400. When these are divided into classes, it appears that some 4,500 must be looked on as irresolvable into discrete points of light. But of these the greater proportion so far resemble resolvable nebulæ as to lead to the belief that increase of optical power alone is wanting to resolve them.

Taking these irresolvable nebulæ, however, as we find them, and marking down their places over the celestial sphere, we recognise certain peculiarities in their arrangement. In the northern heavens they gather into a clustering group as far as possible from the Milky Way. In the southern heavens they form into streams, which run out from a region nearly opposite the northern cluster of nebulæ; but the *extremities* of the streams are the region where nebulæ are most closely crowded. The Milky Way is almost clear of nebulæ.

This withdrawal of the nebulæ from the Milky Way has been accepted by many as clearly indicating that there is *no* association between them and the sidereal system. The opinion of the Herschels, if they had been led to pronounce definitively on this point, would have been different, however; for the younger Herschel quotes (as agreeing with it) a remark of his father's to the effect that the peculiar position of the northern nebular group is not accidental. If not accidental, it can only be due to some association between the nebular group and the galaxy. Every other conceivable explanation will be found to make the relation merely apparent—that is, accidental, which neither of the Herschels admit.

But yet stronger evidence of association exists; evidence which I do not hesitate to speak of as incontrovertible. Space will only permit me to treat it very briefly.

There is a certain well-marked stream of nebulæ in the southern heavens leading to a well-marked cluster of nebulæ. There is an equally well-marked stream of stars leading to an equally well-marked cluster of stars. The nebular stream agrees in position with the star-stream, and the probability is small that this coincidence is accidental. The nebular cluster agrees in position with the star-cluster, and the probability is still smaller that this second coincidence is accidental. Such are the separate chances. It will be seen at once, therefore, how small the chance is that both coincidences are accidental.

The cluster here referred to is the greater of the celebrated Magellanic Clouds. When it is added that the evidence is repeated point for point in the case of the lesser Magellanic Cloud, the indications of association appear overwhelmingly convincing. If the nebulæ really are associated in this manner with fixed stars, the question which heads this paper is disposed of at once.

But there is yet further evidence.

The nebulæ pass by insensible gradations from clusters less and less easily resolvable, to nebulæ properly so called, but still resolvable, and so to irresolvable nebulæ. Now clusters are found not only to aggregate in a general manner near the Milky Way, but in some cases (on which Sir John Herschel has dwelt with particular force) to exhibit the clearest possible signs of belonging to that zone. If they then belong to the Milky Way, can any good reason be given for believing that the various other classes of nebulæ are not associated with the sidereal scheme? Where should the line be drawn?

Again, some of the nebulæ are gaseous, and all the gaseous nebulæ exhibit the same spectrum. Now, two classes of gaseous nebulæ, the planetary and the irregular nebulæ, exhibit a marked preference for the Milky Way, and therefore we must admit the probability that they, at any rate, belong to the sidereal scheme. But then a large proportion of the irresolvable nebulæ are also gaseous, and as they are formed of the same gases, we see good reason for believing that they also must belong to our galaxy. This, however, brings in all the nebulæ, since the recent detection by Lieut. Herschel of the same bright lines in or rather *on* the continuous spectrum of a star-cluster, shows the great probability which exists that with more powerful spectroscopes all the nebulæ may be found to exhibit these bright lines, that is, to contain these particular gases. I pass over the facts, that many nebulæ are found to be closely associated with stars, and that if any doubt could remain as to the association being real and not apparent, it would be removed by a picture of the nebula M 17, as seen in Mr. Lassell's great reflector at Malta. The reader will be more interested by the following quotation, which I extract (by permission) from a letter of Sir John Herschel's:—

"A remark which the structure of Magellanic Clouds has often suggested to me has been strongly recalled by what you say of the inclusion of every variety of nebulous or clustering forms within the galaxy, viz., that if such be the case—*i.e.* if these forms belong to, and form part and parcel of the Galactic system—then that system includes *within itself miniatures of itself* on an almost infinitely reduced scale; and what evidence, then, have we that there exists a universe beyond—unless a sort of argument from analogy, that the Galaxy with all its contents may be but one of these miniatures of a more vast universe, and that there may, in that universe of other systems on a scale as vast as our galaxy, be the analogues of those other nebulous and clustering forms which are not miniatures of our galaxy?"

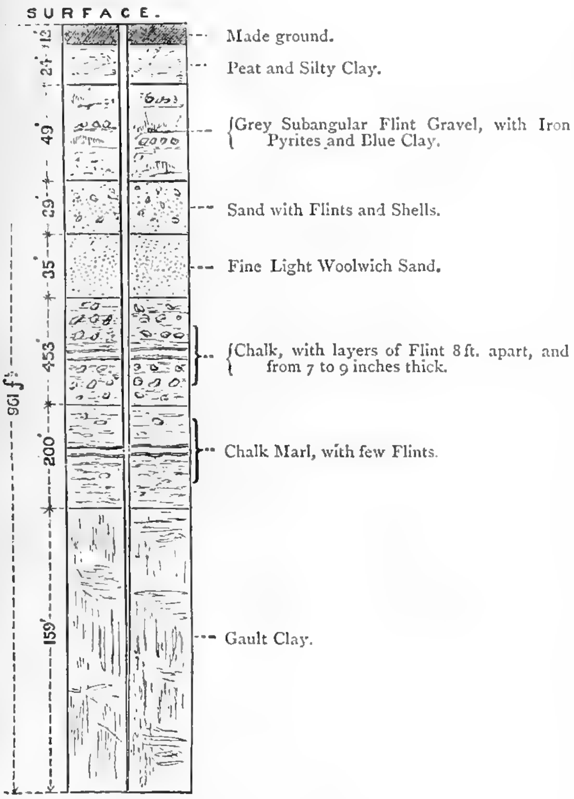
It will be seen that, while Sir John Herschel is quite ready (should the evidence require it) to adopt altogether new views about the nebulæ, he is *not* ready to forego the grandeur of those noble views of the universe which he and his father have established, thereby earning the well-deserved gratitude of every lover of astronomy.

And then with regard to the *actual* form of our galaxy or Milky Way, the figure introduced shows that its apparent one as projected on the heavens may really be due to an arrangement differing both from the cloven disc or flattened ring, a point to which I shall return in a subsequent article.

RICHARD A. PROCTOR

THE CROSSNESS WELL-BORING

THIS boring, which was commenced by the Metropolitan Board of Works for the purpose of supplying the engines and dwelling-houses at Crossness with pure water, has, as may be seen from the accompanying diagram, reached a depth of 961 feet without piercing the Lower Greensand, where it was expected a good supply would be found.

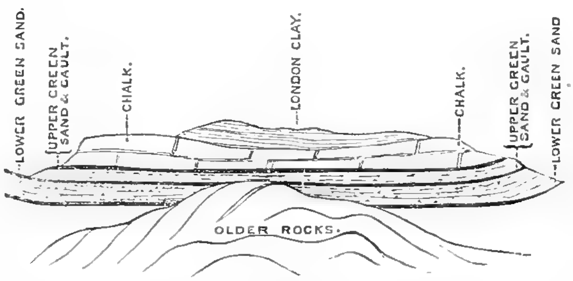


Section of Crossness Well-boring.

In consequence of the great difficulties attending the extraction of broken rods, &c., from the boring at that great depth, together with the uncertainty of the Lower Greensand being present, the boring has been discontinued. This is much to be regretted, as, if persevered with for a further depth of 40 or 50 feet, it would undoubtedly pass through the gault, which seldom exceeds 200 feet in thickness, 147 feet of which are now entered, and would thus add to the knowledge we at present possess of the substratum of London.

The chalk and gault clay at their outcrop to the north and south of London are underlaid by the Lower Greensand, which is from 150 to 400 feet thick; this, if continuous, as are the chalk and gault, would give a water-bearing strata of great capacity.

But it has been proved that its continuity is broken; as at Harwich, where after boring 1,000 feet through chalk, some carboniferous slates were found, and at Kentish Town, where beneath chalk and gault were found red sandstone and clay, though whether they belong to the Old or New Red Sandstone group, could not be ascertained. Mr. W. Whitaker very reasonably supposes that there is an underground ridge of older rocks crossing the London basin, which was an island when the Greensand was deposited, as the accompanying sketch shows, thus accounting for its absence in the places above mentioned.



Section across London Basin, showing Probable Position of Ridge of Old Rocks.

If the Crossness boring were continued, and the Greensand were not found, the direction in which this ridge runs would be ascertained, and thus would be prevented much fruitless outlay to those contemplating well-boring; in addition to which, some important facts connected with the London water supply would be made known; further, it might decide the question as to the existence of the coal measures beneath London, at a practicable depth, which, it will be admitted, is a question of universal interest. Under these circumstances, surely Government aid ought to be invoked, as the Board of Works are unwilling to proceed with the boring on their own responsibility.

UTILISATION OF SEWAGE

THE British Association Committee on the Treatment and Utilisation of Sewage has requested us to state that a number of towns and private individuals have already sent in or promised subscriptions for defraying the expenses of the contemplated investigation referred to in the circular published in NATURE of the 2nd of December, and that a Special Meeting of the Committee will be held on the 15th of February next to decide what further steps are to be taken in furtherance of the object in view.

The Committee therefore requests that town and district authorities who have not yet replied to the circular will at their earliest convenience communicate with the Committee, and state what sum will be subscribed; or, if it be decided not to subscribe, what is the reason for declining.

Should the total amount subscribed be insufficient for adequately continuing the inquiry, it is the intention of the Committee to return the subscriptions received.

The following Towns and Districts have subscribed, or signified their disposition to do so:—Stoke-upon-Trent, Exeter, Plymouth, Devonport, Paisley, Coventry, Oxford, Maidstone, Torquay, Wakefield, Dewsbury, Hereford, West Hartlepool, Kendal, Weymouth, Enfield, Penzance, Balsall Heath, Bromley, Bridport, Malvern, Abingdon, Atherton, Toxteth Park, and Walton-on-the-Hill.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Kant's View of Space

ALTHOUGH I do not feel myself called upon to modify in the least what was said in my former letter on this subject, the three letters which appear to-day in answer to it are too important to be left unnoticed.

The case is briefly this: In the "History of Philosophy" I had to expound Kant's doctrine, and to criticise it, not only in itself, but in reference to the great question of the origin of knowledge. In the pages of exposition I *uniformly* speak of Space and Time as forms of Intuition; no language can be plainer. I also mark the distinction between Sensibility and Understanding, as that of Intuition and Thought. After enumerating the Categories, I add, "In those Categories Kant finds the pure forms of the Understanding. They render Thought possible."

But when, ceasing to expound the system, I had to criticise it, and especially to consider it in reference to the great question; there was no longer any need to adhere to a mode of expression which would have been obscure and misleading. I therefore *uniformly* class Space and Time *among the forms of Thought*, connecting them with the doctrine of Necessary Truths and Fundamental Ideas, which, according to the *à priori* school, are furnished ready-made—brought by the Mind as its native dowry, not evolved in it through Experience.

Now the question is, Have I put language into Kant's mouth which he would disclaim, or is such language misleading? That Kant would have said the language was not what he had employed, I freely admit; but that he would have disclaimed it as misrepresenting his meaning, I deny. I was not bound to follow his language when the task of exposition was at an end; but only bound not to translate his opinions into language which would distort them.

In classing Space and Time *among* the Forms of Thought I classed them *beside* the Categories of the Understanding and the Ideas of Reason, *i.e.*, the purely intellectual conditions existing *à priori* in the Mind. The Mind is said by Kant to be endowed with three faculties—Sensibility, Understanding, and Reason. The activity of the Mind is threefold—Intuitive Thought, Conceptive or Discursive Thought, and Regulative Thought. There could not be an equivoque in my using the word Thought in its ordinary philosophical acceptation as expressive of all mental activity whatever, exclusive of mere sensation; although Kant assigns a more restricted meaning in his technical use of the word, *i.e.*, what we call Logic. And that Kant *meant* nothing opposed to the ordinary interpretation is obvious. It is obvious because, as I said in my former letter, Intuition without Thought is mere sensuous impression. Mr. Sylvester demurs to this, so I will show it in a single citation:—"In the transcendental Æsthetic," says Kant, "we will first isolate Sensibility by separating from it all that the Understanding through its concepts thinks therewith, so that nothing but empirical Intuition remains. Secondly, we will lop off from this empirical Intuition everything relating to Sensation (*Empfindung*); so that thereby nothing will remain but pure Intuition and the mere form of phenomena, which is the one thing that Sensibility can furnish *à priori*. By this investigation it will appear that there are two pure forms of sensuous Intuition which are *à priori* principles of Cognition." ("Kritik," § 1. ed. Hartenstein, p. 61).

Mr. Sylvester correctly says, that Intuition and Thought are not convertible terms. But he is incorrect in assuming that they differ as potential and actual; they differ as species and genus; therefore whatever is a form of Intuition, though not a form of Logic, must be a form of Thought; unless intuitive Thought be denied altogether. How little Kant denied it is evident in every section of his work. In asserting that Space and Time as Intuitions belong to the subjective constitution of the Mind—*subjectiven Beschaffenheit unseres Gemüths* (p. 62)—he expresses this; but it is unequivocally expressed in the following definition:—"A perception, when it refers solely to the subject, as a modification of its states, is *sensation*, an objective perception is *cognition: this is either Intuition or Concept*, 'intuitus vel conceptus.'" ("Kritik," p. 294.) Is not thought implied in cognition? Again:—"The proposition 'I think' is an undetermined empirical Intuition, *i.e.*, Perception; consequently, it proves that Sensation, which belongs to Sensibility, must lie at the basis of this proposition......I do not mean thereby that the 'I' in the 'I think' is an empirical representation (*Vorstellung*), on the contrary, it is *purely intellectual because it belongs to thought in general*. But without some empirical representation which would give Thought its material there could be no such act of Thought as the 'I think'" (p. 324, *note*).

"Man is always thinking," says Hegel, "even when he has nothing but intuitions; *denkend ist der Mensch immer auch wenn er nur anschaut*." (Encyclop. § 24.)

If, because Kant has a restricted use of the term Thought, all who venture on the more ordinary use are said to misrepresent his philosophical meaning, I must call upon those who criticise this laxity to refrain henceforth from speaking of Reason as Thought, since Kant no less excluded Reason from the province of the Understanding. If "the only forms of thought, in Kant's sense, are the Categories," this sweeps away Reason on the one side, as it sweeps away Sensibility on the other; and Ideas are not more correctly named Thoughts than Intuitions are. Kant, it is true, speaks of the concepts of Reason, and defines an Idea to be a "Vernunft begriff" (page 294); but Kant, equally and in a hundred places, speaks of the "concept of Space" (Begriff des Raumes). The truth is, as already intimated, that in spite of his technical restriction of Thought to the formation of concepts, he recognised intuitive and regulative Thought no less than discursive Thought; nor would his system have had any coherence without such a recognition. Why does he call his work the "Critik of Pure Reason," unless he intended to display the common intellectual ground of Sensibility, Understanding, and Reason? and does not the word Thought, in ordinary philosophical language mean this activity of the Intellect? When, by Sir W. Hamilton, Dr. Whewell, Mr. Spencer, and myself, the phrase Forms of Thought is used, does not every reader understand it as meaning Forms of intellectual activity?

In conclusion, I affirm that in the ordinary acceptation of the term Thought—the activity of the Mind—Space and Time as forms of Intuition are forms of Thought, conditions of mental action; and to suppose that because Kant's language is different, his meaning is misrepresented by classing forms of Intuition among the forms of Thought is to misunderstand Kant's doctrine and its purpose. GEORGE HENRY LEWES

January 22.

DR. INGLEBY, I should think, is quite entitled to say not only that Kant might, but that he would, have disclaimed the phrase Form of Thought as applied to Space or Time taken simply. The remark of Mr. Lewes, that "intuition without thought is mere sensuous impression,"—or, as it might have been put, that phenomena of sense (constituted such in the forms of Space and Time) must further be thought under Categories of Understanding, before they can be said to be known or to become intellectual experience—cannot be a sufficient reason for making a Form of Thought proper out of a Form of Intuition.

There is, nevertheless (and Mr. Lewes does not fail to suggest it), a sense in which, when taken along with the Categories of the Understanding, and with or without the Ideas of the Reason, the Forms of Intuition may be spoken of as Forms of Thought: Thought being understood, with the same extension that Kant himself gives to Reason in the title (not the body) of his work, as equivalent to faculty of Knowledge in general. It is in this sense that Kant calls all the forms alike, *à priori* principles of Knowledge; and the ambiguity of the word Thought is so well recognised, that the English writers, arraigned by Prof. Sylvester, take no great liberty, when for their purpose, which commonly is the discussion of the general question as to the origin of Knowledge, they talk generally of Kant's "Forms of Thought." If, indeed, any of them ever speaks of Space as a "form of the Understanding," which was part of the original charge, the case is very different; Kant being so careful with his *Verstand*. But Mr. Lewes at least would never be caught speaking thus, even though his main reason for merging Intuition in Thought might seem to justify this also. G. CROOM ROBERTSON

University College, January 22.

YOU will perhaps permit me to make a remark on a controversy at present going on in your columns. There has seldom, I believe, been a grosser or more misleading perversion of the Critical Philosophy than ascribing to Kant the view that Space and Time are in any meaning of the terms "forms of thought." One of his chief grounds of complaint against Leibnitz is, that the latter "intellectualised these forms of the sensibility" (Meiklejohn's Translation of the "Critick," p. 198): and lest the import of this assertion should be mistaken, he explicitly tells us that "Space and Time are not merely forms of sensuous intuition, but intuitions themselves" (Meiklejohn's Trans., p. 98): that is, *sensuous* intuitions, as he has been just before asserting that all human intuitions must be. It is precisely on this distinction of pure sensibility and pure thought that Kant founds the possibility of Mathematics—a science which could never be derived from a mere analysis of the concepts employed, but only from the construction of them in intuition. He ridicules, for example, the idea of attempting to deduce the proposition, "Two right lines cannot enclose a space," from the mere concepts or notions of a straight line and the number two. "All your endeavours," says he, "are in vain, and you find yourself compelled to have recourse to intuition, as in fact Geometry always does." (Meiklejohn, p. 39: see also his long contrast of Mathematical and dogmatical methods in the beginning of the "Methodology.") And not only is Kant's Mathematical theory founded on this distinction but his Physical theory also, since it is only by means of pure intuition that he connects pure thought with sensations (see the "Schematism" and still more the "General Remark on the System of Principles," Meiklejohn, pp. 174-7); and when he fails to make out this connection he regards the Ideas of Pure Reason as possessed of no objective validity (Transcendental Dialectic). In the first edition of the "Critick" he went still further, and in his remarks on the Second Paralogism of Rational Psychology he speaks of "that something which lies at the basis of external phenomena, which so *affects* our *sense* as to give it the representations of *space*, matter, *form*, &c." And while he abbreviated his discussion in the second edition he tells us in his preface that he found nothing to alter in the views put forward in the previous one.

I might quote whole pages of the "Critick" in proof of these views, but I ought rather to apologise for writing so much after the letters which you have already published. I believe the mistakes as to Kant's doctrine of Space and Time, his refutation of Idealism, and his discussion of the Antinomies of the Pure Reason, are almost without a parallel in the History of Philosophy.

Trinity College, Jan. 22 W. H. STANLEY MONCK

State Aid to Science

I OBSERVE that both in your leading article and in the correspondence upon Mr. Wallace's letter, the soundness of his theory of taxation seems to be conceded, though you quarrel with his inference that Science ought not to receive Government aid. But will his theory hold water for a moment? The theory as I understand it is this: "No money raised by general taxation ought to be applied for any purpose which does not directly benefit everybody." In other words, "It is not fair to take A's money and use it for the benefit of B." Why not, if at the same time you take a proportionate amount of B's money and use it for the benefit of A? Suppose you tax people who don't want gratuitous education for themselves, and spend the money on primary schools. This is expenditure for the direct benefit of one class only; and indirect benefits, according to Mr. Wallace, are not to be taken into account. This, according to the theory, would be an unfair application of public money. But if at the same time you apply a proportionate amount of public money for the benefit of all those who reap no direct good from gratuitous schools, you exactly redress the injustice; and, so far as it goes, expenditure on Science is an expenditure of this character.

If Mr. Wallace's theory were sound, there is no conceivable application of public money which it would not condemn. There is no public expenditure which directly benefits all. Take the payment of dividends on Consols, which eats up a third of our revenue. How does an agricultural labourer benefit by this? Not directly, certainly, and I am not sure that he does even indirectly. The only indirect good is, that it maintains public credit, and enables the Government to borrow again and to go to war on the strength of it. What good does that do to the labourer? Perhaps it may be said it is the fulfilment of a moral obligation. But whose moral obligation? Not Hodge the ploughman's. Even the least exceptionable of all outlay, that on police, is of very doubtful benefit to those who have nothing to lose. And the theory, if sound, must go a step further than Mr. Wallace carries it. If all public expenditure ought to benefit all, it ought by the same reasoning to benefit each in exact proportion to his contribution, and no system of taxation and expenditure even pretends to approach this condition.

Obviously Mr. Wallace could not have meant what he said. He must have meant this: "Public expenditure as a whole ought to benefit taxpayers in proportion to what they pay." Put in this way it is a fair doctrine, to which our actual adjustment of taxation and expenditure ought to approximate as nearly as may be. But this is quite consistent with special expenditure for the benefit of special classes, provided it is fairly balanced by other special expenditure for all other classes. If, on the whole, men of science are getting more than their share of the good things going, by all means stop the supply; if they are getting less than their share, give them something more. This is surely fair, and it is an intelligible working principle. Mr. Wallace's principle has only this to recommend it, that it would be impossible to find any object which would justify the levying of a single sixpence from your humble servant or any other TAXPAYER

P.S.—I hope that in discussing Mr. Wallace's argument on his own grounds, I shall not be supposed to agree with him that the direct and immediate benefit is the only thing to be looked to. If a man or a class gets a benefit, it does not lose its value by coming indirectly. And, as a matter of fact, expenditure on Science does, as you and others have sufficiently pointed out, confer indirect benefits on the non-scientific classes, incomparably beyond any little direct advantage to the scientific students whose work is promoted by it.

Use of the word "Correlation"

I OBSERVE in your last number you adopt the phrase of Mr. Barrett, "Correlation of colour and music." Will you and Mr. Barrett pardon a criticism on the application of the word "correlation?"

I believe I was the first who ever used the word at all as an English word, though the words "correlate," "correlative," &c., are to be found in Johnson. At all events, I stretched the meaning, and apologised for so doing in my essay on the "Correlation of Physical Forces." Wherever the word "correlative" was used to express a mutual and inseparable relation of two ideas, such as parent and offspring, height and depth, &c., I ventured, for want of a better term, to apply it, and the new substantive "correlation" to reciprocal relations of phenomena, such as heat and electricity, electricity and magnetism, &c.—not then (1842) supposed, except by me, to be relations of necessity, and not even now supposed to be inseparable in idea.

The application of the word has latterly been much extended, and we hear of correlation of growth, correlation of diseases, correlation of sciences, &c. I rather regret this; there is nothing of greater importance, especially for works on physical science, than accuracy, as far as may be, in the use of words: perfect accuracy is impossible.

Mr. Barrett has, I think, extended the import of the word beyond reasonable limits. There is no correlation between colour and music, further than there is a correlation between anything and everything. The word "analogy," used also by Mr. Barrett, is, in my humble judgment, far more accurate as applied to the classes of phenomena he treats of. I hope he will excuse a "parent" when complaining of ill-treatment to his "offspring," although the offspring may have had a little congenital deformity.

January 22 W. R. GROVE

Rainbow Colours

I AM reminded by Mr. Grove's statement at p. 314 (that he has seen three repetitions of the spectrum within the primary) of a splendid rainbow, which I saw at the Falls of the Handeck, near Meyringen, last summer.

The sun was very bright, about midday, and looking down at the Fall there appeared the most beautiful rainbow I ever saw. The colours were intense, probably from the spray being in fine drops; and I observed between the primary and secondary, *i.e.* between the two violets, a band of *a fine rich brown colour*.

I have often observed when rainbows are bright, that there is a dark band of a neutral tint between the two. This effect was shown very beautifully in a drawing by Mr. Alfred W. Hunt, exhibited at the Water Colour Society two or three years ago. He appears to have seen the same effect, but I had never seen the rich brown colour before. It was no effect of background, for when I varied my position the brown moved with the bows.

I have also often seen four or five, what may be called tertiary bows, inside the primary. They are grouped together as it were, and form a band of alternate red and green, becoming fainter as they recede from the primary. They appear to be a repetition of the primary in which the red and green are the most prominent colours.

Gateshead, January 23 R. S. NEWALL

Cuckows' Eggs

WILL you kindly allow me space to thank Prof. Newton for the trouble he has taken in replying to my inquiries, although I must confess I am still unconvinced?

My omission of the name of the eminent oölogist in my last letter was entirely accidental, for I had no purpose in concealing it, but rather the reverse. My quotation was from a letter of Mr. Hewitson's, in the *Field* of March 17, 1868.

Mr. Newton mentions the eggs of the Black Cap Warbler and the Tree Pipit, as some indication of the existence of a condition which I doubted in my sixth question. I have not found the eggs of the Black Cap vary more than this, that in some the ground colour was of a warmer tone than in others. The eggs of the Tree Pipit, I freely admit, do vary greatly, but their variations are all confined to different shades of nearly the *same colour*—viz., purple; ranging from purplish red on the one side, to bluish purple on the other, but these variations have, nevertheless, so much similitude that there is no difficulty in at once recognising them.

Mr. Newton says: "If the eggs in question were not cuckows', what birds laid them?" My reply is, simply, that they were laid by the birds in whose nests they were found. It seems to me far more likely that an egg laid by a certain bird should vary slightly from the rest of her eggs in the same nest, than that another species should lay eggs varying to the extent mentioned by Dr. Baldamus—viz., from vinous red to greenish blue, olive green, plain brown, &c., or even pure white, or light blue green, mentioned by Degland and Gerbe, as quoted by Mr. Newton.

Mr. Newton will excuse me for saying that I did not refer to the German authors mentioned by him in the footnote to his letter, excepting where quoted by Dr. Baldamus, for unfortunately I do not possess a knowledge of the German language, and am therefore unacquainted with their writings.

The doubts I have expressed, and still feel, have nothing personal in them, but only apply to the theory and the evidence on which it is supported. It does seem to me singular that these extreme variations of colour in the eggs of the cuckoo should only have been remarked in Germany. They do not appear to have been observed in Britain. Mr. Newton does not say he has found them himself, and admits that the evidence on which these German eggs are pronounced cuckoos' might have been more satisfactory. Mr. Hewitson says "few eggs differ less," and Mr. Dawson Rowley has remarked, in a letter to the *Field*, "I believe few men have taken with their own hands so many eggs of *cuculus canorus* as myself;" and yet his experience does not confirm the theory, but the contrary.

I cannot help feeling that we still want more positive information on this point. Were all the varied eggs alleged to be cuckoos' really laid by that bird? I can easily conceive an enthusiastic naturalist, with a favourite theory to maintain, imagine when he takes out of the nest of the hedge-sparrow, or tree pipit, an egg rather larger than the rest, but marked and coloured in a similar manner, that it is that of the cuckoo. I hold, however, that nothing less than *positive proof* that it was deposited by a cuckoo will suffice. I admit this may be difficult to obtain, but it is not the less necessary. A dogma like the one in question must be based on evidence that is not only unimpeachable, but above suspicion, and this I think the advocates of the theory have not yet furnished.

May I ask you to be good enough to allow my orthography of the word "cuckoo" to remain? With all deference to so high an authority as Prof. Newton, I prefer and always use the common mode of spelling the word to the one adopted by him, as better representing the call-note, from which the name is derived.

W. J. STERLAND

January 17

Dr. Livingstone's Discoveries

IN the conclusion of a letter which has lately appeared in your journal on the subject of Dr. Livingstone's recent letters, Dr. Beke gives the opinion that the river and lake chain which forms the main part of the great traveller's latest discoveries, is the head stream of the Nile. Though I am unwilling to differ from such an authority as Dr. Beke, yet there appear to me to be considerable difficulties in the way of his conclusions.

Will you allow me to show how it seems equally, if not more probable, that Dr. Livingstone, whilst he has ascertained the sources of the Nile, has also the merit of being the discoverer of the head streams of one of the great rivers which flow to the Atlantic, perhaps of the Congo. The Chambeze, the head stream of the lake chain in question, has its rise somewhere in the eastern part of the great plateau or ridge which skirts the whole side of Africa, next the Indian Ocean. Dr. Livingstone crossed it in lat. 10° 34′ south; from this it flows first westwards to Lake Bangweolo, then north to Lake Moero. The position of Lake Moero can only be determined as yet by reference to that of Lunda, the capital of the kingdom of the Cazembe, twelve miles beyond which town the lake is said to begin. Portuguese travellers are the only Europeans who are known to have previously visited this town, and the two routes from which we can assign it a position on the map, are those of Dr. Lacerda in 1798, and of Major Monteiro in 1831. These two travellers, with their escorts, have passed over almost the same route from Tete on the Zambesi to the Cazembe. From the former traveller there remain two astronomically fixed positions in the middle of this route, and the latter has published a volume which contains the distances and directions of his journey, but no astronomical positions. The route of Monteirò then, justified by the now ascertained position of Tete at the beginning, and by the positions formerly determined by Lacerda for its middle course, gives the place of the Cazembe town of Lunda, at its termination, in lat. 8° 40′ S., lon. 28° 20′ E.

Dr. Livingstone describes Lake Moero as beginning twelve miles below this position and extending for fifty miles to northward. Since he proceeded north from Cazembe town along the eastern shore of Lake Moero, in his attempt to reach Ujiji in the end of 1867, the great bulk of this lake must lie to westward of the meridian of Lunda. The centre of Moero would then be in the latitude of the south end of Tanganyika, and at about 120 miles to westward of its longitude. Dr. Livingstone has seen the river at its outflow from this lake and also at the point where it emerged from the "crack in the mountains of Rua," when, according to his own observation, the river turned to *north-north-west* to form Ulenge, a third lake or marsh in the country west of Tanganyika.

This north-north-westerly direction would carry this river quite out of the line of Tanganyika or of the Albert Nyanza; besides, both of these lakes appear to be closed-in on the western side by high mountains.

The levels of the river also appear to present a great obstacle to its joining the Nile lakes.

Leaving the Valley of the Loangwa, Dr. Livingstone tells us that he ascended to a great plateau which extends for 350 miles square, southward of Tanganyika. This table-land is at an elevation of from 3,000 to 6,000 feet above the sea. The valley of the Chambeze crosses this plateau from east to west, and the river descends from it into the great valley of the Lakes Bangweolo and Moero, not far west from the point where it was crossed by Dr. Livingstone. The valley of the Chambeze is no doubt one of the greatest hollows in this plateau, and so the bed of the river here may be taken to be at the lowest general height of the plateau given by Dr. Livingstone—that is, 3,000 feet, or 200 feet above the Tanganyika. From the point at which the Chambeze was crossed, its course is for perhaps 200 miles westward to Lake Bangweolo, and in this part of its flow from the plateau to the valley the fall of the river must be considerable. Between Bangweolo and Moero the course of perhaps 120 miles to northward seems to be through a more level part of the valley. Still, here there must be another descent to Lake Moero. According to the Portuguese traveller, Monteiro, the kingdom of the Cazembe extends on the east and north-east to the land of the Auembas, apparently the same as the Luwemba of Burton and Speke on the south-east of Tanganyika. His country is described as low and flat, and this would seem to be confirmed by the absence of current in the marshy rivers visited by the Portuguese to the east of Cazembe's town, and also by the Lake Liemba of Dr. Livingstone, which he has found to be the termination of a long river-like arm of Tanganyika, stretching south-south-east to the north edge of the before-mentioned plateau. Lake Moero, then, cannot be above the level of Tanganyika, else its outflow would surely be over this level country, and not through the mountains to northward. From Lake Moero the river flows on through a "rent in the Mountains of Rua." In passing through this gorge, it appears certain that the river must have a further and rapid descent, lowering its bed still more beneath the level of Tanganyika.

In his letter of 30th May, 1869, from Ujiji, which has the brevity of a telegram, Dr. Livingstone says: "Tanganyika, Nyige Chowambe (Baker's) are one water, and the head of it is 300 miles to south of this. The western and central lines of drainage converge into an unvisited lake west or south-west of this." If the expression "one water" here means that these two lakes are united by an extension of one into the other, and not by a river, then it is evident that the river and lake chain under consideration can never flow up to join either of them after having passed down through the rent in the Mountains of Rua; if it means that these lakes are joined together by a river, still the small difference in height between that computed for Lake Tanganyika by Mr. Finlay, of 2,800 feet (afterwards so curiously confirmed by Livingstone's height of Lake Liemba), and that found for the Albert Nyanza by Baker, would not give a sufficient lowness to the latter lake to allow this river to flow down to it through the five degrees of latitude which separate its outfall from the Mountains of Rua, from the southern end of the Albert Lake. Dr. Livingstone's statement in his letter above quoted from Ujiji, that the head waters of the Tanganyika and Albert Lakes are 300 miles south of that place, is not at all opposed to the view that the Chambeze River and its lake chain may join the Congo, for the streams which flow into his Lake Liemba may rise at this distance from Ujiji. In this case the sources of the Nile would be side by side with those of the Congo; and the man who has the claim to be called the greatest explorer that the world has ever known, has the double honour of having solved the two greatest of African problems.

74, Strand, W.C. KEITH JOHNSTON, Jun.

Physical Meteorology

ASSUMING with your correspondent that there is an ascending current in the heart of a cyclone, no doubt latent heat will play its part. I presume, however, your correspondent does not imagine that air is ever actually heated by such means to 370° F.

Suppose, for instance, that two cubic feet of saturated air, both at thirty inches pressure, but one at the temperature 32° F. and the other at the temperature 90° F., become mixed. The cubic foot at 32° F. will contain 2·37 grains of vapour, that at 90° F. 14·50 grains. Hence, after mixture the average weight of vapour in unit of volume will be 8·43 grains. This would saturate a temperature = 71·7° F. But this is greater than the mean between the two temperatures or 61° F. There will, therefore, be hardly enough heat to keep the mixture at 71°·7 F. and prevent deposition.

On the other hand, we cannot imagine the temperature of the mixture to fall as low as 61° F.

The temperature of the mixture will therefore, I presume, be greater than 61° and less than 71·7°.

B. STEWART

Veined Structure in Ice

FEW men have had better opportunities of examining glacial phenomena than Mr. Whymper, and his explanation of the veined structure is certainly an ingenious one. I venture, however, to doubt whether it can be regarded as generally satisfactory, although, possibly, it might explain some isolated cases.

The following, which, so far as my experience goes, are common facts in glaciers, appear to me difficult to reconcile with his explanation.

(1.) One common case in which the veined structure becomes conspicuous is after the glacier has been pressed into a narrower channel than has been occupied by its *névé*. The structure planes are then roughly parallel to the *sides* of the channel. Dr. Tyndall has pointed this out in his "Glaciers of the Alps," p. 387, and I have frequently observed the same thing myself. Three instances occur to me at this moment: one on the Gorner Glacier, under the Gorner Grat; another in the middle part of the Glacier de la Pilatte (Dauphine); a third on the upper part of the Mer de Glace. Did I search through my note-book I have no doubt I could find plenty more. If now, say in the second example, the veined structure was due to the crevasses in the ice fall below the Col du Sélé, surely its planes would hardly be twisted through a right angle in the comparatively short distance intervening between the ice fall and the rocky spur from the Crête des Bœufs Rouges which causes the "nip." Moreover, if the planes have been turned by the unequal motion of the centre and sides of the ice stream, ought we to find them so uniform in direction as they now are, often extending with a very general parallelism over the greater part of the glacier?

(2.) If the veined structure is the result of healed crevasses, how are we to explain the great number of these plates of different coloured ice on glaciers which are not remarkable for very numerous crevasses. For example, on the Roseg Glacier, near Pontresina, these plates of blue and white ice alternate with each other for at least several hundred yards as you walk up the glacier, and are commonly only an inch or so thick. I have in my notebook a diagram of a piece to exhibit the weathering of the two kinds of ice, in which are shown five plates, three blue and two white. One of the former is about an inch thick, and all the rest are thinner. Each of the white is about half an inch, and I remember that this was a fair sample of most of the ice near. If, then, the crevasses, from whose healing this platy structure has resulted, were formed simultaneously or in close succession, how are we to explain the thinness of the white portion, its layers being, if anything, thinner than the blue? Crevasses are not usually so near together as this, and if they were not thus formed is it probable that the plates would be so produced as to be, for about as far as one could trace them, parallel one to another, so accurately that my diagram looks like a bit from a cliff of midland lias?

Cambridge, Jan. 7 T. G. BONNEY

Personal Equation of Astronomical Observers

IN the number for November 18, 1869, of NATURE, "J." asks if an experiment has hitherto been tried to ascertain the value of the personal equation of astronomical observers. The fact is, that it has been tried in different manners, as by Mr. Wolf in Paris, and Mr. Hirsch in Neuchâtel, but first of all by Dr. F. Kaiser, Astronomical Professor, and Director of the Observatory of Leiden. The apparatus of Prof. Kaiser was first constructed in 1851, but was afterwards highly improved, so that it is fitted equally well for observations with or without the chronograph.

A description of the method and apparatus of M. Kaiser is to be found in the "Archives Néerlandaises des Sciences exactes et Naturelles," vol. i. p. 194, and of the improved one in the reports and communications of the Royal Academy of Science of the Netherlands (Verslagen en mededeelingen der Koninklijke Academie van Wetenschappen), Second Series, vol. ii.; the former is written in French, and titled: "Sur la détermination absolue de l'erreur personelle dans les observations astronomiques;" the latter, in German: "Uebereinen neuen Apparat zur absoluten Bestimmung von persönlichen Fehlern bei astronomischen Beobachtungen." H. VON DE STADT, Ph.D.

Arnheim, Netherlands, January 3

Anatomical Lectures to Female Medical Students

I HAVE great pleasure in hearing that the Professors of Anatomy in Scotland have not all forgotten that women ought to be treated with some degree of chivalry.

Professor Struthers, of Aberdeen, and Professor Bell, of St. Andrews, hearing that the five ladies who are studying at the Edinburgh University are excluded from the opportunity of studying anatomy there, have severally offered their services as instructors. Many a lady will rejoice that the numbers of those willing and ready to help in the good cause of fuller knowledge for women are increased by two professors, who have bravely come forward with much moral courage and chivalrous feeling.

Edinburgh, Jan. 22. A NON-MEDICAL WOMAN

NOTES

THE Physical Section of the Academy of Sciences at their last meeting recommended Professor Kirchhoff, of Heidelberg, to fill the place of correspondent of the section, vacant by the death of Principal Forbes. The other candidates were MM. Ångström, Billet, Dove, Grove, Henry (of Philadelphia), Jacobi, Joule, Lloyd (of Dublin), Riess, Stokes, Tyndall, Volpicelli, and Sir William Thomson.

IN our statement last week that "the Senate of London University has proposed to establish a Faculty of Science," "London University" should have been "University College, London;" the fact being that the Senate of the University of London—in advance of every other university of the kingdom—established a Faculty of Science *ten years ago;* constituting, at the suggestion, and with the advantage of the advice, of the ablest men of science in this country, a scheme for graduation in science, which has continued in efficient operation from that time to the present. And we may add that in the new building of the University the four Faculties—Arts, Sciences, Law, and Medicine—are typified by the four sitting statues over the portico, representing Milton, Newton, Bentham, and Harvey.

WE are happy to be able to announce that the council of the Chemical Society has decided to have a report of their proceedings and an abstract of the papers read before the society drawn up immediately after its meetings, and to offer copies of this report to the editors of journals who may be likely to wish to publish it. The days when the newest results of science were regarded as something secret—or, at all events, of no concern to the ordinary man of education—are gone by, we trust, for ever. It may now be confidently expected that the example of the Chemical Society in thus seeking a wide publicity for the reports of their proceedings will be followed by those societies—such as the Linnean and the Astronomical—which have not offered hitherto such facilities to those who endeavour to inform the general scientific public and the world of letters of the latest researches in science.

WE learn from the fifth annual report of the Sanitary Commissioner with the Government of India, just received, that the first scientific report on the inquiry into epidemic cholera in India, the instructions for which were prepared by the Army Sanitary Commission, has been presented. The reporters state that they have been making "careful and systematic examinations of cholera excreta, and the changes taking place in them during decomposition as compared with healthy excreta, and the changes occurring in them as well as in other fluids and solids during the same process. These changes have been studied as occurring under various circumstances, associated with various substrata and media. In addition to the above experiments, others on the effects of cholera excreta on growing rice plants have been entered upon. Careful daily observations have been made, and notes and *camera lucida* drawings of all the changes observed to occur have been accumulated. As far as the observations have as yet gone, they have not been confirmatory of those of Hallier. For, though fungi have frequently appeared on choleraic materials, yet—(1) several species have appeared; (2) the same species have occurred in abundance on other substrata in like circumstances; (3) the species observed have not belonged to the cholera series of Hallier. As yet, however, it would be premature to draw any definite conclusions in the matter, as any series of observations on such points is beset with innumerable difficulties and fallacies, necessitating careful and frequent repetition of each experiment before coming to a final decision as to the value of its results." Observations are being conducted at various stations to ascertain whether Pettenkofer's theory of the relation of cholera to subsoil water level is borne out in India.

THE Boston Society of Natural History, at its last meeting, passed the following vote:—

"That the net proceeds of the celebration of the centennial anniversary of the birth of Humboldt, together with the money received from the sale of Prof. Agassiz's Address, previous to Jan. 1, 1870, and the money subscribed at the solicitation of the society's committee, be given to the trustees of the Museum of Comparative Zoölogy at Harvard College, in trust, for the establishment of an endowment, under the title of the Humboldt Scholarship, the income of which is to be solely applied, under the direction of the Faculty, toward the maintenance of one or more young and needy persons engaged in study at said museum."

THE subject of the Ravizza prize of a thousand lire for 1870 is, the effect which emigration to foreign countries and removal to cities produce on the population of agricultural districts. Manuscripts are to be marked with a motto, and accompanied by a sealed letter containing the author's name. They must be written in Italian, addressed *Presidenza del Regio Liceo, Cesare, Beccaria, Milan*, and delivered not later than the last day of December next.

A MONTHLY Journal, devoted to social and sanitary economy, is advertised to appear on the 1st proximo, under the title of the *Food Journal*. Judging by the names included in the published list of contributors, we may confidently expect that the important subjects to be dealt with in this periodical will be treated of with ability, and in accordance with the most recent results of scientific research.

THAT interesting and useful periodical the *American Naturalist*, which is devoted to the popularisation of Natural History, commences a new volume in March next. The first article in the volume will be an illustrated paper by Mr. E. G. Squier, the eminent archæologist, on the Ancient Megalithic Monuments of Peru compared with those in other parts of the world. The second article will be on Sponges, by Prof. Leidy, of Philadelphia.

WE have received from the Mannheim Association for Natural Science the annual report published in February of last year, and giving an account of the society's operations during the year 1868-9. The usefulness of the Association appears to have been somewhat limited by the want of funds. To the same cause must doubtless be ascribed the fact that the only papers published with the report before us are on the meteorology of Mannheim. We are glad, however, to learn from the Secretary that the volume for 1870 will shortly appear, and that it is to contain several interesting astronomical, meteorological, and botanical communications.

M. DUMERIL, Member of the Institute and Professor at the Jardin des Plantes, commenced on the 15th inst. at the Museum of Natural History, a course of lectures on the general history of reptiles, batrachians, and fish.

MR. DYER, of Cirencester College, has been appointed by Earl De Grey to the Professorship of Botany in the Royal College of Science, Dublin.

IT was some time since announced that the prize offered by Lieut.-Colonel Scott, R.E., the secretary of the Royal Horticultural Society, for an essay on the Principles of Floral Criticism, would be awarded on January 19th. It is now stated that the award will not be made till Wednesday, May 4th, 1870.

WE note the appearance of a new edition of the very handy geological map of Germany, France, England, and the neighbouring countries, originally drawn up by Von Dechen in 1839. It will be found very useful to any continental tourists who have some geological knowledge, and who care to take an intelligent survey of the countries they travel through. Copies may be obtained of Messrs. Nutt, 270, Strand. The scale is 1:2,500,000.

A COMMITTEE has been formed at Liverpool for the purpose of establishing a Zoölogical Society. It is hoped that the corporation will grant a site for the society's garden in one of the public parks.

MELBOURNE has recently acquired a fresh utility and ornament in the shape of a turret-clock, the first manufactured in the colony, which for perfection of work and peculiarities of construction challenges the admiration of all horologists. The dials, six feet in diameter, consisting of frames of cast-iron—the rings, figures, and minute marks (eight inches long and one broad) all formed in one casting—are eighty feet from the level of Bourke Street. The weight is about 120 pounds, suspended on a barrel seventeen inches long and ten inches in diameter, revolving twenty-nine times a week, giving a downfall of about seventy feet. The pendulum swings once in two seconds, and consists of a dry and varnished pine rod fifteen feet six inches long, with a cylinder of lead weighing 320 pounds. As it was thought desirable to make the hands move by easily seen impulses every half-minute, so as to ascertain the time to a second, a special arrangement, called a spring *remontoire*, has been added, by means of which the wheels of the clock are detained for thirty seconds and escape at the half-minute, allowing the weight to move the hands over half a minute's space, and wind up a small clock-spring in the spindle, which revolves in two minutes. This keeps the pendulum and the escapement going while the rest of the works are held back. The following is a technical description of this *remontoire*:—"The wheel in the spindle, which revolves once in five minutes, drives a second pinion with eight teeth, the spindle of which projects through the back of the clock frame, and carries a little cylinder with two notches at the end, one broad and shallow, the other narrow and deep. At the end of the *remontoire* arms are two steel projections, one of which passes through the broad notch and the other through the narrow one. As the two-minute spindle revolves, with the notched cylinder, it brings a notch in a right position to let one of the arm projections through every half-minute, allowing the train to move the hands, and wind up the small spring. To effect this the pinion with sixteen leaves is loose on the two-minute spindle, and is only attached to one end of the spring. The clock is also supplied with Denison's double three-legged gravity escapement.

THE Mount Washington Railway, which ascends the White Mountains, New Hampshire, U.S., is about three miles in length, the average gradient being a little more than 1 in 4, which is increased in some places to the extraordinary extent of 1 in 3. The engine draws itself up the line by means of a "pinion," which works into a strong "rack" fixed between the rails, and the ascent of three miles is completed in about one hour.

M. MOHN, Director of the Observatory of Christiania, has recently surveyed the *névé* field of Fostedalsbrœn, which occupies 750 square kilometres. He finds that it feeds twenty-two glaciers of the first order and more than 200 smaller ones. The *névé* is seventy kilometres from the sea.

MESSRS. BELL AND DALDY have just issued the first part of a work bearing the title "Natural Phenomena and Chronology of the Seasons," and containing a chronological register of the remarkable frosts, droughts, thunderstorms, gales, floods, earthquakes, &c. which have occurred in the British Isles since A.D. 220. The author, Mr. E. J. Lowe, F.R.S., the well-known meteorologist, wishes it to be understood that his chief object in publishing what is confessedly a very imperfect record is to call attention to the subject, and elicit further information for a more extensive work, embracing the more remarkable natural phenomena of foreign countries. The compilation of a catalogue of this nature, if it is to be of any real benefit to science, involves an enormous amount of labour and much critical skill. The original authorities for the phenomena recorded should, in each case, be referred to so precisely that the quotations may be readily verified. It is hardly satisfactory to see the *Preston Herald* quoted in support of the assertion that 1,500 houses were unroofed and destroyed in London, in the year 944.

MR. JOHN H. MARTIN, secretary to the Maidstone and Mid-Kent Natural History Society, has just brought out the first number of a new publication, "Microscopic Objects figured and described," containing 16 wood-cuts and short descriptions of vegetable objects, from the yeast-plant to the spiral-vascular tissue from garden rhubarb. The work is intended, when complete, to contain about 200 figures, all of them original, to be issued in monthly numbers. It is proposed to commence with the primary forms of vegetable life, and to proceed onwards through the tissues to the woody structures of the Exogens and Endogens, next descending to the Acrogens, and so passing to the extreme limits of vegetable life, as the Desmidiæ, &c., thence to the lower forms of animal life, the Infusoria, and on through the Radiata to the Insects, which will be drawn and described in their various orders, and the minute organs figured separately.

THE *Architect* states that Lieutenant Cole, R.A., and three sappers, sent out by the Secretary of State for India to take casts of the Sanchi Tope, have arrived in Calcutta. For the benefit of those of our readers who have not had the privilege of seeing Mr. Fergusson's magnificent work "On Tree and Serpent Worship," we may mention that the Sanchi Tope, a monument of very high antiquity, is surrounded by walls and gateways covered with elaborate sculptured decorations of the greatest interest to the student of the early history of the human race.

THE *Field* of Saturday last contains some interesting notes on special agricultural training-schools in France, Germany, and Switzerland. At Rütte in the Canton of Berne, and at Santhoven in Bavaria, particular attention is given to the theory and practice of dairy operations, and the general treatment of cow stock. The school of Lézardeau, on the estate of Count Conédic, in the Department of Finisterre, offers special facilities for the study of draining and irrigation. In this school there is a technical library, a museum, a collection of meteorological instruments, a laboratory, and tools of all descriptions. The general course of study includes elementary mechanics, agricultural chemistry and botany, the pruning and grafting of fruit-trees, the making of roads, and other practical knowledge. At Görtz, in Austria, is a special institution for silkworm culture, supporting a journal exclusively devoted to that branch of industry. The *Athenæum* states that the Ottoman Government is giving its support to a project of M. Netter, of Constantinople, to found an agricultural school for Jews in Palestine.

We have been requested to notify that the following premiums have been placed at the disposal of the Council of the Society for the Encouragement of Arts, Manufactures, and Commerce, for the term of seven years, by M. Septimus Piesse:—1. A premium of £5, for one pound of Otto of Bergamot, of the value of 16*s*. or more in the London market, being the produce of plants (*Citrus bergamia*) grown in Australia, New Zealand, Natal, any of the British West India Islands, or any other British Colony or Dependency. 2. A premium of £5, for one ounce of Otto of Roses, of the value of 20*s*. or more in the London market, being the produce of any variety of roses grown together in one plantation in Australia, New Zealand, Natal, any of the British West India Islands, or any other British Colony or Dependency. 3. A premium of £10, for a canister of Enflowered Butter or Fat, so scented with any kind or sort of flower, either by infusion or enfleurage, or by means of these processes jointly, of the weight of 3 lbs. or more, and of the value of 6*s*. per lb. in London. The said butter or fat to be enflowered or infused with flowers grown for the purpose in Australia, New Zealand, Natal, any of the British West India Islands, or any other British Colony or Dependency.

ON HAZE AND DUST

SOLAR light in passing through a dark room reveals its track by illuminating the dust floating in the air. "The sun," says Daniel Culverwell, "discovers atomes, though they be invisible by candle-light, and makes them dance naked in his beams."

In my researches on the decomposition of vapours by light, I was compelled to remove these "atomes" and this dust. It was essential that the space containing the vapours should embrace no visible thing; that no substance capable of scattering the light in the slightest sensible degree should, at the outset of an experiment, be found in the "experimental tube" traversed by the luminous beam.

For a long time I was troubled by the appearance there of floating dust, which, though invisible in diffuse daylight, was at once revealed by a powerfully condensed beam. Two tubes were placed in succession in the path of the dust: the one containing fragments of glass wetted with concentrated sulphuric acid; the other, fragments of marble wetted with a strong solution of caustic potash. To my astonishment it passed through both. The air of the Royal Institution, sent through these tubes at a rate sufficiently slow to dry it and to remove its carbonic acid, carried into the experimental tube a considerable amount of mechanically-suspended matter, which was illuminated when the beam passed through the tube. The effect was substantially the same when the air was permitted to bubble through the liquid acid and through the solution of potash.

Thus, on the 5th of October, 1868, successive charges of air were admitted through the potash and sulphuric acid into the exhausted experimental tube. Prior to the admission of the air the tube was *optically empty;* it contained nothing competent to scatter the light. After the air had entered the tube, the conical track of the electric beam was in all cases clearly revealed. This indeed was a daily observation at the time to which I now refer.

I tried to intercept this floating matter in various ways; and on the day just mentioned, prior to sending the air through the drying apparatus, I carefully permitted it to pass over the tip of a spirit-lamp flame. The floating matter no longer appeared, having been burnt up by the flame. It was therefore *organic matter.* When the air was sent too rapidly through the flame, a fine blue cloud was found in the experimental tube. This was the *smoke* of the organic particles. I was by no means prepared for this result; for I had thought, with the rest of the world, that the dust of our air was, in great part, inorganic and non-combustible.

Mr. Valentin had the kindness to procure for me a small gas-furnace, containing a platinum tube, which could be heated to vivid redness. The tube also contained a roll of platinum gauze, which, while it permitted the air to pass through it, ensured the practical contact of the dust with the incandescent metal. The air of the laboratory was permitted to enter the experimental tube, sometimes through the cold, and sometimes through the heated tube of platinum. The rapidity of admission was also varied. In the first column of the following table the quantity of air operated on is expressed by the number of inches which the mercury gauge of the air-pump sank when the air entered. In the second column the condition of the platinum tube is mentioned, and in the third the state of the air which entered the experimental tube.

Quantity of Air.	State of Platinum Tube.	State of Experimental Tube.
15 inches . . .	Cold . . .	Full of particles.
15 ,, . . .	Red-hot . .	Optically empty.
15 ,, . . .	Cold . . .	Full of particles.
15 ,, . . .	Red-hot . .	Optically empty.
15 ,, . . .	Cold . . .	Full of particles.
15 ,, . . .	Red-hot . .	Optically empty.

The phrase "optically empty" shows that when the conditions of perfect combustion were present, the floating matter totally disappeared. It was wholly burnt up, leaving not a trace of residue. From spectrum analysis, however, we know that soda floats in the air; these organic dust particles are, I believe, the *rafts* that support it, and when they are removed it sinks and vanishes.

When the passage of the air was so rapid as to render imperfect the combustion of the floating matter, instead of optical emptiness a fine blue cloud made its appearance in the experimental tube. The following series of results illustrate this point:—

Quantity.	Platinum Tube.	Experimental Tube.
15 inches, slow .	Cold . . .	Full of particles.
15 ,, ,, .	Red-hot . .	Optically empty.
15 ,, quick .	,, . .	A blue cloud.
15 ,, ,, .	Intensely hot .	A fine blue cloud.

The optical character of these clouds was totally different from that of the dust which produced them. At right angles to the illuminating beam they discharged perfectly polarised light. The cloud could be utterly quenched by a transparent Nicol's prism, and the tube containing it reduced to optical emptiness.

The particles floating in the air of London being thus proved to be organic, I sought to burn them up at the focus of a concave reflector. One of the powerfully convergent mirrors employed in my experiments on combustion by dark rays was here made use of, but I failed in the attempt. Doubtless the floating particles are in part transparent to radiant heat, and are so far incombustible by such heat. Their rapid motion through the focus also aids their escape. They do not linger there sufficiently long to be consumed. A flame it was evident would burn them up, but I thought the presence of the flame would mask its own action among the particles.

In a cylindrical beam, which powerfully illuminated the dust of the laboratory, was placed an ignited spirit-lamp. Mingling with the flame, and round its rim, were seen wreaths of darkness resembling an intensely black smoke. On lowering the flame below the beam the same dark masses stormed upwards. They were at times blacker than the blackest smoke that I have ever seen issuing from the funnel of a steamer, and their resemblance to smoke was so perfect as to lead the most practised observer to conclude that the apparently pure flame of the alcohol lamp required but a beam of sufficient intensity to reveal its clouds of liberated carbon.

But is the blackness smoke? The question presented itself in a moment. A red-hot poker was placed underneath the beam, and from it the black wreaths also ascended. A large hydrogen flame was next employed, and it produced those whirling masses of darkness far more copiously than either the spirit-flame or poker. Smoke was therefore out of the question.

What, then, was the blackness? It was simply that of stellar space; that is to say, blackness resulting from the absence from the track of the beam of all matter competent to scatter its light. When the flame was placed below the beam the floating matter was destroyed *in situ;* and the air, freed from this matter, rose into the beam, jostled aside the illuminated particles, and substituted for their light the darkness due to its own perfect transparency. Nothing could more forcibly illustrate the invisibility of the agent which renders all things visible. The beam crossed, unseen, the black chasm formed by the transparent air, while at both sides of the gap the thick-strewn particles shone out like a luminous solid under the powerful illumination.

But here a difficulty meets us. It is not necessary to burn the particles to produce a stream of darkness. Without actual combustion, currents may be generated which shall exclude the floating matter, and therefore appear dark amid the surrounding brightness. I noticed this effect first on placing a red-hot copper ball below the beam, and permitting it to remain there until its temperature had fallen below that of boiling water. The dark currents, though much enfeebled, were still produced. They may also be produced by a flask filled with hot water.

To study this effect a platinum wire was stretched across the beam, the two ends of the wire being connected with the two poles of a voltaic battery. To regulate the strength of the current a rheostat was placed in the circuit. Beginning with a feeble current the temperature of the wire was gradually augmented, but before it reached the heat of ignition, a flat stream of air rose from it, which when looked at edgeways appeared darker and sharper than one of the blackest lines of Fraunhofer in the solar spectrum. Right and left of this dark vertical band the floating matter rose upwards, bounding definitely the non-luminous stream of air. What is the explanation? Simply this. The hot wire rarefied the air in contact with it, but it did not equally lighten the floating matter. The convection current of pure air therefore passed upwards *among the particles*, dragging them after it right and left, but forming between them an impassable black partition. In this way we render an account of the dark currents produced by bodies at a temperature below that of combustion.

Oxygen, hydrogen, nitrogen, carbonic acid, so prepared as to exclude all floating particles, produce the darkness when poured or blown into the beam. Coal-gas does the same. An ordinary glass shade placed in the air with its mouth downwards permits the track of the beam to be seen crossing it. Let coal-gas or hydrogen enter the shade by a tube reaching to its top, the gas gradually fills the shade from the top downwards. As soon as it occupies the space crossed by the beam, the luminous track is instantly abolished. Lifting the shade so as to bring the common boundary of gas and air above the beam, the track flashes forth. After the shade is full, if it be inverted, the gas passes upwards like a black smoke among the illuminated particles.

The air of our London rooms is loaded with this organic dust, nor is the country air free from its pollution. However ordinary daylight may permit it to disguise itself, a sufficiently powerful beam causes the air in which the dust is suspended to appear as a semi-solid rather than as a gas. Nobody could, in the first instance, without repugnance place the mouth at the illuminated focus of the electric beam and inhale the dirt revealed there. Nor is the disgust abolished by the reflection that, although we do not see the nastiness, we are churning it in our lungs every hour and minute of our lives. There is no respite to this contact with dirt; and the wonder is, not that we should from time to time suffer from its presence, but that so small a portion of it would appear to be deadly to man.

And what is this portion? It was some time ago the current belief that epidemic diseases generally were propagated by a kind of malaria, which consisted of organic matter in a state of *motor-decay;* that when such matter was taken into the body through the lungs or skin, it had the power of spreading there the destroying process which had attacked itself. Such a spreading power was visibly exerted in the case of yeast. A little leaven was seen to leaven the whole lump, a mere speck of matter in this supposed state of decomposition being apparently competent to propagate indefinitely its own decay. Why should not a bit of rotten malaria work in a similar manner within the human frame? In 1836 a very wonderful reply was given to this question. In that year Cagniard de la Tour discovered the *yeast plant*, a living organism, which when placed in a proper medium, feeds, grows, and reproduces itself, and in this way carries on the process which we name fermentation. Fermentation was thus proved to be a product of life instead of a process of decay.

Schwann, of Berlin, discovered the yeast plant independently, and in February 1837 he also announced the important result, that when a decoction of meat is effectually screened from ordinary air, and supplied solely with air which has been raised to a high temperature, putrefaction never sets in. Putrefaction, therefore, he affirmed to be caused by something derived from the air, which something could be destroyed by a sufficiently high temperature. The experiments of Schwann were repeated and confirmed by Helmholtz and Ure. But as regards fermentation, the minds of chemists, influenced probably by the great authority of Gay-Lussac, who ascribed putrefaction to the action of oxygen, fell back upon the old notion of matter in a state of decay. It was not the living yeast plant, but the dead or dying parts of it, which, assailed by oxygen, produced the fermentation. This notion was finally exploded by Pasteur. He proved that the so-called "ferments" are not such; that the true ferments are organised beings which find in the reputed ferments their necessary food.

Side by side with these researches and discoveries, and fortified by them and others, has run the *germ theory* of epidemic disease. The notion was expressed by Kircher, and favoured by Linnæus, that epidemic diseases are due to germs which float in the atmosphere, enter the body, and produce disturbance by the development within the body of parasitic life. While it was still struggling against great odds, this theory found an expounder and a defender in the President of this Institution. At a time when most of his medical brethren considered it a wild dream, Sir Henry Holland contended that some form of the germ theory was probably true. The strength of this theory consists in the perfect parallelism of the phenomena of contagious disease with those of life. As a planted acorn gives birth to an oak competent to produce a whole crop of acorns, each gifted with the power of reproducing its parent tree, and as thus from a single seedling a whole forest may spring, so these epidemic diseases literally plant their seeds, grow, and shake abroad new germs, which, meeting in the human body their proper food and temperature, finally take possession of whole populations. Thus Asiatic cholera, beginning in a small way in the Delta of the Ganges, contrived in seventeen years to spread itself over nearly the whole habitable world. The development from an infinitesimal speck of the virus of small-pox of a crop of pustules, each charged with the original poison, is another illustration. The reappearance of the scourge, as in the case of the *Dreadnought* at Greenwich, reported on so ably by Dr. Budd and Mr. Busk, receives a satisfactory explanation from the theory which ascribes it to the lingering of germs about the infected place.

Surgeons have long known the danger of permitting air to enter an open abscess. To prevent its entrance they employ a tube called a cannula, to which is attached a sharp steel point called a trocar. They puncture with the steel point, and by gentle pressure they force the pus through the cannula. It is necessary to be very careful in cleansing the instrument; and it is difficult to see how it can be cleansed by ordinary methods in air loaded with organic impurities, as we have proved our air to be. The instrument ought, in fact, to be made as hot as its temper will bear. But this is not done, and hence, notwithstanding all the surgeon's care, inflammation often sets in after the first operation, rendering necessary a second and a third. Rapid putrefaction is found to accompany this new inflammation. The pus, moreover, which was sweet at first, and showed no trace of animal life, is now fetid, and swarming with active little organisms called vibrios. Prof. Lister, from whose recent lecture this fact is derived, contends, with every show of reason, that this rapid putrefaction and this astounding development of animal life are due to the entry of germs into the abscess during the first operation, and their subsequent nurture and development under favourable conditions of food and temperature. The celebrated physiologist and physicist Helmholtz is attacked annually by hay-fever. From the 20th of May to the end of June he suffers from a catarrh of the upper air-passages; and he has found during this period, and at no other, that his nasal secretions are peopled by these vibrios. They appear to nestle by preference in the cavities and recesses of the nose, for a strong sneeze is necessary to dislodge them.

These statements sound uncomfortable; but by disclosing our enemy they enable us to fight him. When he clearly eyes his quarry the eagle's strength is doubled, and his swoop is rendered sure. If the germ theory be proved true, it will give a definiteness to our efforts to stamp out disease which they could not previously possess. And it is only by definite effort under its guidance that its truth or falsehood can be established. It is difficult for an outsider like myself to read without sympathetic emotion such papers as those of Dr. Budd, of Bristol, on cholera, scarlet-fever, and small-pox. He is a man of strong imagination, and may occasionally take a flight beyond his facts; but without this dynamic heat of heart, the stolid inertia of the free-born Briton cannot be overcome. And as long as the heat is employed to warm up the truth without singeing it over-much; as long as this enthusiasm can overmatch its mistakes by unequivocal examples of success, so long am I disposed to give it a fair field to work in, and to wish it God speed.

But let us return to our dust. It is needless to remark that it cannot be blown away by an ordinary bellows; or, more correctly, the place of the particles blown away is in this case supplied by others ejected from the bellows, so that the track of the beam remains unimpaired. But if the nozzle of a good bellows be filled with cotton wool not too tightly packed, the air urged through the wool is filtered of its floating matter, and it then forms a clean band of darkness in the illuminated dust. This was the filter used by Schroëder in his experiments on spontaneous generation, and turned subsequently to account in the excellent researches of Pasteur. Since 1868 I have constantly employed it myself.

But by far the most interesting and important illustration of this filtering process is furnished by the human breath. I fill my lungs with ordinary air and breathe through a glass tube across the electric beam. The condensation of the aqueous vapour of the breath is shown by the formation of a luminous white cloud of delicate texture. It is necessary to abolish this cloud, and this may be done by drying the breath previous to its entering into the beam; or still more simply, by warming the glass tube. When this is done the luminous track of the beam is for a time uninterrupted. The breath impresses upon the floating matter a transverse motion, but the dust from the lungs makes good the particles displaced. But after some time an obscure disc appears upon the beam, the darkness of which increases, until finally, towards the end of the expiration, the beam is, as it were, pierced by an intensely black hole, in which no particles whatever can be discerned. The air, in fact, has so lodged its dirt within the lungs as to render the last portions of the expired breath absolutely free from suspended matter. This experiment may be repeated any number of times with the same result. It renders the distribution of the dirt within the lungs as manifest as if the chest were transparent.

I now empty my lungs as perfectly as possible, and placing a handful of cotton wool against my mouth and nostrils, inhale through it. There is no difficulty in thus filling the lungs with air. On expiring this air through the glass tube, its freedom from floating matter is at once manifest. From the very beginning of the act of expiration the beam is pierced by a black aperture. The first puff from the lungs abolishes the illuminated dust and puts a patch of darkness in its place, and the darkness continues throughout the entire course of the expiration. When the tube is placed below the beam and moved to and fro, the same smoke-like appearance as that obtained with a flame is observed. In short, the cotton wool, when used in sufficient quantity, completely intercepts the floating matter on its way to the lungs.

And here we have revealed to us the true philosophy of a practice followed by medical men, more from instinct than from actual knowledge. In a contagious atmosphere the physician places a handkerchief to his mouth and inhales through it. In doing so he unconsciously holds back the dirt and germs of the air. If the poison were a gas it would not be thus intercepted. On showing this experiment with the cotton wool to Dr. Bence Jones, he immediately repeated it with a silk handkerchief. The result was substantially the same, though, as might be expected, the wool is by far the surest filter. The application of these experiments is obvious. If a physician wishes to hold back from the lungs of his patient, or from his own, the germs by which contagious disease is said to be propagated, he will employ a cotton-wool respirator. After the revelations of this evening such respirators must, I think, come into general use as a defence against contagion. In the crowded dwellings of the London poor, where the isolation of the sick is difficult, if not impossible, the noxious air around the patient may, by this simple means, be restored to practical purity. Thus filtered, attendants may breathe the air unharmed. In all probability the protection of the lungs will be protection of the entire system. For it is exceedingly probable that the germs which lodge in the air-passages, and which, at their leisure, can work their way across the mucous membrane, are those which sow in the body epidemic disease. If this be so, then disease can certainly be warded off by filters of cotton wool. I should be most willing to test their efficacy in my own person. And time will decide whether in lung diseases also the woollen respirator cannot abate irritation, if not arrest decay. By its means, so far as the germs are concerned, the air of the highest Alps may be brought into the chamber of the invalid.

JOHN TYNDALL

SCIENTIFIC SERIALS

THE *Zeitschrift für Chemie* (No. 1) contains an account of some unfinished experiments by Muck on manganous sulphide, and a note by Dr. Baumhauer, of Bonn, on the action of aqueous hydric chloride on nitrobenzol. In the latter of these the author points out the interesting fact that dichloraniline is a principal product of the reaction. Robert Otto communicates several papers containing the results of experiments which he has performed, for the most part, with the co-operation of Eugen Dreher. The subjects of the papers are "Mercuric Diphenyl," under which title a tolerably exhaustive account of this body is given; "Mercuric Ditolyl," which was not so extensively examined; "On the deportment of Dibenzyl at a high temperature" (it splits into Toluol and Toluylene); "On the transformation of hydro-phenylic sulphide into phenylic sulphide" (the mercuric derivative decomposes thus at 180°:—$(C_6H_5)_2H_gS_2 = (C_6H_5)_2, S_2 + H_g$); "On mercuric dinaphtyl," from which it appears that the presence of ethylic acetate is very advantageous in the usual mixture whereby the body is prepared; "On mono-ethylic and mono-methylic mercuric acetate;" and "On the preparation of organic sulphur-compounds by means of sodic hyposulphite."—A. Geuther contributes a short article "On the volatile acids of croton oil." He finds that the oil contains no crotonic acid, which name is consequently a misnomer. Of the two metamers, $C_4H_6O_2$, he consequently designates the solid modification *tetranylic*, and the liquid variety *quartenylic* acid. Croton oil contains a metamer of angelic acid, for which the author proposes the name *tiglinic* acid.—Markownikoff finds that the butylic (fermentation) alcohol, when transformed into iodide, and then, by alcoholic potash, into olefiant, furnishes with hydric iodide the tertiary pseudo-butylic iodide.—Petrieff describes *solid* azoxytoluide (fusing at 57°).

THE *Annales de Chimie et de Physique* for December last contains a short note by M. Soliel on an ocular micrometer, the principle of which was discovered independently by Prof. Govi and himself. The rest of the number is wholly occupied by abstracts of foreign scientific papers.

THE *Annals and Magazine of Natural History*, fourth series, No. 25. The January number of this journal contains the conclusion of Mr. Wollaston's descriptions of the Coleoptera of St. Helena, to which we shall refer elsewhere. Mr. D. Sharp also publishes a paper on the species of *Philhydrus* found in the Atlantic Islands, which may be regarded as supplementary to and rectificatory of Mr. Wollaston's works on the Coleoptera of those islands. Dr. Lycett describes a byssiferous fossil *Trigonia* (*T. carniata* Ag.) Messrs. A. Hancock and R. Howse describe in considerable detail the remains of a fossil fish (*Janassa bituminosa* Schloth.) from the Permian marl-slate of Midderidge in the county of Durham. They identify with the genus *Janassa* the coal-measure form described by Messrs. Hancock and Atthey under the name of *Climaxodus linguæformis*, and regard the genus as belonging to the Rays, and probably allied to *Myliobates*. The known specimens consist chiefly of the teeth, which were originally described by Schlotheim as Trilobites, under the name of *T. bituminosus;* different examples have been described as fish-remains under various names, and the authors refer to their species the *Janassa angulata*, *Humboldti*, *bituminosa*, and *dictea*, *Dictea striata* and *Byzenos latipinnatus* of Count Münster, and the *Acrodus larva* of Professor Agassiz. This paper is illustrated with two excellent plates. Dr. Carl Semper describes the *Helix inæqualis* (Pfeiff.) from Australia as forming a new genus of Testacellidæ, to which he gives the name of *Rhytida*. Professor E. Perceval Wright describes and figures a new parasitic Crustacean, *Pennella orthagorisci*, obtained from a sun-fish in Cork Harbour; and Mr. John Gould describes a new Pigeon, *Otidiphaps nobilis*, forming the type of a new genus.—The only botanical paper in the number is the thirty-first instalment of the Rev. W. A. Leighton's "Notulæ Lichenologicæ," containing an analytical examination of certain new characters in the species of the genera *Nephroma* and *Nephromium*.—Besides the translations and abstracts of foreign papers which appear among the miscellaneous contributions, this number contains the first part of a translation of Professor Häckel's memoir on the organisation of sponges, and their relationship to corals, in which the author maintains that the corals (*Anthozoa*) are very nearly related to the Sponges, that the latter belong to the great group of the Cœlenterata, and that "the sole morphological character which sharply and decidedly separates" them from the rest of the Cœlenterata is to be found in the "deficiency of the urticating organs in all sponges."

THE *Moniteur Scientifique* for January 1st has much of its space occupied by an account of the legal inquiry resulting from the remarkable explosion of potassic picrate which occurred in the Place de la Sorbonne on the 16th June last. The evidence and the speeches of counsel are given at considerable length. M. Dubrunfant contributes an article on the Saline Analysis of Sugars, and on Melassimetry. There is also the usual account of the sittings of the Academy of Sciences; a Photographic Review, and a review of foreign journals—both very carefully written. A new feature in this serial, introduced this year, is a price-current of the principal products referred to in the papers it contains, and for the general use of subscribers. We cannot, however, help thinking that our able contemporary, in seeking to oblige its readers, has undertaken a task which, from the smallness of available space, it cannot adequately fulfil. A full price-current ought to have a periodical to itself.

Revue des Cours Scientifiques, January 22.—The first paper consists of extracts from an eloquent obituary notice of Trousseau, read by M. J. Béchard, the Secretary of the French Academy of Medicine, at the recent annual general meeting. "In this *éloge* of the man who is one of the most distinguished personifications of the old empirical medicine, M. Béchard has skilfully contrived to afford us a glimpse of the advent—possibly close at hand—of scientific medicine." A lecture by M. Lortet on the physiological effects of mountain climbing is the second paper in the present number of the *Revue*. We hope shortly to lay before our readers a full account of M. Lortet's observations. The other papers are one by Prof. Mayer, of Heilbronn, the recently elected Corresponding Member of the Institute of France, on the necessary consequences and inconsequences of the mechanical theory of heat, and a communication, lately presented to the Academy of Sciences, by M. St. Claire Deville, on the nascent state of bodies.

THE *American Naturalist*.—In the number for the present month there is an original article on the microscopic examination of shavings, and two others on the birds of Massachusetts; likewise a continuation of a review of Professor Huxley's Classification of Animals, in which the opinion is expressed that the publication of that book will not endanger the Cuvierian system. A reprint is also given from the *Popular Science Review* of the temperate and well-written article in which Prof. Cleland, of Glasgow, once more lays the ghost of phrenology, and gives, in a popular way, much solid information.

BOTANY

British Museum Herbarium

THE national Herbarium at the British Museum, though not equal in extent to that at Kew, is one of very great value to botanists from the numbers of "type-specimens" it contains; that is, specimens named by the original discoverer or describer, thus serving as a standard for reference. According to the official report lately issued by the Curator, Mr. J. J. Bennett, the herbarium has received large and important additions during the past year, by purchase and donation, from all parts of the world, including flowering plants, ferns, lichens, mosses, sea-weeds, the microscopic Diatoms, fossil plants, sections of wood, &c.; while collections previously received have been arranged and incorporated.

Wood for Gunpowder

ALTHOUGH the materials of which gunpowder is made have not varied since its first invention, there has been considerable variety in the kind of wood from which the charcoal has been obtained. Dense woods are always rejected and the lighter kinds chosen, especially those most free from silica, and capable of producing a friable porous charcoal which burns quickly and leaves the least possible quantity of ash; the kind now generally used by gunpowder manufacturers is known as "Dog-wood," and is usually described as being obtained from the small tree popularly known under that name, the *Cornus sanguinea.* Dr. Hooker has, however, recently discovered that this is a popular error, and that the wood is really almost universally obtained from the Buckthorn, or *Rhamnus frangula*; the former tree being now never used for this purpose, if indeed it ever was. Till a few years since, the bulk of the Buckthorn wood used in this manufacture was supplied from English plantations in Suffolk, Norfolk, Essex, and Kent, but the great increase recently in the demand for the finer descriptions of gunpowder has rendered this source insufficient; and it is now cultivated in immense districts of forest and marsh in North Germany, lying between Berlin and Frankfort, where it forms the natural undergrowth. From the high price obtained for the wood, 10*l.* to 15*l.* per ton, its cultivation would be exceedingly lucrative in this country, as it will grow in almost any soil.

Action of Ether on Plants

THE action of ether as an anæsthetic on the animal frame has induced Dr. Maxwell Masters to experiment on its effects on plants. He states that if a drop is placed gently on the leaf of the Sensitive plant, it produces a paralysing effect, rendering it insensible to subsequent contact. If, however, the ether impinges on the leaf with force, or is allowed to drop from a considerable height, contraction of the leaf immediately takes place, the impact of the falling drop counteracting any paralysing power. It is well known that in the contraction of the leaves of the Sensitive plant a certain amount of vital force is expended, and that if often repeated the plant becomes exhausted, and a time of rest is required before the phenomena are repeated.

Viridescence of Leaves

M. PRILLIEUX has established, as the result of a large number of observations on the leaves of barley, that viridescence is more rapid in diffused light than in the direct light of the sun, in contrast to the production of oxygen, which is more abundant the stronger the light. He introduced into a dark chamber a pencil of solar rays, and, by means of a lens, produced a diverging cone, in which he placed the barley at different distances from the lens, consequently under different intensities of light determinable with precision. He found that near the lens, that is, placed in a very intense light, the etiolated leaves scarcely became green, while at a greater distance the viridescence took place more rapidly, and attained its maximum at a distance of three or four metres, beyond which the activity decreased; so that in a too feeble light the effect was the same as in too strong a light. [L'Institut].

MÖLLER has prepared a beautiful microscopic slide, containing 300 distinct species of Diatoms, showing an extraordinary variety of form, and arranged with marvellous regularity. It forms one of the most interesting objects for the microscope we have seen.

THE "Prodromus Systematis naturalis Regni vegetabilis," the work of three generations of De Candolles, is now approaching completion, as it is not intended to continue it beyond the Exogens. The first section of the sixteenth volume, just published, includes two important monographs, the *Urticaceæ* by Weddell, and the *Piperaceæ* by Casimir De Candolle.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 20.—The following papers were read:—

"On the mechanical performance of logical inference," by W. Stanley Jevons, M.A. Lond., Professor of Logic, &c., in Owens College; communicated by Professor E. Roscoe, F.R.S. The author first referred to the general use of mechanical contrivances for the purpose of mathematical computation, and then contrasted this fact with the utter absence of machines for aiding logical operations. This absence he attributed to the incompleteness of the old logical doctrines. The problem of logical science in its complete generality was first solved by Boole. His logical views, when simplified and corrected, give us a method of indirect deduction of extreme generality and power, founded directly upon the fundamental laws of thought. A proof of the truthfulness and power of this system is to be found in the fact that it can be embodied in a machine just as the calculus of differences is embodied in Mr. Babbage's calculating machine. To explain the nature of the logical machine alluded to, it may be pointed out that the third of the fundamental laws of thought allow us to affirm of any object one or the other of two contradictory attributes, and that we are thus enabled to develope a series of alternatives which must contain the description of a given class or object. Thus, if we are considering the propositions,

Iron is metal,
Metal is element,

we can at once affirm of iron that it is included among the four alternatives:—

Metal, element,
Metal, not element,
Not metal, element,
Not metal, not element.

But according to the second law of thought, nothing can combine contradictory attributes, and this law prevents us from supposing that *iron* can be *not-metal*, while the first premise affirms that it is *metal*. The second premise again prevents our supposing that the combination *metal*, *not-element*, can exist. Hence the only combination of properties which the premises allow us to affirm of *iron* is *metal*, *element*. In a similar manner a complete solution of any logical problem may be effected by forming the complete list of combination in which the terms of the problem can manifest themselves, and then striking out such of the combinations as cannot exist in consistency with the conditions of the problem. The logical machine actually constructed represents the combination, 16 in number, of four positive terms, denoted by A, B, C, D, and their corresponding negatives, *a*, *b*, *c*, *d*. The instrument is provided with eight keys, representing these terms when appearing in the subject of a proposition, with eight keys, placed to the right hand of the former, representing the terms when occurring in the predicate of a proposition, and with the certain *operation* keys denoting the *copular* of the proposition, the *full stop* at the end of it, and the conjunction *or*, according as it occurs in the subject or predicate. There is also a key denoting the *finis* or end of an argument, which has the effect of obliterating any previous impressions, and making the machine a *tabula rasa*. If now each of the letter terms, A, B, C, D, be taken to represent some logical term or noun, and propositions concerning them be, as it were, played upon the machine, as upon a telegraphic instrument, the machine effects thereby such a classification and selection of certain rods representing the 16 possible combinations of the terms, that only those combinations consistent with the propositions remain indicated by the machine at the end of the operations. When once a series of propositions is thus impressed upon the machine, it is capable of exhibiting an answer to any question which may be put to it concerning the possible combinations which form any class. The machine thus embodies almost all the powers of Boole's logical system up to problems involving four distinct terms, and to represent problems of any complexity involving any number of terms only requires the multiplication of the parts of the machine. The construction involves no mechanical difficulties, and depends upon a peculiar arrangement of pins and levers, which it would not be easy to explain without drawings. In this arrangement of the parts the conditions of correct thinking are observed; the representative rods are just as numerous as the laws of thought require, and no rod represents inconsistent attributes. The representative rods are classified, selected, or rejected by the reading of a proposition in a manner exactly answering to that in which a reasoning mind should treat its ideas, and at every step in the progress of a problem the machine indicates the proper condition of a mind exempt from mistake. It is believed that this logical machine may be usefully employed in the logical class-room to exhibit the complete analysis of any argument or logical problem; and it is considered by the author superior for this purpose to a more rudimentary contrivance, the logical abacus, constructed by him for the same purpose. But by far the chief importance of the machine is in a theoretical point of view as demonstrating in the simplest and most evident manner the character and powers of a universal system of logical deduction, of which the first, although obscure solution, was given by Dr. Boole.

"On Jacobi's theorem respecting the relative equilibrium of a revolving ellipsoid of fluid; and on Ivory's discussion of the theorem," by I. Todhunter, F.R.S. Jacobi discovered the theorem that a fluid ellipsoid revolving with uniform angular velocity round its least axis might be in equilibrium. Ivory discussed the theorem, and made several statements regarding the limitations of the proportions of the axis. Ivory's statements contain various errors, and truths based on erroneous reasoning. The object of the present memoir is to correct Ivory's errors, to supply his imperfections, and to add something to what is already known respecting the theorem.

Geological Society, January 12.—Professor Huxley, LL.D., F.R.S., president, in the chair. Messrs. J. Aitken, J.P., president of the Manchester Geological Society; E. Allen, C. Cadle, A. W. Edgell, C. F. Leaf, F.L.S., and S. J. Smith, were elected Fellows. Prof. Otto Torell, of Lund, was elected a foreign correspondent. The following communications were read:—1. "On the geological position and geological distribution of the reptilian or dolomitic conglomerate of the Bristol area." By R. Etheridge, Esq., F.G.S., Palæontologist to the Geological Survey of Great Britain. The author noticed the history of our knowledge of the dolomitic conglomerates of the Bristol area from which the remains of dinosaurian reptiles have been obtained, and then described their mode of occurrence and distribution over the district near Bristol. He regarded these deposits as due to the action of the sea-waves of the later or middle Triassic periods upon the rocks of older Triassic (Bunter) or Permian age during the gradual elevation of the land, and as the probable representatives in point of time of the Muschelkalk, otherwise deficient in Britain. The author then noticed the influence of the conglomerate upon the production of certain minerals, such as calamine and hæmatitic iron-ores, and discussed at some length the probable course of the phenomena of denudation which furnished the materials for the formation of the conglomerate at different levels, in which he recognised two great periods of oscillation, the first witnessing a downward movement of the palæozoic lands and lasting throughout the deposition of the New Red marl and sands, and the second, during which the accumulations of the former were again, at least partly, denuded. With regard to the time at which the remains of thecodont reptiles were imbedded in the conglomerate, the author inferred from the evidence that this took place late in the period of the Keuper. The President inquired on what ground the author considered these reptiles to belong to a late period in the Keuper, and was informed that the author spoke especially with relation to the Keuper of the Bristol area, of which the beds containing them occupied the highest position. Prof. Ramsay considered these conglomerates not merely as of marine origin, but as breccias which had covered the old land surface, which had been worked up by the water of the New Red period. He objected to the term Sea having been introduced into the paper; as, though the tracts may have been islands and promontories, and though the water which surrounded them was salt, there was no open sea, but merely a large inland salt-lake, in which the New Red Marl was formed. The marl was less connected with the New Red Sandstone than with the Lias. The Muschelkalk being absent, it was constantly the case that the marl rested immediately on the palæozoic rocks without the intervention of the Bunter Sandstone. He thought that there were good grounds for connecting the Rhætic beds with the New Red Marl below and the Lias above. The probability was that the change in character was due to a gradual influx of the sea into the inland lakes. He thought that the Thecodont Saurians might also eventually be found even in beds of Liassic age. Prof. T. Rupert Jones remarked that Mr. Tawney and Dr. Duncan had already intimated the St. Cassian aspect and character of the Sutton beds. The freshwater character of some of the Keuper beds was, he remarked, indicated by the presence of *Estheriæ*, and he alluded to the fact of the Bristol palæosaurians having been erroneously used as Permian characteristics in Russia and Carolina. Mr. W. Boyd Dawkins had found at Cheddar that the Dolomitic conglomerate formed two great tongues running up ravines in the older rocks, which had probably been due to subaërial action. Prof. Morris alluded to some sections which seemed to corroborate the views of Mr. Etheridge, and pointed out the relation of the conglomerate beds to the overlying strata at those points. He also mentioned certain peculiarities in the structure of the conglomerate itself. Mr. Etheridge stated in reply that the marls in the Bristol area were the exception, the greater part of the New Red beds being sandstone.

2. "On the superficial deposits of portions of the Avon and Severn Valleys and adjoining districts." By Mr. T. G. B. Lloyd, C.E., F.G.S. The author, after describing the general characters of what he termed the Drifts of the Upper and Lower series, and the freshwater gravels of the Lower Avon, comprised within the district of the Avon Valley between Tewkesbury and Rugby, and of the Severn Valley above and below the town of Worcester, endeavoured to show that there was a balance of evidence in favour of the existence of an upper and lower platform of drift in the main valley of the Lower Avon, the upper one being of marine origin, and probably belonging to the same epoch as the stratified beds of gravel in the neighbourhood of Worcester, which contain marine shells and mammalian remains, whilst the lower one, of freshwater origin, had been derived from the former by fluviatile action, as supposed by the late Prof. Strickland. Further, that there was no evidence to warrant the supposition of the existence of high and low level river-gravels in those portions of the Severn and Avon Valleys under review, and that the apparent absence of any freshwater shells in the gravels of the Severn Valley between Bridgnorth and Tewkesbury led to the inference that the freshwater gravels of the Avon were not represented in the adjoining portions of the Severn Valley, although remains of some of the same species of mammalia occurred in both localities. After stating his opinion that the time had not yet arrived for indulging in theoretical speculations concerning the phenomena of the Drifts of the Upper and Lower series exhibited in so small an area as the one under consideration, the author concluded by expressing hopes that the facts which he had brought forward would contribute their share of help to the further elucidation of the question.

3. "On the surface-deposits in the neighbourhood of Rugby." By Mr. J. M. Wilson, F.G.S. The author commenced by noticing the general configuration of the surface of the district under review, which he stated to consist of an elevated plateau, bounded and rendered irregular in its outlines by valleys. The district consists chiefly of Lower Lias, with a few patches of Middle Lias. The surface-deposits on the plateau and on similar high lands in the neighbourhood consist of—1. Flinty or quartzose drift; 2. Sugary sand, with grains of chalk; 3. Clay, with pebbles, principally of chalk, and distinctly striated. The valleys bounding the plateau were described as belonging to two systems, those of the Avon and Leam. The bottom of each valley is generally a narrow strip of alluvial soil, bordered by sand in some places, and by drift in others. The author has bored down into the surface-deposits in the valley of Low Morton. In one boring, which reached a depth of 53 feet, he stopped in a greyish clay containing chalk-particles; in another, through similar clay to a depth of 57 feet, the rock was reached, and fragments of limestone were brought up.

Mr. Searles V. Wood, jun., had long been aware of the existence of the Middle Glacial Sand near Rugby. He pointed out the difference in the fauna of the sands of the Severn Valley below the glacial clay and those of similar deposits in the east of England, but notwithstanding thought they might be of the same age. Mr. Gwyn Jeffreys was doubtful as to the authenticity of some of the shells which had been brought to Mr. Maw. The fossil shells from the Severn Valley, Wolverhampton, Manchester, and Moel Tryfaen were nearly identical, and indicated raised beaches. He thought it possible that a definite line of such beaches might eventually be recognised through that part of England. Mr. W. Boyd Dawkins did not consider that there was any marked difference in the mammalian fauna of the Avon and Severn Valleys. He had failed to discover any traces of *Elephas antiquus* in either. Mr. Prestwich thought that the author had probably divided the superficial beds into too many separate deposits, though the facts brought forward were of great value. Mr. Evans mentioned that he had received information of the discovery many years ago of a flint implement in association with the bones of extinct mammals at Lawford. This implement had been exhibited at the time to the Geological Society, but had disappeared after the meeting. Mr. Lloyd and Mr. Wilson briefly replied.

Chemical Society, January 20.—Professor Williamson, President, in the chair. The following gentlemen were elected Fellows:—T. Bell, A. Bird, G. R. Hislop, E. Lapper, H. Seward. The first paper read was a note on the absorption of mixed vapours by charcoal, by John Hunter, M.A., Queen's College, Belfast. The author some time ago, published in the *Journal of the Chemical Society* (May 1868), the results obtained by absorbing the mixture of two vapours by means of cocoa-nut charcoal. He found that the absorption was increased when one of the vapours was at a temperature near to its point of condensation; and he explained the phenomenon by assuming that when a fragment of charcoal is introduced into a mixture of two vapours, the one which is nearest to its point of condensation is first absorbed, and this, in its condensed state, aids the absorption of the other. According to this view, a succession of condensations is going on. The theory is strikingly illustrated in experimenting with a mixture of water vapour and ammonia gas—obtained by heating an aqueous solution of ammonia of spec. grav. 0·88—when the mixture is much more largely absorbed than either the gas or the vapour separately. The mean of a set of experiments made at 100° C and 706·2 mm. pressure was 316·6 vols. of the mixture absorbed by one vol. of cocoa-nut charcoal. The President remarked that the results of the experiments were entirely in accordance with what was expected on theoretical grounds.—The next communication was "On the composition of iron rust," by Dr. Crace Calvert. The author had lately occasion to analyse rust obtained from two different places—from the outside of the Conway Bridge, and from Llangollen, North Wales—and he found both specimens to be composed as follows:—

Sesquioxide of iron	92·900
Protoxide of iron	6·177
Carbonate of iron	0·617
Carbonate of lime	0·295
Silica	0·121
Ammonia	traces
	100·000

This result induced the author to inquire to which of the constituents of the atmosphere the formation of rust is chiefly due. With the view of ascertaining this, carefully cleaned blades of steel and iron were put into tubes filled respectively with oxygen, oxygen and a little carbonic acid, oxygen and moisture, &c. The blades were introduced into gas-collecting cylinders, which were then filled above mercury with oxygen, &c. But this proved to be an unsatisfactory method, inasmuch as always some globules of mercury remained adhering to the iron, whereby a galvanic action was produced which of course induced a rapid oxidation. To avoid this the tubes were filled simply by displacement of atmospheric air. The blades were then left exposed to the action of the different agents for a period of four months. The results were as follows:—

Blades in dry oxygen	No oxidation.
„ moist „	Out of three experiments only in one a slight oxidation.
„ dry carb. acid	No oxidation.
„ moist „	Slight incrustation of a white colour. (Out of six experiments two did not give this result.)
„ dry carb. acid and oxygen	No oxidation.
„ moist carb. acid and oxygen	Most rapid oxidation.
„ dry oxygen and ammonia	No oxidation.
„ moist oxygen and ammonia	No oxidation.

These facts led the author to assume that it is the presence of carbonic acid in the atmosphere, and not oxygen or water vapour, which determines the oxidation of iron. The author next investigated the behaviour of iron in water in which successively oxygen, carbonic acid, a mixture of the two gases, &c., were conducted. He immersed only a part of the blade in the water. The results were analogous to those above mentioned, inasmuch as the most rapid oxidation took place when a mixture of oxygen with carbonic acid was introduced into the water. The action commenced immediately, and in a short time a dark precipitate covered the bottom of the vessel. Now the oxidation in this case was not due to a fixation of the oxygen dissolved in the water, but to oxygen liberated from the water by galvanic action; the occurrence of large quantities of hydrogen above the liquid in the bottle proved this sufficiently. A striking evidence in favour of the supposition that the iron is oxidised through the decomposition of the water, is to be found in the fact that when a bright blade was introduced into distilled water which had previously been deprived of all its absorbed gases by long-continued boiling, it became, in the course of a few days, covered here and there with rust. The spots upon which the rust appeared proved to be impurities in the iron. It is obvious they induced galvanic action, just as a mere trace of zinc placed on one end of the blade would establish a voltaic current.—Finally, Dr. Calvert investigated the state of iron in alkalies, and he discovered that not only the solution of caustic soda, but that of the carbonate of it as well, protects iron against any oxidising action.

Linnean Society, January 20.—Prof. Babington read a paper, being a revision of the Flora of Iceland. He gave an extempore sketch of the country, its climate and character, and then read the introductory part of his paper containing an historical account of what had been done towards ascertaining the vegetable products of the island. It appears there are about 450 species of phanerogamous plants (the exact number at present recorded is 467), of which only about 60 are not natives of Britain. None are peculiar to the island; all the remainder, with three exceptions, are to be found on the European continent, chiefly in Scandinavia; the three arctic plants not otherwise known as European are *Gentiana detonsa*, *Pleurogyne rotata*, and *Epilobium latifolium*. No woods are now to be found in the country, although some existed recently: they have been destroyed by the carelessness of the inhabitants. Now that more care is taken of their remains, it is expected that they will again spring up. The trees were all birch, nor is there any trace of the former existence of pine or other trees. Extensive woods of dwarf birch-trees are found in several places, and some fruticose willows exist, especially an abundance of *S. lanata*. No grain of any kind is grown on the island.

Zoological Society of London, January 13.—John Gould, F.R.S., V.P., in the chair. The secretary called attention to certain additions to the society's menagerie during November and December last, amongst which was particularly noticed a rare American monkey (*Pithecia ouakari*) from the Rio Negro, deposited by L. Joel, Esq., C.M.Z.S.—A letter was read from Lord Lilford, F.Z.S., relating to the exact locality of a specimen of *Otus capensis*, lately living in the society's gardens.—A letter was read from Dr. A. Ernst, of Caraccas, C.M.Z.S., containing some notes on animals recently obtained in the vicinity of that city.—The Rev. H. B. Tristram, F.R.S., exhibited a pair of tawny eagles (*Aquila nævioides*) obtained near Etawah, N.W. India, by Mr. W. G. Brooks, C.E., being the first authentic examples of this species received from that country.—Mr. Swinhoe exhibited and made remarks on some skins of tigers and leopards from various parts of China.—Mr. Gould exhibited a new and very remarkable pigeon, supposed to be from New Guinea, which he had recently described under the name *Otidiphaps nobilis*.—A communication was read from Mr. Henry Adams containing descriptions of a new genus, and of eighteen new species of land and marine shells from the Red Sea, Hainan, and other localities.—A communication was read from Dr. Cobbold containing the description of a new generic type of Entozoa, discovered in a specimen of the Aard-wolf (*Proteles cristatus*), which had recently died in the menagerie. To this were added remarks on the affinities of this Entozoön, especially in reference to the question of parthenogenesis.—A communication was read from Mr. Morton Allport, F.Z.S., containing a brief history of the introduction of the salmon (*Salmo salar*) and other *Salmonidæ* to the waters of Tasmania.—Dr. Murie read a paper containing additional memoranda on irregularity in the growth of salmon. Dr. Murie's observations were founded principally upon specimens hatched and reared in the society's fish-house.

The Institution of Civil Engineers, January 11.—Mr. C. B. Vignoles, F.R.S., president, in the chair. Five candidates were balloted for and declared to be duly elected, viz.: Mr. A. A. Langley, engineer and manager to the Hereford, Hay, and Brecon Railway; Mr. R. White, first-class engineer upon the Great Southern of India Railway; and Mr. E. Wragge, chief engineer on the Toronto, Grey, and Bruce, and the Toronto and Nipissing Railways in Canada, as members; and Mr. W. Rawlinson, engineer and manager of the Brazilian Street Railway Company, and Mr. C. Willman, Middlesbrough, as associates.—A report was brought up from the council, stating that, under the provisions of Sect. IV. of the Bye-laws, the following candidates had recently been admitted students of the Institution:—W. F. Alphonse Archibald, B.A., A. J. Hess, A. Innes Liddell, W. Allingham Magnus, and H. Goulton Sketchley.

Statistical Society, January 18.—William Newmarch, F.R.S., president, in the chair. The following gentlemen were elected Fellows:—Messrs. Iltuduo Thomas Prichard, Henry Hoare, David Maclagan, and Josiah Samuel Parker. Professor Levi read a paper on "the statistics of joint-stock companies from 1814 to the present time; and of companies with limited and unlimited liability formed since the year 1856."

DUBLIN

Royal Zoological Society of Ireland, January 11.—Dr. Banks in the chair. Rev. Dr. Haughton read the report for 1869, from which it appeared that the number of visitors to the Gardens was 9,000 more for 1869 than for 1868, and that the receipts for 1869 exceeded those of 1868 by 137*l*. It would appear that there are now in the Gardens 143 mammals, 219 birds, and 25 reptiles—specimens, not species, we presume—and that their health and condition are excellent. The fact is mentioned that since 1857 twenty lions and 31 lionesses have been bred in the Gardens. The Earl of Mayo was elected president for this year.

Royal Geological Society of Ireland, January 12.—Mr. W. Andrews in the chair. The secretary read a paper by Dr. L. Lindsay on further researches in the gold-fields of Scotland. Rev. Professor Haughton read a paper by Mr. J. D. Latouche on a spheroidal structure occurring in some Silurian Rocks of Wales. As supplementary to the views put forward in Mr. Latouche's paper, Dr. Haughton stated that this spheroidal structure shows on a small scale what cleavage does on a large one, and that he believed that the latent structure was brought out by the weathering, not caused by it; indeed, the cleavage stream of force might be compared to that of a great river—it might flow along for miles through a country in an even uninterrupted course, then some small obstacles came in its way, and as the result a series of eddies were formed. Spheroidal structures were representatives of these eddies of force, and the ordinary cleavage planes were representatives of the uninterrupted stream—the one was the other on an immense scale. Dr. Haughton also showed that it followed rigorously from the mathematical laws of cleavage, that the parallipipedal blocks formed by cleavage must have themselves an internal spheroidal structure, of a concentric kind. This was the latent structure brought out by weathering in the manner shown in the beautiful drawings of Mr. Latouche.—Dr. Macalister exhibited a portion of a skull which had been dug up recently, while some repairs were being made to the vaults of Trinity College Chapel. This fragment was found laid along with other bones, and had evidently been dug up when the foundations of the chapel were being laid, and then, with the other bones found on that occasion, again buried. The skull was of a low type. Rev. Dr. Haughton agreed with Dr. Macalister as to the low type of the skull. Mr. J. J. Lalor did not agree with Dr. Macalister that this skull was of a low type. He had made a series of accurate measurements of skulls in conjunction with Dr. Carpenter, of London, and therefore could speak on the subject. Absence of forehead was no evidence of absence of brain capacity; lowness of skull was considered a mark of beauty by some. He could not venture to say whether it was the skull of a man or a woman, but its brain capacity did not authorise one in saying that it was a low skull; it might have been the skull of a Provost, and certainly was one of more than ordinary capacity. Dr. Macalister in reply stated that he saw no reason to alter his view on the subject, as it had been based on careful measurements and on exact reasoning, neither of which he thought admitted of contradiction.

Institution of Civil Engineers of Ireland, January 12.—Mr. J. Ball Greene, C.E., in the chair. Mr. B. Stoney read a paper by Mr. C. P. Cotton on a novel means of transit for minerals in the county of Sligo. An extensive barytes quarry was worked on the side of a steep hill, the mineral had to be lowered a depth of over 1,000 feet, and this was effected by means of boxes swung on ropes, forming a wire rope railway. Mr. A McDonnell read a paper on workshop machinery driven by rapidly moving ropes.

Royal Dublin Society, January 18.—Mr. John Adair in the chair. Professor Macalister read a paper on "The Curves in the Spine considered from an æsthetical point of view." Dr. J. Emerson Reynolds read some notes on "the determination of the flashing point of petroleum oils, as settled by Act of Parliament." The author described in detail the apparatus directed to be employed, and pointed out the difficulties and sources of error to be guarded against in using the Government test. He suggested the adoption of an uniform mode of estimating the flashing point of mineral oils, which experience proved to be that most suited for affording reliable results; and further proposed that in all doubtful cases—a special method—which he indicated, should be employed in order to serve as a test of the accuracy of the parliamentary process.—A drawing of the Nebulæ in Argos, and Dr. Monckhoven's new light for photography were exhibited.

MANCHESTER

Literary and Philosophical Society, January 11.—Ordinary Meeting.—Mr. E. W. Binney, F.R.S., F.G.S., vice-president, in the chair. The chairman described the aurora borealis, as observed by him at Cheetham Hill on the evening of Monday, the 3rd inst., at 7-30 P.M. Dr. Joule, F.R.S., said he had noticed some remarkable disturbances of the magnetic dip on the 3rd inst., which no doubt were connected with the auroral display. He had also noticed similar disturbances of the dipping needle during the gale on Saturday, the 8th inst.—Letters were read from Mr. A. H. Green and Mr. E. Hull, defending the accuracy of the Geological Survey map in the matter of the red rock fault referred to in Mr. Binney's paper, read before this society on November 16th (see NATURE, No. 7).—The chairman, with all respect to Messrs. Green and Hull, again denied the correctness of their map and sections so far as the "red rock fault" was concerned. He stated that he was prepared to maintain his position on the ground where the sections were exposed between Stockport and Macclesfield.—Dr. Joule exhibited his current meter, and with it, in connection with a galvanometer, made an experiment to determine the horizontal intensity of the earth's magnetism in absolution measure; the result gave 3·83 as the value of this element in the hall of the society. The current employed was produced by a single cell of a Bunsen's battery.

Microscopical and Natural History Section, January 3.—R. D. Darbishire, B.A., F.G.S., in the chair.—Mr. J. Sidebotham read the following paper:—"Notes on the pupa and imago of *Acherontia atropos*." The peculiar cry or squeak of the death's-head moth is very well known. It has been by some observers thought that this sound is produced by the friction of the joints of the prothorax and mesothorax; this conclusion is, in the opinion of the author of the paper, much strengthened by the following circumstance. A few weeks ago, when he was replacing some damp moss on some pupæ, he heard the peculiar cry of the moth, but much weaker. On examining the pupæ he selected the one from which the cry proceeded, and placed it in the palm of his hand; when at rest there was no sound, but the pupa at once produced it on being touched or pressed gently; on taking hold of it between the finger and thumb, if the head alone were confined, there was no sound, but if the tail, the motion of the joints was more energetic and the sound louder. In five days afterwards a very fine female moth emerged from the pupa, apparently none the worse for his experiments. The fact of the pupa ever producing this cry, disproves all ideas as to its being produced by expelling air through cavities, against a membrane, since in the pupa state all the muscles are as it were bound up in a horny case, and only those able to move which work the joints of the thorax and body, and besides this the amount of air which could be taken through the spiracles of the pupa would be obviously insufficient to produce such a volume of sound.

PARIS

Academy of Sciences, January 17.—M. de Verneuil presented and made some remarks upon a geological map of the Ural, published by M. de Moeller, a Russian officer of Mines. He stated that M. de Moeller had referred the sandstones of Artinsk—regarded as Permian by MM. Murchison, Keyserling, and himself—to the Carboniferous series, on the ground of their containing *Goniatites*, *Nautili*, and *Productus Caccrini*. M. de Verneuil was not inclined to accept this change, as it is possible that a mixture of Carboniferous and Permian types may occur in the same deposit, as has been found to be the case at Nebraska. A memoir was presented by M. B. Renault on some silicified plants of the environs of Autun. He noticed the structure of the stem in *Zygopteris* and *Anachoropteris*, studied by him in two new species, which he named *Zygopteris Brongniartii* and *Anachoropteris Decaisnii*; also that of the stems of some *Lycopodiaceæ*.—M. Delaunay presented a report on a memoir by M. Puiseux, on the secular acceleration of the movement of the moon.—M. Ricour presented a second note on the dispersion of light, and M. Delaurier a memoir containing an account of experiments on electricity, with objections to the electro-chemical theory.—M. Faye presented a note by M. A. Wüllner on the spectra of the simple gases, in which he disputes the results announced by M. Dubrunfant at a former meeting of the Academy (Dec. 13, 1869). A memoir was read by M. Duméry on the results obtained and obtainable on railways by traction on a single rail, in which the author maintained that railways on this principle can be constructed nearly 50 per cent. cheaper than ordinary railways, and can also be worked very advantageously.—M. Baudrimont stated that he had prepared artificial garnets with bases of magnesia, lime, strontian, baryta, and oxide of lead, and had them cut ten years ago. He forwarded specimens for the inspection of the Academy.—M. Maumené read a memoir on a general theory of chemical action, and the necessity of its employment in order to avoid error. No abstract of this memoir is given.—M. Becquerel and M. Dumas remarked upon the electro-chemical deposition of nickel; and M. Wurtz communicated a paper by M. A. Rossi on the synthesis of normal prophylic alcohol by means of æthylic alcohol. The author's process consisted in converting æthylic alcohol, first into cyanide of æthyle, and then into propionic acid; from the latter he prepared propionic aldehyde, and obtained propylic acid by the action of nascent hydrogen upon the aldehyde.—M. P. Levert forwarded for the Bréant prize a note on the action of bitters, especially sulphate of quinine, upon the economy, in the cure of fevers of all kinds; M. A. Marinier exhibited a collyrium for the treatment of affections of the eyelids, and a filtering injector; and M. Guyot presented a notice on the toxical effects of some products of the phenic group, including phenic acid, rosolic acid, and coralline.—A memoir on the "mulberry-tree and the silkworm, considered in themselves and in their relations," by M. Tigri, was read. The author treated of the production of disease with presence of *Bacteria* in the silkworm (*Maladie des morts-flats*), which he ascribed to alterations in the condition of the mulberry-leaves.—M. Robin presented a communication from M. S. Feltz, in which the author denied that the leurocyta, or white corpuscles of the blood, traverse the walls of the capillary vessels, as stated by many writers.—In a note on the movements of the grains of chlorophyll in vegetable cells under the influence of light, M. E. Roze referred to the observations of M. Prillieux, communicated to the Academy on the 3rd January, and stated that by examining the leaves of *Fernaria hygrometrica* under a tolerably high power, he observed that the chlorophyll grains were united by filaments of a viscous, transparent plasma, which undergo a slow displacement, and carry with them the chlorophyll grains.—M. Anez communicated a note on the development and habits of *Phylloxera vastatrix*, and M. Rouby a description of an artificial mineral spring, of which the titles only are given.

MILAN

Royal Lombardian Institute, November 25, 1869.—Professors Garovaglio and Gibelli presented a memoir on the Eudocarpeæ of Central Europe and Italy, containing a monographic revision of the species of that group of lichens.—Dr. Andrea Verga presented a communication on chloral. He stated that the hydrate of chloral prepared in the Laboratory of the Society of Encouragement at Milan was in brilliant prismatic crystals, whilst that obtained from Paris formed a white, opaque mass. — A further note on the production of Infusoria in glass vessels sealed hermetically and heated above 212° F. was communicated by Professor G. Cautoni. The author referred to previous experiments of his, in which vibrios were produced in great numbers in rich solutions of organic materials heated to 212°, 221°, 230°, and even 242·6° F. in vessels hermetically sealed and enclosed in a Papin's digester. He now gave the results of fresh experiments made with an aqueous solution of the so-called Liebig's extract of meat, containing about one part of the latter to about 35 parts of water, heated to various temperatures from 212°—244·4° F. maintained for about ten minutes in the digester. The vessels, heated to 230° and more, showed no traces of vibrios in a fortnight, nor were any produced in them for twelve or fifteen days after their interior had been brought into communication with the air by breaking the sealed extremity of their necks. The solutions which had been heated to 212° and 221°, on the contrary, produced, in two days, an abundance of vibrios and *Leptothrix* whilst still in sealed vessels. The author remarked that the above-mentioned liquid contained considerably less of protein matters than solution of natural flesh or yolk of egg, which might tend to lower the limit of temperature for the production of Infusoria. He referred to some other experiments, and argued from them in favour of heterogenism.—Dr. G. Bizzozero presented a report upon the investigations of Dr. G. Milani on some pathological alterations of the lymphatic glands.

COPENHAGEN

WE have received the "Oversigt over det Konglige Danske Videnskabernes Selskabs Forhandlingar" for the first half of the year 1869, which contains only one strictly scientific paper of importance, namely, a Crystallographico-chemical investigation of the double haloid salts of platinum, by M. Haldor Topsöe. The remaining papers are chiefly of antiquarian interest, and consist of a discussion of the plant known to the ancients under the name of *Silphion* or *Silphium*, by Prof. A. S. Oersted, with an appendix on the Vase of Arcesilas, by M. J. L. Ussing, and a dissertation by the latter on the Apollo Belvedere. The *silphium* is regarded by M. Oersted as a species of *Narthex*, allied to the *Asafœtida*, and is named by him *Narthex silphium*. Of the last two papers, abstracts in French are given.

PHILADELPHIA

American Philosophical Society, January 7. —A memoir on Fossils from the Marshall Group of Michigan and adjoining States, by Prof. Alexander Winchell, Director of the Geological Survey of Michigan, was read by Prof. J. P. Lesley. Prof. Cope read a paper on New Etheostomine Perch from Tennessee and North Carolina. Professor Cope gave the results of investigations on the structure of the extinct Saurian, the *Megadactylus Probyzelus* of Hitchcock, from the red sandstones of the Connecticut valley in Massachusetts. He mentioned that in 1867 he had stated it as his belief that the so-called bird-tracks of the above formation were those of Dinosauria, and that in the following year that view had been confirmed by Prof. Huxley. He stated that at the same time he proposed a system of the Dinosauria which was very similar to one very recently proposed by the same excellent authority. The *Megadactylus* was the only species whose remains had been found in the beds and locality in question, in sufficient preservation for determination, and it was clearly one of those which had made the tracks. The fore limbs were four-toed, the hind limbs three-toed, and with a long metastarsus. The animal was a Dinosaur, and a true representative of the sub-order Symphypoda, which was typified by the *Compsognathus* of the Solenhofen beds. As in the latter the astragalus and calcaneum were coössified with the tibia and fibula, and the carpal bones were much reduced. The bones were pneumatic, and possessed of excessively thin walls. The ischiatic bones were projected far backwards, were in contact for much of their length, forming a solid style which supported the animal when in a sitting position. Length about four feet. He also stated that the red sandstone beds in Pennsylvania and North Carolina contained remains of Dinosauria. The Cadontia (Belodon) and Labyrinthodonts, nearly allied to those of the Keuper of Germany. They occurred in the lower part of the series, which he had already parallelised with the Keuper. On the other hand, the occurrence in the upper part of the series of Symphypoda in Massachusetts and Pterosauria in Pennsylvania *Rhabdopelix longis pinis* Cope) rendered it highly probable that an approach to the lias was to be found in those strata, while the intermediate portion of the whole might be found to represent the time intervening between the Triassic and Oolitic (Purassic) periods.—Prof. Lesley remarked that these investigations threw the first rays of light on a very dark part of American geology. Prof. Marsh gave an account of the impressions of the ischiatic bones behind the tracks on specimens in the museum, Yale College, which he had always referred to as such, though some believed they were made by the tail.

BOSTON

Society of Natural History, November 3, 1869.—Mr. W. H. Dall made a few remarks upon the distribution of marine animals, asserting that their range was influenced more by the temperature of the water than by the depth or other conditions. He showed that the floating-ice line of Behring Sea (which passes between the Pribyloff and St. Matthew groups of islands, touching the continent near Kuskoquim Bay) governed the distribution of the fish and molluscs of those waters. It is the northern limit of all the more southern forms, some of which range as far south as Monterey. It is the southern limit of almost all the truly arctic species. The fur seal is never found to the north of it, though often erroneously spoken of as coming from Behring Strait; the polar bear never passes to the south of this line; the cod invariably keep to the south, and the mullet to the north, of it. It is also the limit of distribution of many fuci and seaside plants. Where the water is cooled by northern currents, or by glaciers, deep-water species of molluscs, especially brachiopods, are found at or even above low-water mark. Where the surface-water is warm, these molluscs, which in the north are found near the shore, are only obtained at a depth of many fathoms.

Section of Microscopy, November 10.—Mr. R. C. Greenleaf in the chair. Dr. H. Hagen called the attention of the section to the statements of Professor Listing, of Göttingen, who had recently (Nachr. d. kgl. Gesell. der Wissench., 1869, No. 1, and Poggendorff's Annalen, 1869, T. xvi. p. 467) given some suggestions concerning the further improvement of the microscope. In all microscopes the dioptric arrangement is now analogous to the astronomic spy-glass; they have but one real image, from which the virtual image is formed and brought to the eye of the observer. Professor Listing proposes to have two real images, and in this way to form three successive augmentations instead of two, as before. It is well known that by a prolongation of the draw tube, or by increasing the distance between the objective and the eye-piece, the image becomes successively greater, but the definition and penetration is by no means better. Professor Listing has made some experiments, and states that with an eye-piece of his construction (a double eye-piece with four lenses, similar to those of terrestrial telescopes) the magnifying power of the instrument, and also to nearly the same degree the penetration, is raised, by a tube of 420 millimetres, 20, 28, 55, 97, and 137 per cent. (the latter, of course, with diminution of the field), more than the same objective (Hartnack's, No. 7) and eye-piece (No. 3) with a tube 200 millimetres in length. The object was *Pleurosigma angulatum*, and Professor Listing assures us that the latent power of the objective is developed by this means in an astonishing manner. He also remarked that the so-called Erectors have long been used, but always with a low power and a short tube. The most advantageous form for the eye-piece would be, for the two superior glasses, achromatic lenses from 15 to 20 millimetres in diameter, and with a diaphragm between, having an aperture of from 8 to 9 millimetres. For the two inferior lenses, a common Huyghen's eye-piece would be the best. Such a combined eye-piece, with a tube 420 millimetres long, would raise the power of the instrument 97 per cent. The use of an achromatic condenser adapted for oblique illumination is necessary for high powers. The experiment was only successfully made with the best objectives of English artists, or with the excellent new Hartnack objectives. According to his calculation, an objective of one millimetre distance will give the first real image at a distance of 200 millimetres from the second chief point of the objective, and combined with an eye-piece in Listing's manner, having a power of 25 diameters by itself, and a tube 405 millimetres long, the magnifying power of the whole instrument would be 5,000 diameters. In the common arrangement of the microscope, the dioptric cardinal points are in the same order as in a concave lens, and the focal distance of the whole microscope (not of the objective) would be equal to —·5 millimetres, with a magnifying power of 400 diameters for a visual distance of 200 millimetres. In the Listing instrument the order of the cardinal points would be inverted and analogous to a convex lens, with a focal distance of the whole microscope equal to × ·04 millimetres, with a magnifying power of 5,000 diameters. In the first case the objective would have a focal distance of 3 millimetres, in the last of 1 millimetre. The difference between the two chief points of the whole microscope is in both cases nearly equal to the whole length of the tube. In the last arrangement the whole microscope is analogous to a convex lens with very short focal distance.

DIARY

THURSDAY, JANUARY 27.

ROYAL INSTITUTION, at 3.—On the Chemistry of Vegetable Products: Prof. Odling.

ROYAL SOCIETY, at 8.30.—Temperature of Strata in Sinking of Rosebridge Colliery: E. Hull.—Action of Rays of High Refrangibility upon Gaseous Matter: Prof. Tyndall, F.R.S.—Eclipse of Sun as observed in United States: J. N. Lockyer, F.R.S.—Theory of Continuous Beams: Mr. Heppel.—Remarks on Heppel's Continuous Beams: Professor Rankine.

ZOOLOGICAL SOCIETY, 8.30.—On Cooking Pits and Kitchen Middens, containing Remains of Dinornis, New Zealand: Professor Owen, F.R.S.

ANTIQUARIES, at 8.30.

LONDON INSTITUTION, at 7.30.

FRIDAY, JANUARY 28.

ROYAL INSTITUTION, at 8.—Graham's Scientific work: Prof. Odling.

QUEKETT MICROSCOPICAL CLUB, at 8.

SATURDAY, JANUARY 29.

ROYAL INSTITUTION, at 3.—On Meteorology: Mr. Scott.

MONDAY, JANUARY 31.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.

INSTITUTE OF ACTUARIES, at 7.

LONDON INSTITUTION, at 4.

MEDICAL SOCIETY, at 8.

TUESDAY, FEBRUARY 1.

ROYAL INSTITUTION, at 3.—On the Architecture of the Human Body: Prof. Humphrey.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Statistics of Income, Expenditure, and Railway management, and their bearing upon future Railway policy: J. T. Harrison, C.E.

PATHOLOGICAL SOCIETY, at 8.

ANTHROPOLOGICAL SOCIETY, at 8.—Negro Slaves in Turkey: Major F. Millengen.

SYRO-EGYPTIAN SOCIETY, at 7.30.

WEDNESDAY, FEBRUARY 2.

SOCIETY OF ARTS, at 8.—On Recent Improvements in Small Arms.

PHARMACEUTICAL SOCIETY, at 8.

OBSTETRICAL SOCIETY, at 8.

THURSDAY, FEBRUARY 3.

LINNEAN SOCIETY, at 8.—Revision of the genera and species of capsular gamophyllous *Liliaceæ*: J. G. Baker, Esq., F.L.S.—On a new form of Cephalopodous ova: Dr. Collingwood, F.L.S.

BOOKS RECEIVED

ENGLISH.—Lichenes Britannici: Crombie (Reeve and Co.)—Elementary Introduction to Physiological Science (Jarrold and Son).—The American Naturalist, No. 11.—The Spherical form of the Earth, a Reply to Parallax; J. Dyer (Trübner and Co).—On the Geographical Distribution and Physical Characteristics of the Coal Fields of the North Pacific Coast: Robert Brown.—Fresenius' Analysis, Quantitative, fifth edition (Arthur Vacher).—Fresenius' Analysis, Qualitative, seventh edition (Arthur Vacher).

FOREIGN.—Ueber die Gährung und die Quelle der Muske'kraft: J. Von Liebig.—Bulletins de la Société d'Anthropologie de Paris.—Pflüger's Archiv für Physiologie — Centralblatt für die medicinischen Wissenschaften, January, 1870.

THE ATMOSPHERIC-GERM THEORY

WE have heard much during the last week or two concerning the presence of organic matter in the atmosphere, and the degree to which this is filled with "germs" of living things. It would have been better, perhaps, had it been always pointed out more distinctly that the two expressions were by no means uniformly convertible. There is unquestionably much mere organic *débris* in the atmosphere which nobody could regard as germs of living things.

The transition, in the minds of many at the present day, however, from the idea of organic matter in the atmosphere, to the identification of this with germs of actual animal and vegetable organisms, occurs only too easily. The air is supposed by them to be teeming with potential living things most varied in kind. Each square foot of atmosphere is thought to contain representatives of innumerable varieties, which are only awaiting the advent of suitable conditions in order to commence their growth and development. Men talk most glibly about germ-theories of disease, and the share which germs take in the origin of epidemics, as though these were proven facts of science rather than, as they are at present, mere questionable hypotheses. And, just as these germ-theories concerning epidemic disease have grown out of the more general *panspermic* doctrine, so did this doctrine itself grow out of the great "spontaneous generation" controversy somewhat more than a century ago. As it was with the derived, so was it with the original doctrine: in each case it was produced, not so much on account of any *direct* evidence in favour of the existence of such germs, but rather on account of the inherent difficulty in the explanation of the subject to which it referred. Previous to the period mentioned, however, no such doctrine had been started. There were, of course, the old pantheistic doctrines of Anaxagoras and his followers—the notion of the universal diffusion of an active principle or νοῦς pervading all things, which was itself the cause and source of all the life on our globe: there was also the doctrine of Leibnitz, concerning "Monads," as centres of force and life existing in all things; but anything like the present "panspermic" doctrine was still wanting.

The Aristotelian notions concerning the "spontaneous generation" of even complex living things, received a severe blow by the experimental demonstration of Rédi, in 1638, before one of the Italian academies. He showed that the larvæ found in putrefying flesh had been deposited there by flies, and had not been engendered (as had been previously supposed) by changes taking place in the flesh itself. Hence a very desirable modification of their views was necessitated on the part of the heterogenists. It was not, however, till about a century after this that the "spontaneous generation" doctrines were again prominently brought before the scientific world. Then, too, they appeared in a form more suited to our present notions. The long controversy carried on between Needham, the English champion of heterogeny, and the Abbé Spallanzani, resulted in the promulgation by the latter of the celebrated "panspermic" doctrine. The question pressing for solution was, What is the mode of origin of the myriads of the lowest forms of life which so soon teem in organic solutions? According to Needham many of these lowest living things had been evolved *de novo* owing to changes taking place in the organic matter of the infusion; according to Spallanzani they had been ultimately derived from "germs" which, floating everywhere in the atmosphere, had, in spite of all precautions, gained access to the solutions. Spallanzani did not pretend that he had seen these "germs," their existence was a mere postulation and no other evidence of their reality was alleged than the occurrence of the very phenomena which their presence was supposed to explain. His position was interpretable in this way. He seemed to think that such new evolution of life was impossible. If living things occurred, therefore, they *must* have originated from pre-existing germs. Against unchangeable convictions of this kind, occurring either then or now, of course no amount of experimental evidence would be of any avail. Spallanzani preferred to believe that the atmosphere carried with it everywhere myriads of germs of elementary organisms, or, at all events, sundry *principes préorganisés*, invisible and imaginary though they might be. On this subject he says*:—"The infusorial animalcules undoubtedly take origin, in the first place, from certain *principes préorganisés;* but these *principes*, are they eggs, germs, or other similar corpuscles?" To which he most honestly adds:—"If it is necessary to offer facts in reply to this question, I frankly acknowledge that we have no certain knowledge on the subject."

Bonnet was the contemporary of Spallanzani, and he was also the advocate of a doctrine similar in its tendency, though infinitely more extravagant. Bonnet's leading notion of the "emboîtement des germes" is thus illustrated in one of the earlier chapters of his work †:—"The sun, a million times larger than the earth, has for an ultimate constituent a globule of light, of which several thousand millions enter at once into the eye of an animal twenty million times smaller than a flesh worm .... But reason can penetrate even further. From this globule of light it can see issue another universe having its sun, its planets, its plants, its animals, and amongst these last an animalcule which is to this new world what that, of which I have just spoken, is to the world which we inhabit." Now, it would certainly be wrong to restrain any man in the exercise of his fancy, but it surely is deplorable when we find the results of such exercise—such mere figments of the imagination as this—warping the reasonings of succeeding generations when they come gravely to argue about questions of fact.

Such, then, has been the origin of the "panspermic" doctrine. Its first supporters commenced with assumptions, which could only be supported by the occurrence of the very phenomena that were the subjects in dispute, and to explain which the assumptions had been started. This was the doctrine of which M. Pasteur first attempted the experimental verification. How far he succeeded in the attempt is another question. On the part of those who first promulgated the "panspermic" doctrine, there certainly was nothing but mere fancy and hypothesis.

ENGLISH SPORT IN THE FIFTEENTH CENTURY

The Debate between the Heralds of France and England. Translated and edited by Henry Pyne. (London: Longmans and Co. 1870.)

IT is not easy to obtain an accurate knowledge of the fauna of England before the sixteenth century, or to ascertain with anything like precision the distribution of wild animals throughout our country. Contemporary authorities are few, and allusions in them to the facts of Natural History are vague and scanty: vague enough to whet our curiosity, and rare enough to augment the interest attaching to them. We are, therefore, grateful when we can derive from any fresh and well-accredited source a side-light upon this obscure subject, and such we seem to have found in a few incidental remarks that occur in a very early tract, bearing the unsuggestive title of "A Debate between the Heralds of France and England." This debate, now for the first time translated into English, appears from internal evidence to have been written by Charles, Duke of Orleans, about the year 1460, and to have been first published in Paris in 1500. Its author, taken prisoner at the battle of Agincourt, was detained in England for some five-and-twenty years, dividing the period of his captivity between London and the Castles of Windsor, Pontefract, Ampthill, Bolingbroke, and Wingfield. To a man of quick observation, as the Duke undoubtedly was, this lengthened exile gave ample opportunity of forming a tolerably correct opinion of the relative merits of the land of his birth and the land of his captivity. Patriotism has, of course, occasionally coloured his views, but on the whole his judgments are wonderfully impartial, and his statements may be accepted with very little qualification. It must, however, be borne in mind that the Duke's acquaintance with England was almost wholly confined to the eastern side, which has very little in common with the rest of the country, and has probably undergone far fewer changes in later times. Thus, in his estimate of the capabilities of our country for sporting purposes, he makes the English Herald say: "England is a level country, well cultivated, and not covered with trees or bushes, which might hinder the game from being easily found and caught; and it has also many partridges, quails, and other birds, as well as hares in great abundance. And with regard to the sport of fowling, no one can imagine a more delightful country, for there are numerous little streams which flow into the great rivers, where it is a fine thing, during the season, to see what a profusion there is of wild fowl." This description is true enough of the eastern counties, especially if we understand the term "wild fowl" to include snipes, plovers, bitterns, and other fen-haunting birds. But, in lauding the superior merits of French sport, the Duke gives some further details, which are not without their value, as illustrating what we may call the antiquarian side of Natural History. "In France," he remarks, "we have not only all the wild animals which you (English) have, as stags, roes, and deer, but we have many other animals for the chase besides these: for we have wild boars or wild black swine, and we have also wolves and foxes, while you have none." Now, it is hardly necessary to observe that the popular story of the extermination of wolves in England by Edward I. must be received with some reservation. There seems some ground to believe that in the valley of the Findhorn, in Scotland, wolves have bred as late as the seventeenth century, and that even in the wilder parts of England—the fells of Yorkshire, and the forest of Dartmoor—they have existed in the fifteenth, and perhaps in the sixteenth century, if we are to give any credence to local traditions. Certain it is that in 1280, John Giffard, the Baron of Brimsfield, had license from King Edward to hunt wolves with dogs and nets in all forests in England; we have also little doubt that a diligent search through the public records would disclose similar grants of later date. Some ten years ago a young wolf was caught in a vermin-trap at Ongar, in Essex, but its occurrence was explained by the fact that the master of a neighbouring hunt had recently imported some fox-cubs from France, and that the wolf had been included in the hamper by mistake. The comparatively small amount of woodland and covert in the East of England would render the breeding of wolves, to any extent, an impossibility, and in a less degree the same remark applies to foxes also. Fox-hunting, in the modern sense of that term, is a sport of recent growth, and such a thing as the preservation of foxes for hunting purposes cannot boast of any antiquity at all. Gervase Markham, indeed, classes the hunting of the fox and the badger together, and describes them as "chases of a great deal lesse use or cunning than stag and hare-hunting, because they are of a much hotter scent, and are not so much desired as the rest,"—an observation which may be balanced by the French Herald's remark, that wolves and foxes "are bloodthirsty animals, so that it requires persons of great courage to overcome them." Wild swine in England were either destroyed or domesticated at a very early period. Pannage was too valuable a privilege to be otherwise than jealously guarded against such unwelcome intruders. Charles I. turned out in the New Forest some boars and sows which he had imported from Germany, and fifty years ago their descendants might be recognised by the smallness of their hind-quarters and greater development of sinew.

The next position asserted by the French Herald in the Debate, if true at the time, has since been curiously reversed. He claims precedence for his country, not only in respect of hares and game-birds generally, but especially or exclusively for the great red-legged or Grecian partridges, and an abundance of pheasants. Hares have always been common in England, but the prevalence of red-legged partridges throughout the stubbles has not been a long-standing grievance to the Suffolk sportsman, for, if Pennant be right, they were introduced from France, as late as the year 1770, and, perhaps from their dislike to a humid soil and atmosphere, have never spread themselves far inland.

With regard to English pheasants, the Duke's experience must, we think, have been exceptionally unfortunate. The bills of fare, in olden times, invariably make mention of them, and Mr. Pyne refers to a statute passed in 1494, prohibiting their destruction by unlicensed persons, and clearly implying that they were common enough. Goshawks and tercelets for hawking purposes were, no doubt, imported from France in the fifteenth century—the accuracy of the French Herald's statement on this point being confirmed by several passages in the *Paston Letters.*

We are rather surprised that no mention of the bustard should be made in the tract. Though now extinct in England, the bird was by no means uncommon in the open country at the commencement of the present century. We can only suggest that the cause of its omission from the Herald's list and its gradual extinction in England, is one and the same. Being slow to take wing, the bird is of little or no use for sporting purposes, and nature has implanted in it a rooted aversion to those enclosures which, in a land like ours, alone are sacred to game.

CHARLES J. ROBINSON

POPULAR LECTURES ON PHYSIOLOGY

Populäre Physiologische Vorträge gehalten in Akademischen Rosensaale zu Jena, 1867-1868-1869. Von Prof. Dr. Joh. Czermak. (Wien, 1869. London: D. Nutt.)

THE daily increasing recognition of the importance of Physiology as an element of liberal culture, no less than as a distinct branch of science, may be said to be intimately connected with the gradual displacement of the old vitalist conception. The old conception of Life as something essentially mysterious and removed from out the circle of natural causes, has been set aside in favour of the conception of Life as something more complex, indeed, but not otherwise more mysterious than other natural phenomena, and dependent upon the physical and chemical agencies recognised in operation in other provinces of research. The consequence of this changed view has been to disclose the need of an incessant application to Physiology of those instruments and methods which have enlarged and given precision to our views of Nature; and a further consequence has been that the problems are found to be more capable of popular exposition, that is to say, the great results of research can now be *shown* to an intelligent public, and made thus to form an element in general culture.

It is under this second aspect that Prof. Czermak's Lectures call for remark. Himself an original investigator and inventor, he here gives excellent examples of the kind of teaching that may become generally effective—namely, an intelligible exposition, for the laity, of the painfully-acquired results of science. This exposition is not confined to an oral statement of results, which statement might be imperfectly apprehended and quickly forgotten, but is accompanied by a visible demonstration which fixes it in the memory as with a burin. In his first lecture he expounds the action of the heart, and the influence of the nervous system on the circulation. In this he exhibits the instrument formerly invented by him, the Cardioscope, which enables an immense audience to *see* the rhythmic beating of the heart when taken from the body; and by the directions and the plates here supplied teachers and private students may easily furnish themselves with the ingenious contrivance. Indeed, we may say at once that this volume will be especially useful to teachers who will gain from it several effective aids for their lectures.

The second lecture is on the Ear and Hearing, and gives a lucid account of all but the very latest discoveries (the startling and *disturbing* discovery which robs the Corti apparatus of its former significance being subsequent to the publication of this volume). The third and fourth lectures are on the Voice and Speech, accompanied like the others with excellent and instructive diagrams, and a very intelligible explanation of the instrument with which Prof. Czermak's name has been carried all over Europe and America—the Laryngoscope.

A mere glance at this volume, and the elaborate application of mechanical aids which it suggests, will indicate at once the great change which has come over physiological investigation in the last twenty years. Not to speak of such works as those of Richerand and Majendie in France, or of Elliotson and Mayo in England, where there is scarcely a trace of the physical and chemical investigation now considered indispensable, let even the great work of Müller be opened at the places where the heart, the ear, and the voice are treated, and compared with these lectures, addressed, be it observed, to a miscellaneous audience of ladies and gentlemen, not to students in a class-room, and the contrast will, as the French say, leap at the eyes. The changed direction is one that attempts to reduce physiological problems to visible and measurable processes, which leave no room for vagueness or inexactness, and which, without getting rid of the mystery of Life, reduces the phenomena of Life to what Prof. Huxley finely names the "realm of *orderly* mystery."

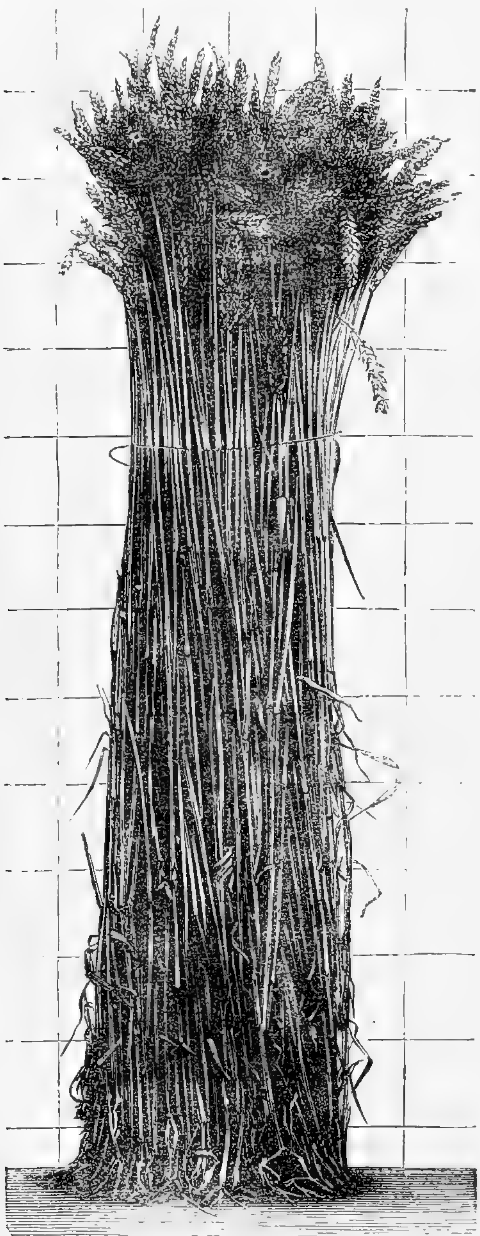
GEORGE HENRY LEWES

AGRICULTURAL CHEMISTRY IN FRANCE

L'Ecole des Engrais Chimiques; premières notions de l'emploi des agents de fertilité. By M. Georges Ville. 12mo., pp. 108, with one plate; price one franc. (Paris: Libraire Agricole de la Maison Rustique, 1869.)

INTELLIGENT visitors to the last annual meeting of the Royal Agricultural Society, held at Manchester, could hardly fail to draw one very important conclusion from the sight of that vast array of implements, machines, and produce, namely, that year by year farming is brought more and more under the application of scientific principles. It is found, too, that farm labourers, not quite so stupid as was thought, are capable of managing agricultural machines, and of adapting themselves to the improved style of work which these necessitate. And among our farmers the number of those increases who know that, however much plants may differ in appearance and properties, they have a character in common, and owe their formation to certain elements which suffice for their requirements, as the letters of the alphabet suffice for the requirements of writing and printing. And their sons at school will learn that of these plant-forming elements, the more important are, carbon, hydrogen, oxygen, nitrogen, phosphorus, sulphur, chlorine, silicon, calcium, magnesium, potassium, sodium, and iron. Schools and colleges have taken the subject in hand, and have demonstrated that the study of the sciences on which agriculture may be said to depend, involves no small amount of intellectual culture—a culture fraught with lasting interest.

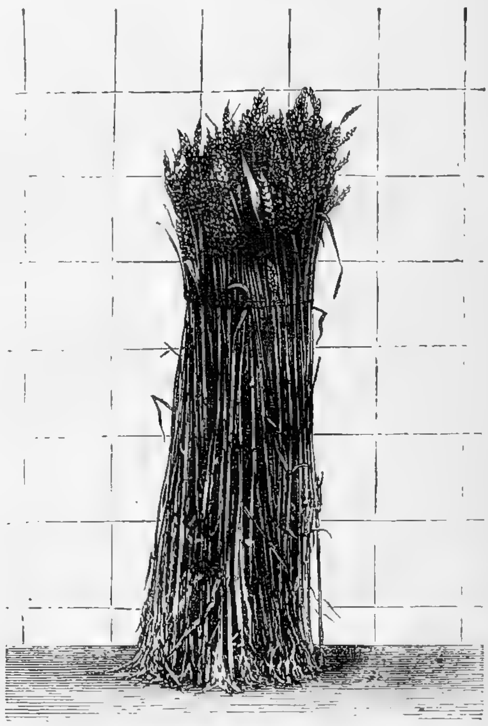
On the Continent, also, a movement has begun for the improvement of agriculture, and it will be instructive to look at what has been accomplished in France. Among the subjects on which lectures are given by the able professors at the Museum of the Jardin des Plantes is *la chimie agricole*—agricultural chemistry—and, in the hands of Prof. G. Ville, who has been experimenting thereon for the past twenty years, it has produced surprising results. Having established his propositions single-handed, and at his own cost, a portion of the imperial domain at Vincennes was allotted to him, as an experimental farm, and the crops he there produced, the *Conférences Agricoles* he there held among the crops, together with his numerous



Comparative size of wheatsheaf produced from soil completely manured.

published works, and the effect of his lectures, have made such an impression, that his method of cultivation has been adopted at more than five hundred places in France; while from Spain, Portugal, Italy, Belgium, and Germany, and from the French colonies, farmers and cultivators have resorted to Paris and to the experimental farm at Vincennes, to acquaint themselves with the method which under ordinary circumstances would more than double their harvest.

Prof. Ville's method of instruction is as simple and definite as his method of fertilisation, as if he had in view the large number of small peasant proprietors in France, and wrote and lectured for their especial benefit. You may sow wheat, he says, in soil wanting nitrogenised matter, phosphates, potash, and lime, and it will grow and bear grain, but the stalk will be very short, thin, and weak, and the vegetation precarious. Mix with the soil a substance composed of carbon, hydrogen, and oxygen, the result will be exactly the same. And why? Because plants take all the carbon they need from the carbonic acid of the atmosphere, and hydrogen and oxygen from water. Hence, to add these three elements to the soil is useless; on the other hand, if some substance containing assimilable nitrogen be added, a salutary effect is at once produced, for plants derive nitrogen partly from the soil, partly from the air. But this effect is as nothing compared with that of manures affording certain mineral elements: mix these as well as the nitrogenised matter with calcined earth, and its fertility will equal that of the richest soil. The vegetation, no longer thin and starved, acquires vigour and activity, the plant grows straight and strong, is of a rich green colour, and produces a well-formed ear filled with large and heavy grain.



Comparative size of wheatsheaf produced from soil without manure.

Many of the mineral elements required by the plant already exist in the soil; consequently, to render it productive the farmer has to discover which of the fertilising elements are wanting, and apply them to his field. To do this, it is not necessary that he should be an analytical chemist: the vegetation of his fields will do it for him. He has only to sow or plant a small experimental plot, and the appearance of the crop will tell him what is deficient in the soil. And in making his experiments, he is not restricted to any special kinds of plants, for the method may be applied to the sugar cane, the sorgho, and other natives of the tropics, to maize, beetroot, the Jerusalem artichoke, the potato, colza, and other varieties of cabbage, and to flax and hemp. Whether saccharine, or oleaginous, or fibrous, or starchy, the plants may be developed to the utmost limit of their productiveness by proper treatment.

The complete fertiliser, or *engrais complet*, as Prof. Ville calls it, varies slightly in composition according to the nature of the crop required. For wheat it is composed of acid calcium phosphate (superphosphate of lime), potassium nitrate (nitre), ammonium sulphate, and calcium sulphate (gypsum). These materials require to be skilfully mixed, so as to retain all their beneficial properties when spread upon the land. The "engrais complet" is to be regarded as the typical fertiliser—the standard by which to judge of the value and the lastingness, so to speak, of any chemical manure. A field properly treated with this will return three or four crops of wheat in immediate succession, without further manuring in the meantime.

For the proper carrying on of the experiments, it would be necessary to have—

1. The complete compost.
2. Compost without potassium salts.
3. " without phosphates.
4. " without nitrogenised matter.

These are to be applied to the experimental plots of land. If then, number 2, or 3, or 4 produces the same effect as number 1, it is evident that the substances represented by those numbers exist already in the soil, that the vegetation has profited by them, and that there is no need to apply them to the land. If, on the contrary, the compost in which any one of the four substances is wanting produces a deficient crop, there is a certain proof that this particular element of productiveness is deficient in the land.

Here, then, is a method of analysing the soil of fields and gardens which even an intelligent labourer might practise. He could hardly continue the practice without learning, better than from books, the true principles of agricultural science. He could determine step by step the loss of any one or more of the fertilising elements, and consequently ascertain which was required to restore the fecundity of the soil.

In support of this argument, Prof. Ville brings forward some remarkable results obtained on his experimental farm at Vincennes, giving tables showing the cost of cultivation and the yield of each experimental plot. He also places before his readers a series of figures in which the results obtained with wheat are displayed in a most forcible manner. The two examples here given indicate the limits of his experimental system. The sheaves are represented on the same scale, so that the results of good feeding and starvation may be readily compared. The intervening figures may be imagined.

If the experiment be made with peas, there is a marked difference in the result: the nitrogenised matter which tells in the culture of wheat has little or no effect on leguminous plants; the reason being that wheat takes up from the soil most of the nitrogen it requires, and that leguminous plants derive it mainly from the air. To produce a good crop of the latter we must employ a manure containing an excess of potassium salts, and for turnips we require an excess of calcium phosphate.

These are important facts, for they show that besides variation and rotation of crops, there can be also rotation of manures. Take any average field, and apply to it the materials which act on the required crop, and so pass from one to the other until the land shall have received all the materials which make up the complete compost.

This, briefly sketched, and with omission of certain practical details, is Prof. Ville's system for the improvement of agriculture in France. The five million small proprietors, who own each from 3 to 14 hectares, have herein a simple and efficacious method, by which their profits may be largely increased, and their own condition materially ameliorated. To quote the Professor's words, "The tiller of the soil is always in presence of a Power superior to himself. Seasons, temperature, rain, and sunshine, which enter so largely into the success of his labours, are above his influence. He learns that skill, foresight and economy are required of him; he knows also that when he has done all that depends on himself he must be resigned and wait. By temperament, as much as by condition, he becomes above all the friend of order, and, in case of need, its firmest support."

OUR BOOK SHELF

Landwirthschaftliche Zoologie. Von Dr. C. G. Giebel. 8vo. pp. 827, with 510 woodcuts. Glogau, 1869. Carl Fleming. (London: Williams and Norgate.)

ALTHOUGH the study of economic zoology ought to be of some importance in this country, we can point to very few English publications relating to it,—Curtis's "Farm Insects," and the translation of Kollar's "Garden Insects," by Westwood and Loudon, being almost the only special works on the subject that we can call to mind, and these are now of old date. This may perhaps be due to the fact that the advantage of attempts at the practical application of zoological and, especially, of entomological knowledge, is very frequently doubtful, but it is certain that in many cases an acquaintance with the natural history of animals must be most valuable to the farmer or gardener, by enabling him to distinguish beneficial from injurious creatures; it is therefore much to be regretted that we possess no good treatise which would place the necessary knowledge within reach of our English agriculturists.

There is another point of view in which the study of economic zoology is of great importance. From the very nature of their relations to man and the organisms which he has taken under his care, useful and injurious animals acquire a remarkable prominence, and thus the phenomena of their existence are brought near to us and, as it were, magnified in such a manner as to render their investigation comparatively easy. Accordingly, there can hardly be any better means of acquiring a practical general knowledge of natural history and, especially, of the intimate and intricate relations of organised beings, than the study of the enemies and benefactors of the farmer and gardener.

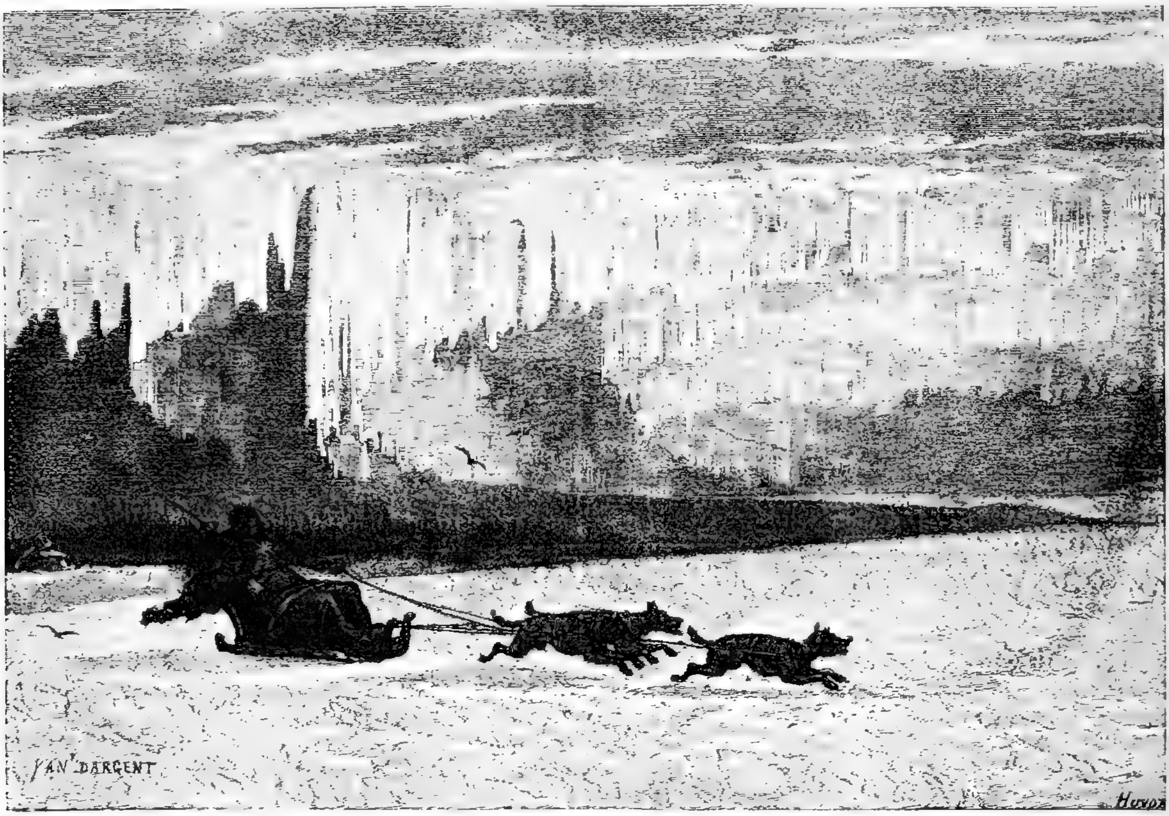
Dr. Giebel seems to have taken this view of the matter, and his "Agricultural Zoology" is really a complete natural history of terrestrial animals, the illustrative examples being drawn from domestic animals, or from species which exert a more or less direct influence upon the results of agricultural operations. Of all these, the natural history is given by Dr. Giebel in considerable detail, and in this way we get most of the families of mammalia, birds, insects, and arachnida legitimately illustrated, whilst by stretching a point here and there, even the classes of reptiles, fishes, and mollusca are more or less represented. Under the Vermes we find a good account of the curious natural history of the Entozoa. Either as a practical guide for the cultivator, or as a first book in the study of general zoology, Dr. Giebel's volume will be found of great value, and we can only repeat our expression of regret that we have nothing like it in our own language.

History of Meteors and of the Grand Phenomena of Nature. By J. Rambosson. (London and Edinburgh: Williams and Norgate.)

NOTHING is more sublime, or more engrossing, or at times more awful than the phenomena of Nature on the large scale; and yet nothing is more prosaic than most of the treatises on meteorology.

Those terrible statisticians with their columns of figures have certainly succeeded marvellously in creating a distaste for the study of the greater natural phenomena. A cyclone at sea is one of the most glorious and awful sights that can be imagined, yet in the pages of meteorological journals it becomes a barometric difference of an inch and a half, a wind equal to 12, and a sea disturbance equal to 9.

But M. Rambosson, with that talent for elucidation which so many Frenchmen and so few Englishmen possess, has spared neither trouble nor expense in order to produce a thoroughly popular and, at the same time, thoroughly scientific description of the grander class of natural phenomena.



THE AURORA BOREALIS

Being himself a traveller as well as a man of science, his descriptions and illustrations are particularly good; and no student can read the book without retaining a vivid impression of the aspects of Nature in her wilder moments. Some of the illustrations remind one of Gustave Doré; that of a hurricane on land and sea, Fig. 3, is particularly good; so is that of a hurricane in the desert, Fig. 33; also his pictures of lightning, Figs. 62, 63, 64; on the other hand, some few illustrations might possibly be dispensed with.

It has often occurred to us that while the student of chemistry and of physics is made acquainted in the laboratory with the forces with which he reasons, so the student of meteorology should, if possible, like the author of this book, be brought face to face with the grander class of natural phenomena; failing which, a well illustrated book, like that of M. Rambosson, is an admirable substitute for the personal experience which few can have.

B. S.

Our Own Birds. A Familiar Natural History of the Birds of the United States. By W. J. Baily. Revised and edited by G. D. Cope, Cor. Sec. Acad. Nat. Sci. With illustrations, after Audubon. (London: Trübner).

ALTHOUGH the object of this work is not to treat ornithology scientifically, but rather to present the subject in a pleasing manner to the young, Mr. Cope's name on the title-page is a guarantee of its scientific accuracy; and although the birds of the United States are mainly dealt with, the volume will doubtless be welcome to many young naturalists in this country, for the habits and interesting peculiarities of each bird are fully dwelt upon. Some of the illustrations are admirable.

MR. BATES'S ADDRESS TO THE ENTOMOLOGICAL SOCIETY

IN printing the following extracts from the address delivered to the Entomological Society on the 24th ult. by the President, Mr. H. W. Bates, we must express our regret that we cannot find space for the insertion of the whole of that able and interesting discourse.

Referring to the "Transactions" of the Society, Mr. Bates remarked:—The volume for the past year comprises twenty-seven memoirs, of which twenty-five belong to the department of systematic or descriptive Entomology, and two only—welcome contributions from Mr. Jenner Weir and Mr. Butler, on the selection of insects as food by insectivorous animals—to other branches of the science. To those who might object that too large a share of our work is occupied by mere descriptions, I would remark that many original and valuable observations on relationships, geographical distribution, and other deeply interesting philosophical questions, are contained in some of our descriptive papers. In fact, it is not at all a necessary consequence that a descriptive treatise should be nothing more than a string of dry definitions. It will become, I hope, more and more the practice of entomologists to give, together with their descriptions, the new data on relationships, distribution, comparison of faunas, &c., which the handling of such subjects most usually brings forth.

In speaking of the contributions of importance which have been made to the science in this country outside the Entomological Society, the President alluded to the examination by Mr. Wollaston of the largest collection of insects which has yet been made in St. Helena. This suggested the following observations: As you are aware, the great interest which attaches to the fauna and flora of oceanic islands arises from the problems involved in the modes in which they obtained their species of animals and plants, and those are rendered more complicated by the existence on some island of anomalous forms, representative, it is considered, of types ages ago extinct on continents. Such islands, however, differ greatly from each other as to degree of peculiarity in their productions; and it often happens that species identical, or nearly so, with those found in the nearest continent, form nearly the whole of their present inhabitants. Thus the investigation of the origin of their faunas and floras is necessarily exceedingly complex. Geology has to be invoked to ascertain whether the islands are of recent or ancient elevation above the sea-surface, and whether the supposition is admissible of a recent connection with the nearest continental land. Oceanic hydrography, deep-sea soundings, and the force and direction of currents and winds, have to be studied in reference to the depth of the surrounding seas; for these must all be taken into consideration in discussions on the probable derivation of the curious mixture of forms which is often found on these isolated spots. On the other hand, it must be noted that the fauna and flora themselves throw light on the geographical and geological relations of the islands to the nearest land. In fact, the classification of islands into oceanic and continental, is founded quite as much on resemblance or difference in organic productions, between islands and the mainland, as on relative proximity. Thus Great Britain is classed as a continental island, quite as much because its fauna and flora are nearly identical with those of continental Europe as because it is separated only by a shallow sea, and is now known to have been actually connected in recent geological times. In these investigations entomology is now generally admitted to have great importance, owing to the large number and variety of species which it offers, as elements in the elaborate comparisons which have to be instituted.

The following remarks well illustrate the high scientific importance of studying the geographical distribution of insect life:—The idea of the value of localities in connection with specimens or species, with some entomologists, I am afraid does not reach very far. They like to know in what countries the different forms are found, and perhaps, as in French collections, show the distribution by writing the specific names in their cabinets on labels coloured according to the part of the world the species inhabit; the primary divisions of the world, as Europe, North and South America, Africa, Australia, perhaps the West Indies, and so forth, being considered sufficient. This brings out the leading facts of distribution very well, such as the restriction of many genera and groups of genera to each of the great divisions, and the distinctive facies which all the products from one region possess; but we seldom see it carried further, and it remains a pretty association of geography with natural history, and no more. Results infinitely more suggestive are brought about if the student labels each *specimen* with its locality, instead of recording it on the ticket which bears the specific name placed below all the specimens, and if he is fortunate enough to be able to amass a large suite of specimens, accurately so ticketed, of genera abounding in local varieties and closely-allied species, indications of the conditions under which varieties, local races, and perhaps species, are formed in nature, are revealed by this method, and a field of investigation is opened which connects the study of a few insect species with some of the most difficult problems that are now engaging the attention of philosophers. The most common event that happens, when a student works at a series of species in this way, is the discovery that even the most constant species vary in some parts of their area of distribution; the next, that a small well-marked difference in a species is generally a local difference, and embraces all the individuals of the district in which it occurs. As the collection increases, further curious facts come out. It is found, for instance, that some highly-variable species give rise to one set of varieties in one area, another distinctly different set in another area, and so on; and further, that in some areas one, or perhaps more, of these variations will be better marked than, and preponderate in number over, the other varieties of the same species. Still further, it is found that in some districts one such variety alone occurs, having apparently prevailed over all the others. To be properly impressed, however, with the great truth and reality of these facts, the student should himself have travelled as an entomological collector over an extent of country embraced by many local varieties of variable species; otherwise his attention will not be sufficiently excited to the curious facts nature presents to him, and he will not take the trouble to amass and obtain the exact localities of numerous specimens of common variable species. Perhaps the most important result of this attention to distribution of varieties is, that a fine gradation of forms or degrees of variation will be found, from the "sport" or variety, such as is liable to be produced in the same brood, to the well-segregated race living in company with another race referable to the same stock. As such, most authors, perhaps rightly, consider these latter as good and true species; and thus the formation of species out of mere variations is illustrated by the facts of geographical distribution.

But it is not this branch of the subject with which we are so much concerned, when we wish to compare the productions of the different Andean valleys and their vertical ranges, as that relating to the nature of barriers to distribution. It has been received as a principle in zoological and botanical geography, that grand physical barriers, such as mountain ranges, form an impassable limit to the faunas and floras of the plains on each side of them. It is repeated, in almost every manual of physical geography, after Humboldt, who, I believe, was the originator of the statement, that the species are all different on the two sides of the Andes of South America. Such a fact, if well established, would be interesting in many ways. First, it would throw light on the geology of the country, as proving that the Andes must have existed as a ridge, sufficiently lofty to prevent the creatures of the plains crossing it, before the origin of the species which now people the plains on each side. Now, it is possible that this broad and important generalisation may have been made on a too slender foundation of facts. Of course, in those parts of the Pacific coast-region (two-thirds of the whole line within the tropics), where the conditions of soil, climate, and vegetation are totally different on the two sides of the Andes, no community of species is possible. A lofty mountain barrier would be here unnecessary, for a few steps of level road, in many parts of the world, would suffice to bring the traveller from the domain of one fauna to that of another—for instance, from an arid plain to a luxuriant forest along some river-valley. This would be a difference of "station," and not of area of distribution,—a distinction long ago recognised in Botany. The question is, then, limited to this: In those parts of the Pacific coast-region, such as Guayaquil, where a humid forest-country exists on both sides of the Cordillera, are the species of the two sides entirely distinct? This would test the efficacy of mountain-barriers better than almost any other case. For the species, at least of insects, which inhabit humid forests near the equator, are probably unable to exist at a higher altitude than 4,000 or 5,000 feet, and no pass over the Cordillera exists of half this depression, throughout the whole line of the Andes from Bolivia to the Isthmus of Darien. The species could not voluntarily pass over, nor by gradual migration along the coast could they well double the end of the chain near the mouths of the Atrato and Magdalena, and so pass to the eastern side; for the Sierra Nevada bars the way.

Insects, I believe, would offer better data in discussing this question of barriers than almost any other group of land animals, or than plants; they are more limited in range than the species of birds, afford a much larger body of facts than reptiles, mammals and shells, and are not so much subject to accidental means of transportation as plants. But although many Entomological collectors have visited Guayaquil and the Cordillera, we have no published lists and no authentic information about localities. Mr. Buckley's journey offers us, then, the chance of obtaining the details so much required, since he collected assiduously all the way up from the level of the sea to the edge of the snow, and the same conversely on the opposite side, writing the locality on the envelope of every specimen.

I am inclined to think that the efficacy of physical or geographical barriers in limiting the distribution of animals and plants has been much over-estimated, and that this circumstance has vitiated much of the reasoning that has been employed in discussing various difficult problems in Natural History. By physical barriers, of course, are meant barriers of the inorganic world, such as a continuous mountain-range with regard to species of the plains and, conversely, a continuous plain with regard to species of the mountains (*e. g.* Parnassius, Erebia, Oreina, Nebria, &c.) The sea is thus a barrier to land-species, a water-shed to freshwater species, a continuous tract of forest to species of the savannah or steppe, and so on. Barriers of the organic world, which of course are "physical" also, are quite a different set of agencies. They are the hindrances offered to the dissemination of a species by other species already in full possession of the domain and well adjusted to its conditions by constitution and habits. To this may be added the limitations to distribution observable without any physical obstacle being perceptible. There are certain classes of facts which seem to me to indicate that these less obvious kinds of barrier are far more effective than those more imposing ones of mountain, desert, sea, and so forth.

One set of these facts is exemplified by the well-known case of distribution of insects between the east and west in the southern part of our own island. I am not aware that comparative lists have yet been published; but it will not be disputed that many hundreds of species of Coleoptera, for instance, are known in the east, many of them abundant, which are totally unknown in the west, and a smaller number are known in the west which are not found in the east. In In cases like these a difference of climate may be the cause of the limitation. But there is another set of facts requiring quite a different explanation: this is the limited ranges of closely-allied species in the plains of Tropical America. I have already elsewhere recorded the fact that, in the forest plains of the Amazons, where there are no differences of level worth mentioning, and no physical barriers, the species of a large number of genera are changed from one locality to another, not more than 200 or 300 miles apart. This is most distinctly marked on the Upper Amazons, where the country may be mapped out into areas of a few hundred square miles each, every one containing numerous species of such genera as Ithomia, Melinæa, Eubagis, Doryphora, Erotylus, &c., &c., allied to but quite distinct from their representatives in the others. From what I have seen of Mr. Buckley's collections on the eastern side of the Andes, I think the same limitation of areas must occur there also; and judging from the few species I know as coming undoubtedly from the Guayaquil side of the Cordillera, the butterfly faunas of these areas in the uniform country of the east are pretty nearly as distinct from each other as the species east of the Andes are distinct from those west of the mountains. We here again feel the want of facts, such as Mr. Buckley collected, but which have not yet been published, to teach us exactly what species are found east and what west of the mountains, and how the great multitude of closely-allied species are distributed in the narrow tract explored on the east. My own observations in the level plain, a few hundred miles further east, show distinctly, however, that the most effective possible barriers are there opposed to the spread of hosts of species without any physical barrier which is perceptible by our senses. The explanation of the fact, I believe, is this, that there really are subtle differences of physical conditions from place to place, even in a uniform region; slight differences in soil, humidity, succulence of foliage, and so forth, which require in each a re-adjustment of the constitution of any new immigrants from adjoining areas; but that each area being kept well stocked with allied species already adjusted to its minute conditions, such migration rarely occurs. Thus a limit is put to the spread of species by species themselves, which produces similar results on the actual distribution of forms throughout the world, to those produced by mighty physical barriers such as the Andes.

There is yet one other consideration remaining. If these barriers are not required to explain the limitation of faunas, it does not follow that they do not act as barriers all the same; but it is, I think, difficult to prove it. If 1,200 miles of sea do not form a sufficient barrier against the stocking of the Azores with insects from Western Europe, I do not think sixty miles of mountain should be assumed to prevent for tens of thousands of years, the transport of species, in the egg state, by birds or currents of air, from one side to the other. I may add, in conclusion, that if the efficacy of barriers of this nature has been overrated, some important conclusions regarding changes on the earth's surface will have to be reconsidered; such, for instance, as that of the extension of a glacial epoch over nearly the whole earth—a hypothesis conceived by Darwin to explain the existence of the same genera and sometimes the some species in high latitudes, both in the northern and southern hemisphere, whilst absent from the intervening zones. I believe that, with some very obvious exceptions, such as Mammals and Batrachians, there can be no limit placed as to the dissemination of a species, provided there are unoccupied areas suitable to it, in any part of the earth, and provided also time sufficient be allowed for the process.

THE GRESHAM LECTURES

TWO lectures were delivered in Gresham College on the evenings of the 14th and 15th January, by Dr. Symes Thompson, the Gresham Professor of Medicine.

The first of these lectures embraced a theme admirably adapted to fulfil the popular object with which this City professorship has been established, and as eminently suited to the present season: it treated of "Catching Cold."

The Professor first described, by reference to large drawings, the structure and arrangement of the parts concerned in the disorder—laying open the arcana of the nose, frontal sinuses, throat, voice-box, and chest, and showing the intimate relations by which these parts are connected, and the way in which modern science has found means to bring their inmost recesses under observation, and contrasting the precise knowledge of the present period with the ante-Schneider days, when all catarrhal defluxions were held to be outpourings of the brain. It was demonstrated that the ordinary cold is simply, in the first instance, congestion of the warm, moist, blood-charged membrane, which lines all these cavities and is continuous throughout the series of them; but that this congestion is apt to pass on, under unfavourable circumstances, to inflammation, and to consequent derangement of structure. The congestion merely means that more blood is thrust upon, and retained in, the minute channels and vessels of the membrane, than those channels and vessels can healthily accommodate The first cause of this forced engorgement is that cold is extensively applied to the internal skin, which then, under the constringing and contracting influence, drives its own blood out, partly into these surcharged tracts of mucous membrane. The injurious effect known as "cold" is now sure to be realised if this external chill is experienced when the general system is weakened by exhaustion. It is also, in some persons, more apt to be produced at certain regular periods.

The prevention of colds is to be accomplished by keeping the skin in a healthy and vigorous state, so that it may at once resume its proper and normal condition when chills have been suddenly applied to it: then the internal congestions are avoided or removed simultaneously with the external contraction and stagnation. The habitual use of cold bathing in the early morning is one very powerful means to this end: it trains the vessels of the skin to rise vigorously into renewed action after the application of a chill. The relaxing influence of over-heated apartments should be avoided, because that saps the power of vigorous reaction; but, in cold weather, the utmost care should be taken to have the entire skin efficiently protected by warm clothing. The powers of the system in periods prone to the production of colds, and most especially when the temperature of the external air is between 32 and 40 degrees of Fahrenheit's heat scale (for that is the condition in which the danger is found to be most certainly incurred), should be most carefully maintained by the judicious use of sustaining food, and by the avoidance of every kind of injurious derangement or excess. When once internal congestion has been set up, and the cold has been "caught," the thing to be done is immediately to bring back vigorous circulation and exhalation in the skin. The Turkish bath is one of the most convenient and certain of all contrivances for ensuring this object: in its absence the vapour bath, or hot air bath may be employed. The action of the bath is to be reinforced by the administration of stimulants, first and foremost amongst which stands concentrated food. Indeed, the Professor's pet stimulant seems to be "Whitehead's Solid Essence of Beef," a New South Wales preparation, in which the nutritious principle of an ox is condensed into about nine pounds of easily transportable material, in which thirty pounds of beef are concentrated into one pound of little cakes, each about the size of an ordinary silver five-shilling piece, and weighing half an ounce. One cake is calculated to prepare two large breakfast cups of good beef-tea. This preparation differs from Liebig's Extract of Meat chiefly in containing the gelatinous as well as the fibrinous constituents of the flesh. The Gresham Professor scattered the little round cakes, out of neat half-pound cases, liberally to his audience, recommending them to begin at once to fortify themselves against the inclement atmospheric influences. He gave one very interesting instance of the value and power of this preparation by alluding to a case that had fallen within his experience on the very day of the lecture. A patient had been brought into the Brompton Hospital in a sinking state, resulting from inability to take food. He was at the time all but pulseless and cold, and evidently on the brink of the grave. He was placed in bed, and a cupfull of the beef-tea prepared from the "solid Essence" administered. The preparation was retained in the stomach, and in ten minutes from the time of its administration, there was steady warmth all over the skin, and restored circulation.

There is one expedient both for preventing and curing "colds." which was not alluded to upon this occasion, but which is nevertheless as powerful as any of the measures which were described, and it may sometimes be drawn upon in circumstances when those plans cannot be adopted, in consequence of the sufferer being compelled by the exigencies of life to continue to meet exposure to chilling influences. This is abstinence from drink, and liquid food of any kind, until the internal congestion is removed. The remedial action through the skin does its work by drawing away the superabundance of the circulating fluid from the overcharged part. But this desirable result is even more certainly ensured if the general bulk of the circulating fluid, or blood, is diminished by withholding supplies of the more liquid, or watery, ingredient; which may be done where the digestive power is unimpaired, without in any way diminishing the richer, or more immediately nourishing portion. The instant the general bulk of the circulating blood is diminished, the excess contained in the congested and overcharged membranes is withdrawn and the cold is relieved. Somewhat severe thirst sets in; but curiously enough, simultaneously with the occurrence of this thirst, the congested internal membranes grow moist, and exhale gently and naturally in consequence of the relief of the overcharged vessels. All that is then necessary is to keep the supply of drink down to the point which enables some measure of thirst to be maintained; and during its maintenance there is not the slightest chance of the recurrence of the cold. Dr. Thompson dwelt emphatically in his lecture, upon the fact that, whereas certain ailments, such as the eruptive fevers, bring with them an almost complete immunity from the recurrence of the affection, it is just otherwise with ordinary colds. The more frequently they occur, the more frequently they may be looked for. They bring with them increased susceptibility of the internal membranes to congestive derangements. Under such circumstances diminution of drink, sustained at the point of persistent moderate thirst, is the most powerful and certain preventive of congestive disorder, and the most sure remover of undue internal susceptibility, that can be adopted.

The second lecture was mainly devoted to a description of stimulants, and an experimental explanation of the way in which the amount of the saccharine, acid, and spirituous ingredients of wines may be ascertained. There is one very noteworthy peculiarity in all these lectures, which renders them peculiarly fit for the class of audience at which the Gresham College is aimed: Dr. Symes Thompson is a master of the art of giving a clear notion of the whereabouts of a fact, or principle, to popular apprehension. It is to be extremely regretted that in a vast metropolis like ours, and, indeed, in all our large towns, such courses as these Gresham Lectures are not more common. It is absolutely impossible to over-estimate the good they can do, not only, as in this case, in showing what "to eat, drink, and avoid," but generally in inducing thought and work. Further lectures of the Gresham course are announced for the months of April, June, and September.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Where are the Nebulæ?

MR. PROCTOR's interesting paper in your last number reminded me of an essay on "The Nebular Hypothesis," originally published in 1858, and re-published, along with others, in a volume in 1863 ("Essays: Scientific, Political, and Speculative." Second Series), in which I had occasion to discuss the question he raises. In that essay I ventured to call in question the inference drawn from the revelations of Lord Rosse's telescope, that nebulæ are remote sidereal systems—an inference at that time generally accepted in the scientific world. On referring back to this essay, I find that, besides sundry of the reasons enumerated by Mr. Proctor for rejecting this inference, I have pointed out one which he has omitted.

Here are some of the passages:—

"'The spaces which precede or which follow simple nebulæ,' says Arago, 'and, *à fortiori*, groups of nebulæ, contain generally few stars. Herschel found this rule to be invariable. Thus, every time that, during a short interval, no star approached, in virtue of the diurnal motion, to place itself in the field of his motionless telescope, he was accustomed to say to the secretary who assisted him, "Prepare to write; nebulæ are about to arrive."' How does this fact consist with the hypothesis that nebulæ are remote galaxies? If there were but one nebula, it would be a curious coincidence were this one nebula so placed in the distant regions of space as to agree in direction with a starless spot in our own sidereal system? If there were but two nebulæ, and both were so placed, the coincidence would be excessively strange. What, then, shall we say on finding that they are habitually so placed? (the last five words replace some that are possibly a little too strong). . . . . When to the fact that the general mass of nebulæ are antithetical in position to the general mass of stars, we add the fact that local regions of nebulæ are regions where stars are scarce, and the further fact that single nebulæ are habitually found in comparatively starless spots, does not the proof of a physical connection become overwhelming?"

The reasonings of Humboldt and others proceeded upon the tacit assumption that differences of apparent magnitude among the stars result mainly from differences of distance. The necessary corollaries from this assumption I compared with the hypothesis that the nebulæ are remote sidereal systems in the following passage:—

"In round numbers, the distance of Sirius from the earth is a million times the distance of the earth from the sun; and according to the hypothesis, the distance of a nebula is something like a million times the distance of Sirius. Now, our own 'starry island, or nebula,' as Humboldt calls it, 'forms a lens-shaped, flattened, and everywhere-detached stratum, whose major axis is estimated at seven or eight hundred, and its minor axis at a hundred and fifty times the distance of Sirius fom the earth.' And since it is concluded that our solar system is near the centre of this aggregation, it follows that our distance from the remotest parts of it is about four hundred distances of Sirius. But the stars forming these remotest parts are not individually visible, even through telescopes of the highest power. How, then, can such telescopes make individually visible the stars of a nebula which is a million times the distance of Sirius? The implication is, that a star rendered invisible by distance becomes visible if taken two thousand five hundred times further off!"

This startling incongruity being deducible if the argument proceeds on the assumption that differences of apparent magnitude among the stars result mainly from differences of distance, I have gone on to consider what must be inferred if this assumption is not true; observing that "awkwardly enough, its truth and its untruth are alike fatal to the conclusions of those who argue after the manner of Humboldt. Note the alternatives":—

"On the one hand, what follows from the untruth of the assumption? If apparent largeness of stars is not due to comparative nearness, and their successively smaller sizes to their greater and greater degrees of remoteness, what becomes of the inferences respecting the dimensions of our sidereal system and the distances of the nebulæ? If, as has lately been shown, the almost invisible star, 61 Cygni, has a greater parallax than α Cygni, though, according to an estimate based on Sir W. Herschel's assumption, it should be about twelve times more distant—if, as it turns out, there exist telescopic stars which are nearer to us than Sirius, of what worth is the conclusion that the nebulæ are very remote, because their component luminous masses are made visible only by high telescopic powers? . . . . On the other hand, what follows if the truth of the assumption be granted? The arguments used to justify this assumption in the case of the stars, equally justify it in the case of the nebulæ. It cannot be contended that, on the average, the *apparent* sizes of the stars indicate their distances, without its being admitted that, on the average, the *apparent* sizes of the nebulæ indicate their distances—that, generally speaking, the larger are the nearer, and the smaller are the more distant. Mark, now, the necessary inference respecting their resolvability. The largest or nearest nebulæ will be most easily resolved into stars; the successively smaller will be successively more difficult of resolution; and the irresolvable ones will be the smaller ones. This, however, is exactly the reverse of the fact. The largest nebulæ are either wholly irresolvable, or but partially resolvable under the highest telescopic powers; while a great proportion of quite small nebulæ are easily resolvable by far less powerful telescopes."

At the time when these passages were written, spectrum-analysis had not yielded the conclusive proof which we now possess, that many nebulæ consist of matter in a diffused form. But quite apart from the evidence yielded by spectrum-analysis, it seems to me that the incongruities and contradictions which may be evolved from the hypothesis that nebulæ are remote sidereal systems, amply suffice to show that hypothesis to be untenable.

37, Queen's Gardens, Jan. 31 HERBERT SPENCER

Kant's View of Space

IN answer to my invitation, Mr. Lewes now "freely admits that Kant nowhere speaks of Space and Time as 'Forms of Thought,'" but still contends that 'Kant would not have disclaimed such language, as misrepresenting his meaning.' As well might he argue that although Euclid never uses the word *epipedon* (our English word *plane* or *plain*), to signify a curved surface (επιφανεια), he would not have remonstrated against the use of the term *cylindrical epipedon* or conical *epipedon*, to denote the surface of a cylinder or cone, in a professed exposition or criticism of his Elements of Geometry, because in common life we speak of rough or undulating plains, or because a plane admits of being bent into the shape of a cylindrical or conical surface. I think the ladies who are getting up their Planes and Solids at St. George's Hall would be of a different opinion from Mr. Lewes in this matter, and with good reason on their side.

Mr. Lewes, reiterating a statement contained in his previous letter, goes out of his way to affirm that he "uniformly speaks of Space and Time as forms of Intuition in his pages of exposition" of Kant's doctrine in his "History of Philosophy." Were the fact so, it would not in any material degree excuse the inaccuracy of subsequently styling them "forms of Thought;" and, moreover, the real point at issue is not Mr. Lewes's general accuracy or inaccuracy, but whether a mode of speech which he, along with others, employs, is right in itself and ought to be persisted in.

However, as Mr. Lewes has thought fit to put in a sort of plea in mitigation of former wrong-doing, I have taken the trouble of looking through his *exposition* and *criticism* of Kant in his History (ed. 1867), and in no single instance have I come upon the phrase *forms of intuition* applied to Space and Time, either in the one or the other; although he states he has *uniformly spoken of them* as such in the former. I have marked the word *intuitions* as occurring once, and *forms of sensibility* several times, but *forms of intuition* never. If *form of sensibility* is as good to use as *form of intuition*, *form of understanding* ought to be as good as *form of thought;* but Mr. Lewes owns that the former is indefensible, whilst he avers that the latter is correct. If Mr. Lewes has ever called Space and Time *forms of intuition* in the History, it will be easy for him to set me right by quoting the passage where the phrase occurs, although that circumstance would not in any degree better his own position, and still less excuse the assertion of his *uniform* use of the term.

If Mr. Lewes cannot quote correctly from his own writings, it will surprise nobody that he misquotes the language of an opponent. He repeats, "Intuition without thought is mere sensuous impression," and adds, "Mr. Sylvester demurs to this." "My words are" (NATURE, Jan. 13, 1870): "To such a misuse of the word energy it would be little to the point to urge that *force without energy is mere potential tendency.* It is just as little to the point in the matter at issue for Mr. Lewes to inform the readers of NATURE that *intuition without thought is mere sensuous impression.*" So that, according to Mr. Lewes, to say that a proposition is *little to the point* is *demurring to its truth.*

I should not hesitate to say if some amiable youth wished to entertain his partner in a quadrille with agreeable conversation, that it would be *little to the point*, according to the German proverb, to regale her with such information as how

> "Long are the days of summer-tide,
> And tall the towers of Strasburg's fane,"

but should be surprised to have it imputed to me on that account that I demurred to the proposition of the length of the days in summer, or the height of Strasburg's towers.

In another passage, Mr. Lewes gives me credit for "saying correctly that Intuition and Thought are not convertible terms"—a platitude I never dreamed of giving utterance to; but that I am "incorrect in assuming that they differ as potential and actual"—words which, or the like of which, in any sort or sense, never flowed from my pen. Surely this is not fair controversy, to misquote the words and allegations of an opponent. It seems to me too much like fighting with poisoned weapons. I decline to continue the contest on such terms; and, passing over Mr. Lewes's very odd statement about *species and genus* with reference to Intuition and Thought, shall conclude with expressing my surprise at his and Mr. G. C. Robertson's confident assumption that Kant uses in the title of his book *pure reason* in a far wider sense than in the body of his work, simply because to arrive at the Pure Reason he has to *go through* the Critick of the Sensibility and of the Understanding. If in a history of the Reign of Queen Victoria the author should find it expedient to go back to the times of the Norman and Saxon conquests, would it be right to infer therefrom that he used in his title-page the name Victoria in a generalised sense, to include not only her most Gracious Majesty, but also the Tanner's daughter and Princess Rowena?

Perhaps by this time many of the Naturalistic readers of the journal who regard the human intelligence as forming no part of the scheme of Nature, wish Space at the bottom of the sea; but the more the subject is canvassed, and the greater the number of English authorities brought forward to back up Mr. Lewes in wresting the words of Kant from their proper scientific signification, the higher meed of praise seems to me to accrue to Dr. Ingleby for stemming the tide of depravation, and banishing, as I feel confident this discussion will have the effect of doing, from the realm of English would-be philosophy, such a loose and incautious way of talking as that of giving to Space and Time the designation which the Master has appropriated to the categories of his system, and to them alone. J. J. SYLVESTER

P.S.—I should be doing injustice to the very sincere sentiments of respect I entertain for Mr. Lewes's varied and brilliant attainments (which constitute him a kind of link between the material and spiritual sides of Nature), and of gratitude for the pleasure the perusal of his "History of Philosophy" has afforded me, were I to part company with him without disclaiming all acrimony of feeling, if perchance any too strident tones should have seemed to mingle with my enforced reply. In naming him in the original offending footnote (the fountain of these tears), my purpose was simply to emphasise the necessity of protesting against what seemed to me an unsound form of words, *àpropos* of Kant, which went on receiving countenance from such and so eminent writers as himself and the others named; and I should be false to my own instincts did I not at heart admire the courageous spirit with which, almost unaided and alone (like a good knight of old), he has done his best to defend his position and maintain his ground against all oppugners.

J. J. S.

It is hardly possible to exaggerate the importance of the question now under discussion in NATURE, "What was Kant's view of Space?" A mistake there is simply fatal. I therefore rejoice to find the columns of that paper are so generously thrown open to those who, like myself, are not primarily concerned with physical science. But this question, like all others in philosophy, has a proclivity to indefinite expansion, and unless its discussion be rigidly restricted to the main issue involved in it, the conductors of NATURE will have to ostracise it. Their space is not an infinite form, but a quantum to be carefully economised. It is, for example, an unwarrantable waste of that commodity to make Hegel the exponent of Kant on a point where Hegel taught that Kant was wrong.

It is fortunate for our interests, as students of Kant, that Mr. Lewes, while committing the strange oversight of criticising Kant's Intuition from Hegel's standpoint, in his last letter (NATURE, Jan. 27) enables us to *démêler* the main issue from the mass of questions which entangle it. He evidently, if tacitly, slights the plank I threw to him, viz., that Thought, in its ultimate relation to Intuition, borrows, or has reflected on it, the forms peculiar to Sense. What are Kant's *Begriff vom. Raume, Begriff der Zeit*, but this? (With these expressions, compare the following:—Also ist die ursprüngliche Vorstellung vom Raume Anschauung *à priori* und nicht Begriff. Transac. Æsth. s. 3, 4.) This reflection of form is not what Mr. Lewes is after. He maintains that, according to Kant, "the activity of mind is threefold—Intuitive Thought, Conceptive or Discursive Thought, and Regulative Thought." (Is not Regulative Thought discursive?) So, then, the main issue between Mr. Lewes and (I think) Professor Croom Robertson on the one hand, and Professors Sylvester and Huxley, Mr. W. H. S. Monck, and myself on the other, is plainly this. *Did Kant mean to teach that man has Intuitive Thought, i.e., Intellectual Intuition?* Now *that* I must be understood emphatically to deny; and in the event of the shortcomings of better men than myself, I hold myself prepared to establish the negative of that question, understanding by Thought the *genus* of which Understanding and Reason are *species.*

Ilford, Jan. 31 C. M. INGLEBY

Dust and Disease

THE extremely important discoveries brought to light by Professor Tyndall will call forth great exertions on the part of thinking persons to carry his plans into operation, and I have no doubt, when due precautions are taken to sift infected air as it passes into the lungs of those whose duties take them where contagion abounds, we shall have the happiest results.

So great will be the tide of interest in this direction, that I am anxious to cast into it a theory I have long held, in hopes that it may drift in some one's way to be turned to use; I commend it to the travelling portion of your readers especially.

Whilst travelling in some very unhealthy parts of Africa, more particularly amongst the marshes bordering on the Shiré and Zambesi rivers, it was often necessary to camp at night just where the canoe happened to be moored when daylight failed us. Reeds, rushes, and mud were never many feet off, and the accumulation of scum, decaying vegetation, &c., lodged in the sedge, made the situation as delightful to mosquitoes as it was trying to the constitution of the European.

Still, with all this, as long as it was possible to rig up a mosquito curtain, I am convinced that really less danger existed in thus sleeping in the midst of miasma than in other places where less of it was supposed to be present, but where the traveller felt no necessity to stretch this thin covering over him.

I have in this way done canoe journeys of twenty to twenty-five days in length without a day's illness from fever, and I could instance similar experiences on the part of others.

Now the reason I assign is this: the mosquito curtain is to miasma, what the Professor's cotton-wool respirator is to the poison of scarlatina, we will say.

The curtain, after being used once or twice, saturated with dew, folded up whilst damp and crammed into the limited space generally provided for it in the safest place, becomes just so much affected by this treatment that each thread loses its smooth glaze, and is soon fluffy and fuzzy for want of a better expression.

The little honeycomb holes in the fine "net" are now a series of small six-sided sieves, each covered over with the fine filaments of cotton which have got disturbed and frayed up. Dew, falling upon a surface of this kind, quickly turns it into an exquisitely fine strainer—in fact almost a film of water—through which all the air has to pass which is breathed by the person reposing beneath it.

Now, it is an old notion that the miasma which produces the bilious remittent fever (the pest of this part of Africa in question) and various other diseases of the tropics, cannot pass across water.

I believe that acting upon this theory, the Admiralty provides that boats' crews shall sleep in their boats anchored off shore in malarious rivers. However, be this as it may, I have a strong belief that the "wet sieve" *does* stop the poison in some way or other, and that it is a great safeguard to the voyager in these places.

The whole subject of miasm is in the dark; it is lawless as a cause of disease; it baffles the most astute, but the day may be coming when such hints as these of Prof. Tyndall's shall fit into an organised attack upon it, and we shall be able to overcome it in a measure.

A curtain, properly made, and taken care of with that instinct which alone is begotten by the buzz of mosquitoes, is perhaps the most valuable possession a man can have a gainst deadly attacks in the night whilst men are asleep: were its merits studied more, we should not find men stuffing their companions so perpetually with quinine, to the keeping up an unhealthy tone by this abuse alone, and to the confusion of this most invaluable medicine when it is really called in to do its duty upon the fever-stricken patient.

Chatham, Jan. 24 HORACE WALLER, F.R.G.S.

Scenery of England and Wales

THE willingness you have hitherto shown to give authors an opportunity of defending themselves against being misunderstood, induces me to hope that you will allow me to disclaim being the author of certain statements, and to deny the truth of other statements, on which an anonymous reviewer in your last number mainly founds the charge of boldness he brings against me for writing the work entitled "Scenery of England and Wales," &c.

In one part of the review *I am made to say* that I "purposely refrained from reading;" in another it is assumed that my reading has "consisted mainly of the recent journals and magazines;" and further on it is asserted that I wrote the book "without reading."

The facts are, that for many years I devoted more or less time to reading on the subject of Denudation, and that, as stated in the Preface, until lately I purposely refrained from "reading *very much* (a distinct thing from not reading) lest a bias should be given to my opinions."

My reason for not quoting the remarks of the late Principal Forbes on the glaciers of Norway, was not, as implied by your reviewer, because I underrated the *denuding power of glaciers*, but because Forbes said very little on the subject.

Mrs. Somerville's estimate of the velocity of the Rhone may be incorrect, and perhaps, likewise, her statement that the declivity of the river is 1 foot in 2,620; but this is no reason why your reviewer should leave the reader to suppose that I misquoted Mrs. Somerville. In other parts of the work I have referred to the velocities of many currents besides the one off the southern promontory of Shetland.

The argument against denudation by currents, derived from the non-displacement of *barnacles*, would, I think, never be brought forward by any one acquainted with the fact that sea-waves often remove stones and large blocks while barnacles in the immediate neighbourhood are left undisturbed—that waves and currents, by their insinuating, undermining, overturning, and removing action, can carry on the work of denudation within a few inches of an unabraded rock-surface—and that a certain amount of resistance to be overcome is necessary to enable all denuding agents to produce effects which can be immediately perceived. On the western shore of Morecambe Bay, sea-waves and currents detach and remove fragments of limestone rock by a lateral process, while the brink of the unremoved mass of rock retains its glacial polish; and many other instances illustrative of this subject might be stated.

The fact that for more than twenty years I have *confined* my observations to England and Wales, and devoted nearly my whole time to visiting, revisiting, and studying every part of the country, is no reason why I should not have ventured to write a work on the Scenery of England and Wales in connection with Denudation. The country stands almost alone as regards the variety and importance of its geological phenomena, including surface-features and types of scenery. My work is not confined, as your reviewer asserts, to a defence of marine denudation, for more than a third of it is devoted to the consideration of the real or assumed effects of atmospheric agents; and instead of being put forward in a self-confident spirit, as your reviewer would likewise lead the reader to suppose, I have stated in the Preface that "my object will be gained if I have said enough to stimulate the geologist and intelligent tourist to further observation." D. MACKINTOSH

"Correlation of Colour and Music."

ANALOGIES between tone and tint are a tempting subject; and sound and light have enough admittedly in common to make it rash to say that the connection may not extend to their effects on the ear and eye; but that your correspondents (Jan. 13th and 20th) are seeking for unity in a direction in which it is not to be found, seems to me to be rendered pretty certain by the very evidence to which one of them, Dr. de Chaumont, appeals (Jan. 20th); I mean by that of "the researches of Helmholtz and others."

I have often wondered at the small attention paid to the general law which these researches have established. Even M. Jamin, in his *Cours de Physique*, dismisses Newton's theory of compound colours as "empirical," and apparently of no significance. It is as much and as little empirical as the Newtonian astronomy; both consist of general laws applied by means of particular constants: the evidence for the laws is in both cases equally inductive, and the determination of the constants equally empirical.

Stated without reference to the geometrical and dynamical analogies which I suspect have had something to do with obscuring its significance and tainting it with "empiricism," the fundamental law of composition of colour is this:—

Of any four colours whatever, either there is one which may be matched by a compound of the other three, or there are two which may be compounded so as to match a compound of the other two.

It is obvious that if negative values of an ingredient can be admitted, these alternative cases are the same; and the geometrical and dynamical analogies depend on the fact that, if *addition of vectors* is substituted for *composition of colours*, the proposition remains true, becoming in fact a very elementary one. And it follows that all colours may be co-ordinated, by means of three independent variables, with reference to any three colours whatever.

Accordingly, when differently coloured lights reach the eye together, the combination produces a single resultant colour varying according to the proportions of the ingredients, and completely superseding them; whereas, when two sounds of different pitch are sounded together, we still hear both: and, though we hear certain other tones besides, these other tones have each a pitch determined by the pitches, but independent of the intensities, of the original sounds.

The truth is, that the ear and eye deal with impressions in totally different manners. The ear deals with a complex musical sound exactly as a system of resonators does; it sensibly decomposes the sound into certain simple tones, just as the complex harmonic motion which produced the sound is theoretically decomposed by Fourier's theorem into the simple harmonic motions which would produce the simple tones. In order to understand the manner in which the eye deals with a compound colour, we must turn our attention to that particular unidimensional series of colours which constitutes the spectrum. As this is what your correspondents have done, the issue will be all the closer.

By the law above stated, all the colours of the spectrum might be co-ordinated with reference to any three colours chosen in the spectrum or out of it. But it has been ascertained by Mr. Maxwell* (to whose labours we are chiefly indebted in England for what we know of the composition of colours) that there are three colours in the spectrum to which all the rest stand in relations giving these the character of "primary" colours. They are the particular red, green, and blue, whose wave-lengths are, in Fraunhofer's measure, respectively 2328, 1914, 1717: and they divide the spectrum into three parts, in each of which every colour, it appears, may be matched by a compound of the two (out of these three) between which it lies. This is very accurately the case between 2328 and 1914 and between 1914 and 1717: it is much less accurately the case on the red side of 2328 and on the violet side of 1717; but in this region observation is difficult, and various eyes variable; and it seems probable that, as Mr. Maxwell infers, every colour in the spectrum, and therefore every colour in nature, is, as felt by us, a compound of three elementary sensations of colour excited separately by those three rays.

Now it must be observed that this result does tend to justify so much of the anticipations mentioned by Mr. Barrett as Sir John Herschel and Mr. Grove had long ago committed themselves to: it shows that the spectrum, like the musical scale, does in a manner return into itself. Beyond this the analogy fails.

In the first place there are, in music, no fixed tones with reference to which other tones possess any general properties at all; much less the property of being matched by combinations of them. In relations of tone, the constant quantities are not constant tones, but constant intervals between tones. Still, no doubt, if the three primary colours stood (as Dr. de Chaumont seems to think they do) in the arithmetical relations of tonic, fourth, and fifth, the fact would be as remarkable as two numerical coincidences could make it. But the case is not so. The ratio 2328 : 1914 (or 1·211) corresponds not to the interval of a fourth, but to an interval about two-ninths of the way from a minor third (6 : 5 or 1·2) to a major third (5 : 4 or 1·25); and the ratio 2328 : 1717 corresponds not to the interval of a fifth, but to an interval about a third of the way from a natural fourth (4 : 3 or 1·333) to a sharp fourth (45 : 32 or 1·406); intervals which, I presume, one can make nothing of.

Mr. Barrett's principal argument depends upon Prof. Listing's demarcation of the colours answering to the names red, orange, &c.: much too vague a basis, I should have thought, for exact inference, even if Mr. Barrett had not been obliged to sacrifice a boundary to obtain his most important interval; moreover the, correspondences in Table IV. are somewhat exaggerated for orange and yellow by errors of computation. Mr. Barrett does certainly get a good fourth, fifth, and sixth; but these coincidences seem to me to offer a simpler and more effectual key than that which he has applied to the lock. What this key is will be evident on substituting for the numbers in Table I. or II., the reciprocals of the same numbers. Take Table I. and divide ten millions by each of the numbers. The results, with a column of differences, are as follows:—

1382·3	
	162·8
1545·1	
	162·6
1707·7	
	162·5
1870·2	
	162·7
2032·9	
	162·5
2195·4	
	162·5
2357·9	
	162·9
2520·8	

I suppose this speaks for itself. Professor Listing has simply divided his spectrum into seven equal parts upon some scale which varies inversely as the wave-length. Such a scale would of course be furnished by comparative rapidities of vibration; but it is no use guessing. Whatever led him to this particular measure, it is evident what his measure virtually was, and it nearly corresponds with the ratios of the musical scale because these approximately form a "harmonic" progression.

The other suggested analogies are less definite. "The juxtaposition of two colours nearly alike is *bad*," but surely not what would be called *discordant*, except for the sake of finding an analogy between colour and music. The fact probably depends upon the extreme sensitiveness of the eye to the effect called *relief*; a sensitiveness shared in a different degree by the ear, but shared also by all modes of feeling, even the least material, as men count materiality. The best results of juxtaposition are generally those given by complementary colours: but the relation between complementary colours is one which depends partly on relief and partly on the laws of composition above stated, and has nothing corresponding to it in music. But indeed I am surprised that anybody should even look for an analogy between the effect of *simultaneous* sounds and the effect of *contiguous*, not *coincident*, colours.

For these reasons I venture to think it is only by the unphilosophical restriction of the word *physical*, which excludes biological relations, that "harmony in colour and music" can be said to "have a common physical basis."

With regard to the coloured bands within the rainbow, it is not doubtless without solid reasons that Mr. Grove can have decided against identifying the phenomenon he describes with

* Phil. Trans. 1860, pp. 57—84. On the theory of compound colours and the relations of the colours of the spectrum.

the phenomenon usually attributed to the interference of the two rays which, distinct at incidence, coincide on emergence. However this may be, the fact can have nothing to do with the present question. It is impossible, when the most refined spectroscopic observation hardly gives us one octave, that the rainbow should disclose three or four.

Hyères, Jan. 25 C. J. MONRO

Flight of Birds

WITH reference to an abstract of a paper by Mr. Southwell on the flight of birds, which appeared in your paper a few weeks back, I venture to make the following note and inquiry.

A late brother of mine who had been round the Cape, and had frequently observed carefully the flight of the albatross, told me that though he had watched individual birds on several occasions for many minutes together, he had seldom or never seen any of them flap their wings. Has this fact been observed by other persons, and if it be authenticated, has Mr. Southwell any explanation to offer? J. H.

Turdus Whitei

IT may interest some of your ornithological readers to know that a specimen of White's Thrush, *Turdus Whitei*, was killed near here on the 7th inst. It was shot by Mr. J. Beadon, of Gotten House, and presented by him to Mr. Cecil Smith, of Lydeard House, for his collection. This is, I believe, the fourth occurrence of this bird in Britain; it is, I think, even less known on the Continent. W. BIDGOOD

Museum, Taunton, Jan. 15

THE SARS FUND

WE are glad to find that the appeal made in our pages by Mr. Gwyn Jeffreys, on behalf of the family of the late Professor Sars of Christiania, is being warmly seconded in Paris by M. Alglave, the Editor of the *Revue des Cours Scientifiques*. In the last number of the *Revue* Mr. Gwyn Jeffreys' article is reprinted *in extenso*, and an announcement made that subscriptions to the Sars Fund will be received at the office of that journal. But M. Alglave has not waited for the publication of his notice before beginning his good work; he has already collected the sum of 2,026 francs (81*l.*), and publishes with the notice a first subscription-list containing the names of many of the most eminent naturalists in France. We have now the pleasure of giving in our advertising columns a list of the contributions already promised to Mr. Gwyn Jeffreys. Sars belonged to the best type of scientific men, the genuine lover of science, contented to work in obscurity without thought of honours or reward. His family have a special claim to help, inasmuch as the distress in which they are left is not due to neglect or extravagance on the part of the lamented Professor, but is solely attributable to his having devoted himself to studies, which, notwithstanding the most self-denying labours, did not enable him to make any provision for the future. Those of our readers who have visited Norway, who know the genuine unworldly ways of the Norwegians, and who have enjoyed the enthusiastic welcome so readily given to the English, have now a graceful opportunity of reciprocating the kindly feeling shown them by the countrymen of Sars.

NOTES

LORD DE GREY will to-morrow receive the Council of the British Association, as a deputation to urge upon her Majesty's Government the desirableness of a Royal Commission being issued to inquire into the present state of Science in this country.

THE Royal Society and the Royal Astronomical Society have both appointed committees of council, to report upon the steps which it may be desirable to take in connection with the total eclipse of the sun, visible in Algeria, Spain, and Sicily, in December next.

IT is proposed to celebrate the fiftieth anniversary of the Royal Astronomical Society by a dinner on the day of the annual meeting, February 11.

THE lectures annually delivered in the theatre of the Royal College of Surgeons were commenced yesterday by Professor Erasmus Wilson, F.R.S., who will deliver six lectures on Dermatology. To illustrate that of yesterday, there were a large number of exquisitely-prepared models, duplicates of those prepared for the Hôpital St. Louis, Paris. Professor Wilson's course will be followed by Professor Flower, F.R.S., Conservator of the Museum, who will deliver 18 lectures introductory to the study of the anatomy of the class mammalia.

THERE is a terrible rumour to which we are compelled to refer, though it has reached us in a—let us hope—doubtful way. The news is, that Livingstone has been murdered and burnt ninety days' journey from the Congo.

THE Zoölogical Society of London have now in the press a memoir by Dr. O. Fiusch, of Bremen, one of their corresponding members, upon the birds collected by Mr. William Jesse during the recent Abyssinian expedition. This memoir, which was read before the society at one of their meetings last year, will appear in their quarto Transactions, and will be illustrated by coloured figures of the new or little-known species. It will be in the recollection of some of our readers that Mr. Jesse was selected by the Zoölogical Society, at the request of the Treasury, to accompany the Abyssinian expedition as zoölogist, and that the society undertook the task of bringing the results of his investigations before the public. Dr. W. Peters, of Berlin, has undertaken to prepare a memoir upon some of the rarer mammalia obtained by Mr. Jesse during the expedition, which will likewise appear in the Transactions. Mr. W. T. Blanford, who was sent out by the Indian Government as geologist to the expedition, is preparing a separate work upon his discoveries, which will be published by Messrs. Macmillan.

AT its last meeting (January 24), the Academy of Sciences elected a new correspondent for the Physical section in the place of the late Professor Forbes. M. Kirchhoff, who was the successful candidate, obtained forty votes; Mr. Lloyd and Sir William Thomson received one vote each.—A committee of the three sections of Astronomy, Geometry, and Navigation selected the following candidates for the vacancy in the *Bureau des Longitudes*:—1. M. de la Roche Poncié; 2. M. Gaussin.

IT is no secret that the present *régime* at the Observatory of Paris has been rather more autocratic than could be patiently endured, even in a country subjected to eighteen years of personal government. Matters have at length reached a crisis, and the Minister of Public Instruction is placed in the awkward position of having to dismiss from the public service one of the most eminent of modern astronomers, or accept the resignation of the whole of the rest of the staff of the Observatory.

THE chair of Chemistry at the University of Tübingen has been offered to Prof. Fittig.

WE regret to have to announce the death of a naturalist of great promise, Dr. Wilhelm Keferstein, Ordinary Professor of Zoölogy and Comparative Anatomy in the University of Göttingen. He died on the 25th ult., at the early age of 37.

THOSE of our readers who are acquainted with the grand series of ethnographical photographs contained in the four volumes already published of the work entitled the "People of India," will be glad to hear that four more instalments completing the volume are now in progress. The publishers are Messrs. W. H. Allen and Co., of Waterloo Place.

M. SCHAFARIK, Professor of Chemistry in the Polytechnic Institute of Bohemia, writing on the 15th ult. to the Bohemian newspaper *Politik*, announces the discovery of a diamond in a granite quarry in the Dlaschkowitz estate of Count Schönborn, about eight miles north-west of Prague. The stone weighs 57 milligrams, is of a light yellow colour, and nearly cubtical in shape, the edges and corners being slightly rounded. In hardness it equals the East Indian, and exceeds the Brazilian diamonds. After the careful examination which the stone has been subjected to, by Prof. Schafarik, there can be little doubt of its genuineness; but that simple fact will hardly justify us in believing that a diamond has really been found associated with basalt and other minerals of plutonic origin, seeing that the beds which, in other parts of the world, have yielded this precious stone, are all sedimentary deposits. The Dlaschkowitz diamond had confessedly passed through the hands of a lapidary (who was unable to polish it on account of its hardness) before it reached M. Schafarik, and it would be reasonable, for the present, to suppose that an East India diamond had by some accident become mixed up with the various Bohemian stones sent to the lapidary. It has been suggested in Bohemia that the Dlaschkowitz diamond is nothing but zircon; but the stone does not agree with that mineral, either in specific gravity or in hardness. To those of our readers who are interested in the diamond discoveries in the Cape Colony we may commend an article "On the Diamond Regions of South Africa" in the *Field* newspaper of the 22nd ult.

In a recent number of NATURE we gave an account of some experiments by Lenz on the occlusion of hydrogen by electro-deposited iron. It will be remembered that in the discussion that followed the reading of M. de Jacobi's paper before the British Association at Exeter, Mr. W. Chandler Roberts stated that electro-type iron occluded at least twenty times its volume of hydrogen. The extraction of the gas was followed by a contraction of the metal. This Mr. Roberts considered important, from its connection with the behaviour of Palladium under similar conditions.

THE last bulletin of the Association Scientifique de France publishes three accounts of shocks of earthquakes at Marseilles and Toulon on the morning of the 18th ult. M. Stephan, of Marseilles, speaks of a smart shock at 2.50 A.M., the direction of the oscillation being from north to south, and lasting three seconds. Another slight shock, having the same direction, was noted by him at 3.5 A.M. M. Ferrier, of Marseilles, observed prolonged oscillations at 2.45 A.M. According to him, there were twenty or twenty-five oscillations from south-west to north-east, the intensity of the oscillations being all equal, and the duration of each one-third of a second. M. Zurchen, writing from Toulon, mentions two violent shocks at 3.7 A.M. There was an interval of two seconds between them. The oscillations appeared to be from north to south.

IN the matter of sewage, as in so many other particulars, the metropolis allows itself to be outdone by provincial towns. Leamington, for example, has had its sewage examined by Dr. Letheby; one sample after it had passed the charcoal filter, the other before being subjected to that process, although it had undergone chemical influences. In one of these, Dr. Letheby found only 8·40 grains of organic matter (in solution), and in the other, only 9·40 grains; whereas, ordinary London sewage contains 15·08 grains. Again, of mineral or organic matters in suspension, the two Leamington samples yielded none whatever, but on the other hand, the London sewage contained 22·04 grains of mineral, and 16·11 grains of organic matters in suspension. Now, why is there this contrast? And yet nearly all the towns of the Thames valley are under strict orders from the conservators to discontinue draining into the river at a given time.

ACCORDING to the *Avenir* of Auch, 130 tumuli, one of them containing a hundred skeletons, have just been discovered in the *landes* of Ossun.

PROF. R. S. BALL will commence a series of twenty lectures on Mechanics, in the Royal College of Science, Dublin, on the 7th of February. It is expected that this course will be found useful to artisans, as well as to students commencing the study of mechanics.

THE Natural History Museum of the Royal Dublin Society has been open for the last few months on one evening in each week to the public. The success that has attended this experiment has been something quite unexpected. The artisan class have flocked into the Museum in such numbers as to inconveniently fill it; the building, which can scarcely accommodate 2,000, being on at least one evening overcrowded with upwards of 3,000. In the meanwhile, the Department of Science and Art is greatly to blame in not increasing the number of porters, whose duty it is to regulate the movements of this great crowd as it circulates up staircases not four feet wide, and along the narrow slender galleries. If we except one porter, who acts as "turnstile" (counting the number of visitors), and another who takes the pennies for sticks and umbrellas, there are not *three* porters to do the duty of a dozen. The success of the experiment ought not to be endangered for the sake of a little expense.

ON Saturday last M. Murez resumed his lectures at the College of France, on the mechanism involved in the flight of birds. His lectures of last year on this subject were published in the *Revue des Cours Scientifiques.*

MR. HULL's paper read last week at the Royal Society has a value beyond that of recording the temperature of the strata through which the shaft of a coal-mine was sunk near Wigan. A mine 808 yards deep, nearly half-a-mile, is the deepest in the world, penetrates the "crust" of the globe farther than any other mine, and so has an especial interest for those who concern themselves about our supplies of coal. Geologists have told us that if we dig down through the "old red" we shall find coal-beds of greater extent than those which we have worked so profitably for the last two hundred years. This, however, did not comfort those uneasy people who looked forward to the exhaustion of coal; for the "old red" is so thick, it would never pay to raise coal from such a depth! And here the Rose Bridge Colliery, near Wigan, above referred to, becomes of especial importance. It may be regarded as an experiment towards a solution of the question of very deep mining. Already the proprietor finds that the cost of "getting" the coal is greater than when the mine was but 600 yards deep. This is the natural consequence of increase of temperature and increase of pressure. The temperature of the coal at the bottom of the mine, as stated in Mr. Hull's paper, is ninety-three degrees and a half! How long will the timber props last in such a temperature and under such a pressure as they have to bear? If the mine yields a profit under such circumstances, then some enterprising coalowner may be tempted to go deeper.

WE learn from the *Athenæum* that the sixth and concluding part of the first volume of annals of the Public Museum of Buenos Ayres has been issued, and that the work still bears the name of Dr. Burmeister as editor. The papers contained in this part, which is handsomely illustrated like its predecessors, are as follows:—"Descripcion de Cuatro Especies de Delfines de la Costa Argentina," and "Catologo de los Mamiferos Argentinos con los del Museo Público."

THE election of the new Council (Commission Centrale) of the French Geographical Society took place on the 7th ultimo with the following result:—President, M. de Quartrefages; Vice-Presidents, MM. d'Avezac and E. Cortumbert; General Secretary, M. Mannoir; Assistant Secretaries, MM. R. Cortambert and C. Delamarre.

SCIENTIFIC SERIALS

POLLI'S *Annali di Chimica applicati alla Medicina* (No. 1, 1870) has a long preface relating to *miasma palustre* and the use of febrifuges; these topics being discussed in view of the competition for which the Royal Institute of Lombardy has offered a prize in 1872. The competition is restricted to a discussion of the use of sulphites and hyposulphites in intermittent fevers. The editor adds to his preface a list of thirty-seven memoirs which have been published on these subjects between 1863 and 1869. Carlo Pavesi contributes a note on a speedy method of preparing mercurial ointment, in which the use of oil of turpentine as an ingredient is specially recommended. Belardi draws attention to the fact that pharmaceutical preparations of bismuth are liable to contain antimony. Pagano gives an illustration of the therapeutic value of magnesic sulphite; and Moretti records some clinical observations on the use of the same salt as well as sodic sulphite.

THE *Moniteur Scientifique* (January 15th) contains an unnecessarily tedious article on Sodic Bromide, by Casthélaz, which does not contain any original matter. M. E. Kopp contributes extracts from foreign journals (practical chemistry). M. J. Personne compares the process of Roussin for preparing hydrated chloral, which he condemns as imperfect, with that given in Dumas' *Traité de Chimie*, which he eulogises (it yields 185 per cent.) M. Jonglet reports ably on the progress of the sugar industry in France.

THE *Astronomische Nacrichten*, No. 1788, January 19, 1870, contains (1) Observations with the Reichenbach Circle at the Warsaw Observatory, by C. Deike, Second Assistant at the Observatory; (2) Observations of Comet III., 1869, by Argelander; (3) and (4) Elements and Ephemeris of the same Comet, by Bruhns and Von Littrow. Von Littrow states that the comet will hardly be visible after the end of January, as its brilliancy on 13th January only amounted to one-fifth the brilliancy at the time of its discovery. The fifth paper in the present number is by Peters, and gives Elements and Ephemeris of Felicitas (109) from January 30th to 22nd March. In the sixth and last paper Dr. Oppolzer communicates a definitive determination of the orbit of the planet (64) Angelina.

Annales de Chimie et de Physique, January.—M. Achille Cazin contributes a memoir on "internal work in gases." It contains a theoretical discussion and an experimental proof of such work, the latter being in principle a repetition of Joule's experiment, in which air is allowed to flow from a full into an exhausted receiver. M. Boussingault determines carbon in iron by mixing the filings with mercuric chloride and a little water, allowing the mixture to repose in contact with aqueous hydric chloride for about an hour, filtering and igniting the precipitate (carbon, mercurous chloride, &c.) in hydrogen. Successive ignitions in air and hydrogen then give the *combined* carbon; successive ignitions in oxygen and hydrogen next give the graphite. This number also contains an unfinished paper, by M. Vicaire, on the "temperature of flames and dissociation."

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 27.—The following papers were read: "Observations on the temperature of the strata taken during the sinking of the Rose Bridge Colliery, Wigan, Lancashire, 1868-69." By Edward Hull, M.A., F.R.S., Director of the Geological Survey of Ireland. The manager of the Rose Bridge Colliery, Mr. Bryham, sensible of the value of observations of the temperature of the strata in what is probably the deepest colliery in the world, certainly in Britain, made a series of observations with as much care as the circumstances of the sinking of the shaft would admit, and entrusted them to Mr. Hull for publication. The mode of taking the observations was as follows:—On a favourable stratum, such as shale, or even coal, having been reached, a hole was drilled with water in the solid strata to a depth of one yard from the bottom of the pit. A thermometer was then inserted for the space of thirty minutes, the hole having been sealed and made air-tight with clay. At the expiration of the half-hour the thermometer was taken up and the reading noted. While the temperatures of the strata were being measured, observations were carried on *pari passu* on those of the open pit during the descent. These are given in the Table annexed. By a comparison of the results in the two columns, it will be observed that, as the depth increased, the differences between the corresponding temperatures in the pit and the strata tended to augment; in other words, the temperature of the strata was found to augment more rapidly than that of the open pit. The effects of the high temperature and pressure on the strata at the depth of 2,425 feet are making themselves felt, and cause an increase in the expense both of labour and timber for props. This colliery, in fact, will be in a position to put to the test our views and speculations on the effects of high temperature and pressure on mining operations. In order to obtain the average rate of increase of heat, as shown by the experiments at Rose Bridge Colliery, we may assume (in the absence of direct observation) the position and temperature of the *invariable stratum* to be 50 feet from the surface and 50° F., which is probably nearly the mean temperature of the place. With these data, the increase is 1° F. for every 54·57 feet, which approximates to that obtained by Professor Phillips at Monkwearmouth of 1° F. for about every 60 feet. If, on the other hand, for the purpose of comparison, the measurements for the *invariable stratum* as obtained at Dukenfield be adopted, the rate of increase is found to be 1° F. for every 47·2 feet as against 1° F. for every 83·2 feet in the case of Dukenfield itself. So great a discordance in the results is remarkable, and is not, in the opinion of the author, attributable to inaccuracy of observation in making the experiments. On the other hand, he suggests that it is due, at least in some measure, to dissimilarity in the position and inclination of the strata in each case.

THERMOMETRICAL OBSERVATIONS AT ROSE BRIDGE COLLIERY.

Date.	Depth, in yards.	Strata.	Temperature in open pit.	Temperature in solid strata.
			F. °	F. °
July 1854	161	Blue shale	...	64·5
August 1854	183	Warrant earth	...	66
May 1858	550	Blue shale	...	78
July 1858	600	Warrant earth	...	80
May 18, 1868	630	"Raven" coal	73	83
July 24, 1868	665	Linn and wool	75	85
April 29, 1869	673	"Yard Coal" mine	76	86
November 18, 1868	700	Strong Blue Metal	76	87
February 22, 1869	736	Do.	76	88½
March 12, 1869	748	Shale	77	89
April 17, 1869	762	Linn and wool, or strong shale	78	90·5
May 3, 1869	774	Strong shale	80	91·5
May 19, 1869	782	Blue metal	79	92
July 8, 1869	801	Strong blue shale	79	93
July 16, 1869	808	Coal (Arley mine)	79	93½

Remarks.—All holes vertical in solid at bottom of pit drilled with water one yard deep, and thermometer remained thirty minutes in hole made air-tight with clay.

"On the Theory of Continuous Beams." By John Mortimer Heppel, Mem. Inst. C.E. Communicated by W. J. Macquorn Rankine, F.R.S. The chief object of this communication was to remedy some acknowledged defects in the theory of the above-mentioned subject. The principal steps by which it has reached its present state of development were also noticed, and may be briefly recapitulated as follows:—The great defect in the theory up to the present time has been that, in order to avoid an inextricable complexity, it has been necessary to consider the load in each span as uniformly distributed over it, and the moment of inertia of the section as uniform throughout each span. The method now given treats these conditions rigorously; and although the equations obtained are such as necessarily require some laborious computation to obtain numerical results, they are by no means inextricable.

"Remarks on Mr. Heppel's Theory of Continuous Beams." By W. J. Macquorn Rankine, C.E., LL.D., F.R.S. The author states that the advantages possessed by Mr. Heppel's method will probably cause it to be used both in practice and in scientific study. With a view to the instruction of students in engineering science, he proposes an abridged way of stating the theoretical principles of Mr. Heppel's method, considering at the same time that Mr. Heppel's more detailed investigation forms the best model for numerical calculation. He then uses Mr. Heppel's improved form of the "Theorem of the Three Moments" to test the accuracy of the formulæ which he obtained in another way, and published in "A Manual of Civil Engineering," for the case of an uniform continuous beam with an indefinite number of equal spans, the successive spans being loaded alternately with an uniform fixed load only, and with an uniform travelling load in addition to the fixed load; and he finds the results of the two methods to agree in every respect.

"Remarks on the recent eclipse of the sun as observed in the United States," by J. N. Lockyer, F.R.S.

By the kindness of Professors Winlock, Morton, and Newton, I have been favoured with photographs, and as yet unpublished accounts, of the results of the recent total eclipse of the sun observed in America. I am anxious, therefore, to take the opportunity afforded by the subject being under discussion, to lay a few remarks thus early before the Royal Society.

The points which I hoped might be more especially elucidated by this eclipse were as follows:—

1. Is it possible to differentiate between the chromosphere and the corona?

2. What is the real photographic evidence of the structure of the base of the chromosphere in reference to Mr. W. De la Rue's enlarged photographs of the eclipse of 1860?

3. What is the amount of the obliterating effect of the illumination of our atmosphere on the spectrum of the chromosphere?

4. Is there any cooler hydrogen above the prominences?

5. Can the spectroscope settle the nature of the corona during eclipses?

With regard to 1, the evidence is conclusive. The chromosphere, including a "radiance," as it has been termed by Dr. Gould (the edge of the radiance as photographed being strangely like the edge of the chromosphere in places viewed with the open slit), is not to be confounded with the corona.

On this subject, in a letter to Professor Morton, Dr. B. A. Gould writes:—"An examination of the beautiful photographs made at Burlington and Ottumwa by the sections of your party in charge of Professors Mayer and Haines, and a comparison of them with my sketches of the corona, have led me to the conviction that the radiance around the moon in the pictures made during totality is not the corona at all, but is actually the image of what Lockyer has called the chromosphere.

"This interesting fact is indicated by many different considerations. The directions of maximum radiance do not coincide with those of the great beams of the corona; they remain constant, while the latter were variable. There is a diameter approximately corresponding to the solar axis, near the extremities of which the radiance upon the photographs is a minimum, whereas the coronal beams in these directions were especially marked during a great part of the total obscuration. The coronal beams stood in no apparent relation to the protuberances, whereas the aureole seen upon the photographs is most marked in their immediate vicinity; indeed the great protuberance, at 230° to 245°, seems to have formed a southern limit to the radiance on the western side, while a sharp northern limit is seen on all the photographs at about 350°, the intermediate are being thickly studded with protuberances which the moon displayed at the close of totality. The exquisite masses of flocculent light on the following limb are upon the two sides of that curious prominence at 93°, which at first resembled an ear of corn, as you have said, but which, in the later pictures, after it had been more occulted, and its southern branch thus rendered more conspicuous, was like a pair of antelope's horns, to which some observers compare it. Whatever of this aureole is shown upon the photographs was occulted or displayed by the lunar motion, precisely as the protuberances were. The variations in the form of the corona, on the other hand, did not seem to be dependent in any degree upon the moon's motion. The singular and elegant structural indication in the special aggregations of light on the eastern side may be of high value in guiding to a further knowledge of the chromosphere. They are manifest in all the photographs by your parties which I have seen, but are especially marked in those of shortest exposure, such as the first one at Ottumwa. In some of the later views they may be detected on the other side of the sun, though less distinct; but the very irregular and jagged outline of the chromosphere, as described by Janssen and Lockyer, is exhibited in perfection."

2. The second point is also referred to in the same letter. I think the American photographs afford evidence that certain appearances in parts of Mr. De la Rue's photographs, which represent the chromosphere as billowy on its under side, are really due to some action either of the moon's surface or of a possible rare lunar atmosphere, so that it is not desirable to confound these effects with others that might be due to a possible suspension of the chromosphere in transparent atmosphere, if only a *section* of the chromosphere were photographed.

Dr. Gould writes:—"You will observe that some of the brighter, petal-like flocculi of light have produced apparent indentations in the moon's limb at their base, like those at the bases of the protuberances. These indentations are evidently due to specular reflection from the moon's surface, as I stated to the American Association at Salem last month. Had any doubt existed in my mind previously, it would have been removed by an inspection of the photographs."

Where the chromosphere is so uniformly bright that the actinic effect on the plate is pretty nearly equal, the base of the chromosphere is absolutely continuous in the American photographs; but in the case of some of the larger prominences, notably those at + 146 (Young) and − 130 (Young), there are strong apparent indents on the moon's limb.

3. I next come to the obliterating effect of the illumination of our atmosphere on the spectrum of the chromosphere.

This is considerable; in fact, the evidences of it are very much stronger than one could have wished, but hardly more decided than I had anticipated. Professor Winlock's evidence on this point, in a letter to myself, is as follows:—"I examined the principal protuberances before, during, and after totality. I saw three lines (C, near D and F) before and after totality, and eleven during totality; *eight were instantly extinguished on the first appearance of sunlight.*"

This effect was observed with two flint prisms and seven inches aperture. Professor Young, with five prisms of 45° and four inches aperture, found the same result in the part of the spectrum he was examining at the end of the totality.

He writes:—"I had just completed the measurements of 2,602, when the totality ended. *This line disappeared instantly*, but 2,796 [the hydrogen line near G] was nearly a minute in resuming its usual faintness."

These observations I consider among the most important ones made during the eclipse; for they show most unmistakably that, as I have already reported to the secretary of the Government-Grant Committee, the new method to be employed under the best conditions must be used with large apertures and large dispersion.

On the 4th point the evidence is negative only, and therefore in favour of the view I have some time ago communicated to the Royal Society.

5. We next come to the question of the corona, a question which has been made more difficult than ever, in appearance only, I think, by the American observations.

I propose to discuss only the spectroscopic observations of Professors Young and Pickering in connection with Dr. Gould's before-quoted remarks.

[After this discussion, for which we have not space, the author continues:—]

I have first to do with the continuous spectrum, deduced from Professor Pickering's observations.

I think in such a method of observation, even if the corona were terrestrial and gave a dark line spectrum, the lines visible with such a dim light would in great part be obliterated by the corresponding bright lines given out by the long arc of chromosphere visible, to say nothing of the prominences, in which it would be strange if C, D, E, *b*, F, and many other lines were not reversed. This suggestion, I think, is strengthened by the statement that two bright lines were seen "near C" and "near E;" should we not rather read (for the "near" shows that we are only dealing with approximations) C and F, which is exactly what we might expect?

But even this is not all that may be hazarded on the subject of the continuous spectrum, which was also seen by Prof. Young under different conditions.

Assuming the corona to be an atmospheric effect merely, as I have before asserted it to be, in part at least, it seems to me that its spectrum should be continuous, or nearly so; for is it not as much due to the light of the prominences as to the light of the photosphere, which it may be said roughly are complementary to each other?

With regard to the aurora theory, I gather from Prof. Young's note that, if not already withdrawn, he is anxious to wait till the next eclipse for further facts. I consider the fact that I often see the line at 1,474, and often do not, is fatal to it, as it should be constantly visible on the proposed hypothesis. The observation of iron-vapour, as I hold it to be at this elevation, is of extreme value coupled with its simple spectrum, *seen during an eclipse*, as it entirely confirms my observations made at a lower level in the case, not only of iron but of magnesium.

Geological Society, January 26.—Professor Huxley, LL.D., F.R.S., president, in the chair. Thomas Daniel Bott, Esq., 20, Osborne Villas, Talfourd Road, Peckham; Edwin Buckland Kemp-Welch, Esq., 3, Beaumont Terrace, Bournemouth; James Parkinson, Esq., F.C.S., Sarum House, Church Road, Upper Norwood, S.; Henry Sewell, Esq., Villa del Valle, Mexico; and Thomas F. W. Walker, Esq., M.A., F.R.G.S., Athenæum Club, London, and 6, Brock Street, Bath, were elected Fellows of the society. The Rev. Dr. Oswald Heer, of Zurich, was elected a foreign member of the society. The following communication was read:—"On the crag of Norfolk and associated beds." By Joseph Prestwich, Esq., F.R.S., F.G.S. The author commenced by referring to his last paper, in which he divided the Red Crag into two divisions—a lower one, of variable oblique bedded strata, and an upper one of sands passing up into the clay known as the Chillesford clay. In 1849 he had alluded to the possibility of this clay being synchronous with the Norwich Crag. He has since traced this upper or Chillesford division of the Red Crag northwards, with a view to determine its relation to the Norwich Crag. He has found it at various places inland, but the best exhibition of it occurs in the Easton Bavant Cliffs. He there found in it a group of shells similar to those at Chillesford, and under it the well-known bed of mammaliferous or Norwich Crag, with the usual shells. The author also showed that in this cliff and the one nearer Lowestoft traces of the Forest-bed clearly set in upon the Chillesford clay. He next traced these beds at the base of Horton Cliff, and then passed on to the well-known cliffs of Happisburgh and Mundesley. He considered the Chillesford clay to pass beneath the Elephant bed, and to represent some part of the Forest-bed. The same clay may be traced to near Weybourne. The crag under these beds he referred to the Chillesford sands. Mention was then made of the sands and shingle above the Chillesford, to which the author proposed the names of "Southwold Sands and Shingle." These usually are very unfossiliferous, but at two or three places near Southwold the author found indications of an abundance of shells (*Mytilus*, &c.) and Foraminifera in some iron sandstones intercalated in this series. In the Norfolk cliffs these beds contain alternating seams of marine and freshwater shells. The inland range of the beds to Aldeby, Norwich, and Coltishall was next traced, and the Chillesford clay shown to be present in each section, and the sands beneath to be referable to the Chillesford sands, as already shown by other geologists on the evidence of the organic remains. Mr. Gwyn Jeffreys, who had carefully examined the shells of the Norwich Crag for the author, stated that a considerable number of Arctic species were found in the Norfolk Crag which did not occur in Suffolk. While, therefore, the Norwich Crag seems to be synchronous with a portion of the Suffolk Crag, that portion is the upper division, and, therefore, the triple arrangement proposed by Mr. Charlesworth and advocated by Sir C. Lyell, together with the fact of the setting in of a gradually more severe climate, pointed out by the late Dr. Woodward and by Sir C. Lyell, are confirmed. Mr. Prestwich then referred to the origin of the materials of the Southwold shingle, and showed that, with few exceptions, they came from the south. In it he had found a considerable number of worn fragments of chert and ragstone from the Lower Greensand of Kent. He considered this a convenient base-line for the Quaternary period; as then commenced the spread of the marine gravels over the south of England, and soon after commenced the great denudations which give the great features to the country. Mr. Gwyn Jeffreys observed that no littoral shells occur in the Coralline Crag, while in the Red Crag they abound. In the Norwich Crag there is also evidence of littoral conditions, but in certain places the shells exhibit a deep-water character. In the Norwich Crag, after eliminating as derivative or extraneous certain species (as had already been done by the late Dr. Woodward), he finds, exclusive of varieties, 140 species, of which 123 are living, and 17 are supposed to be extinct. Of these 123, 101 still live in the British Seas, 12 are Arctic and North American, 8 Mediterranean, and 2 Asiatic. The southern species were probably derived from the Coralline Crag. The two Asiatic species were the *Corbicula fluminalis* and *Paludina unicolor*. Twenty species in the Norwich Crag have not been found in the Red or Coralline Crag, and he therefore thought there was some difference in their geological age, the Norwich Crag being both more recent than the Red Crag, and its shells of an Arctic or more northern kind. *Tellina balthica* he regarded as significant of brackish water conditions. *Actæon Noæ*, a characteristic shell of the Red and Norwich Crag, had been found fossil by Prof. Steenstrup in Iceland. Sir Charles Lyell had been struck with the similarity of the beds at Chillesford and at Aldeby, in which also the shells, though 40 in one case and 70 in the other, were very similar in character; but in neither was *Tellina balthica* found, though common in the glacial beds. He called attention to the condition of the shells as they occurred at Aldeby, and suggested that where the two shells of a bivalve were found in contact, they would probably afford some evidence whether they were derivative or no. Mr. Searles V. Wood, jun., was inclined to differ to a large extent from the author, especially with regard to the beds above the Chillesford clay. The sands containing *Tellina solidula* he placed as the lowest member of the glacial series; the fauna they contain is different from that of the Chillesford bed. He regarded the sand-beds at Kessingland as above the lower boulder-clay and contorted drift of Cromer, and considered that it might be traced as occupying this position along a great part of the coast of Norfolk. He had, in company with Mr. Harmer, surveyed a great part of the Norfolk and Suffolk district, and they intended to place their maps and sections at the disposal of the Geological Society and the Survey. He recommended that any examination of the country should commence from the east rather than from the west. Mr. Boyd Dawkins, speaking of the fossil mammalia of the crag, mentioned that, at the base of the crag at Horstead, immediately on the chalk, was a bed exhibiting an old land-surface, and in this were found the principal perfect mammalian remains, whereas in the crag above they were water-worn. But though these bones occurred in the marine deposit, the animals had lived on the land, and there was no evidence but that they belonged to a much earlier period than that at which it was submerged. He thought that the facies of the Cervidæ found at Horstead was that of an early Pliocene age. The mammals of the London Clay had in some cases become confounded with those of the Suffolk Crag, but these he regarded also as belonging to an old Pliocene land-surface. He differed from the author in not regarding the Forest-bed as Quaternary, as the remains of *Rhinoceros etruscus*, *Ursus arvernensis*, and *Elephas meridionalis*, &c., had occurred in it, in many cases in fine condition. He could see no reason for splitting up the Cainozoic series into four divisions, as there was no break in the life between the Tertiary and Quarternary periods. Though there might be a break in England, the forms of life were continuous from the Miocene of Pikermi on the Continent. The President suggested that if we were to admit a Quaternary period we must go back to the Miocene, as the mammalian fauna of that period was the direct ancestor of that of the present day. Mr. Prestwich, in reply, remarked that he did not quite agree with Mr. Jeffreys as to the number of derivative species in the different members of the Crag. The fauna, however, required further investigation. With regard to the objections of Mr. Wood, he had not on this occasion intended going into details as to the beds above the Chillesford clays; his object had rather been to show that these latter extended over a large area, and contained in other places than Chillesford the same shells as those occurring there. He did not attach the same value to the presence of *Tellina balthica* as did Mr. Wood, it being a shell now living and found on the coast. He had not overlooked the importance of the mammalian remains, but, like Mr. Dawkins, he had felt the uncertainty which, in the case of the Crag, so often attached to their origin, and therefore had not much insisted on them. He thought the divisions of Miocene and Pliocene were well known and generally accepted; and though the division was arbitrary, he thought the setting in of the Glacial period a good epoch at which to commence the Quaternary period. If we were to go back to some break in the forms of life, we might go back indefinitely.

Ethnological Society, January 25.—Professor Huxley, president, in the chair. The following new members were announced at this and the preceding meeting:—The Earl of Dunraven and Mount-earl, K.P., Lord Rosehill; Messrs. J. W. Barnes, T. H. Baylis, D. Duncan, M.A., J. E. Edwards, J. F. McLennan, W. Morrison, M.P., and R. L. Nash. Dr. Hooker, C.B., exhibited a collection of figures in unbaked clay, modelled by a native Zulu; and Colonel Lane Fox exhibited some stone mullers used for pounding grain.—Mr. Borwick, F.R.G.S., read a paper on the origin of the Tasmanians geologically considered. The Tasmanians have now become almost extinct, an old woman being the only survivor of the race. They were related in manners and in general *physique* to the neighbouring Australians, but were allied by black skin and woolly hair to the distant Africans, while they were assimilated by resemblance of language, customs, and habits of thought to many races scattered over vast areas. The author sought to explain this relation by constructing an ideal southern continent, whence all the dark-coloured races surrounding the Indian Ocean, and extending into the Pacific and Southern Oceans, may have radiated. He regards the Tasmanian as probably older than the Australian. Dr. Hooker, whose authority had frequently been quoted in the paper, pointed out the similarity and differences that obtain between the floras of Australia, Tasmania, New Zealand, South Africa, &c. It has recently been found that the flora of the Howe Islands is very unlike that of Australia, although so near to the coast. He protested, however, against the inference that the line of migration followed by plants is necessarily the same as that pursued by the higher animals. The President alluded to the great difference between the Australian and Tasmanian, especially in the character of the hair, and he regarded it as physically impossible that the Tasmanian could have come from Australia. He suggested that an interrupted communication, by a chain of islands, may have extended from New Caledonia to Tasmania, similar to that which now connects New Caledonia with New Guinea; and that by this means a low negrito type may have spread eastwards over this area.—Mr. Howorth's paper, "On a frontier-line of Ethnology and Geology," was then read. Siberia and North America form a well-defined province, botanically, zoologically, and ethnologically. North of the isothermal line forming the southern boundary of this province dwell the Ugrian races, whose conditions of existence were compared by the author with those of the prehistoric period. In Europe the isothermals have been gradually twisted to the north by the Gulf Stream; and the author believes that the gradual advent of the stream may be traced from no earlier period than about the twelfth century B.C.; Remarks on this paper were made by the President, Dr. Hyde Clarke, Dr. Richard King, and Colonel Lane Fox.—Mr. Atkinson read a "Note on the Nicobar Islands," and exhibited some grotesque figures carved in wood, taken from the Nicobars by Capt. Edge in 1867, and recently brought to this country by Capt. Mackenzie. These figures are to be placed in the Christy collection, and similar objects have been forwarded to the Museum in Edinburgh.

London Mathematical Society, January 13.—Prof. Cayley, president, in the chair. Mr. Walker gave an account of a paper "On the Equations of Centres and Foci of, and Conditions for, certain Involutions." In this communication it is shown that the three points corresponding to one having an assigned distance (x') from the origin, in one of three involutions determined by a quartic, and found from the equation—

$(abcd \between x', 1)^3$, $(bcde \between x', 1)^3$, $(cdef \between x', 1)^3$, $(defg \between x', 1)^3$, $(x, 1)^3 = 0$,

the sextic covariant of the quartic being written $(a\,b\,c\,d\,e\,f\,g \between x\,y)^6$, This form has been arrived at in carrying out a suggestion of the president, Prof. Cayley. It contains the equations giving the three centres of the involutions determined by the quartic, as well as that giving the six double points (the geometrical significance of which latter equation has been already pointed out by Dr. Salmon), by making x' infinitely great, and equal to x, successively. The case of the quartic breaking up into two quadratics is next discussed, when the roots of one correspond respectively to those of the other. The condition for two cubics ($u\,v$) determining an involution, of such a kind that the three roots of one correspond each to a root of the other, is investigated. This has (since the meeting) been identified by the author with $\Delta\,\Theta'^2 - \Delta'\Theta^2 = 0$, Δ, Δ', being discriminants of u and v, while $\Theta\,\Theta'$ are the co-efficients of λ and λ^3 respectively in the discriminant of $u + \lambda\,v$. The equations for determining the centre and double points—or, more generally, that determining the point corresponding to an assigned one—in the involution determined by two cubics, satisfying the above condition, are also investigated. Dr. Henrici, Prof. Hirst, Mr. Clifford, and the President took part in a discussion on the paper. The President then made a statement of some results he had arrived at with reference to quartic surfaces. Mr. Roberts exhibited and explained diagrams of the pedals of conic sections which he had constructed by the methods described in his paper read before the society, January 14th, 1869.

Quekett Microscopical Club, January 28.—P. Le Neve Foster, Esq., president, in the chair.—A paper was read by Dr. Robert Braithwaite on the geographical distribution of mosses. The paper gave an abstract of the arrangement proposed by Prof. Schimper, who divides the whole of Europe into three areas in latitude—viz. (1), a northern zone, comprising N. Russia, Scandinavia, and N. Scotland; (2), a middle zone, extending south of this to the foot of the Alps, and including all central Europe; (3), a southern zone, reaching from the last to the Mediterranean. More important than these is their distribution in altitude, or height above the sea level, and for this five regions are indicated, each characterised by certain predominant species, and marked out by lines gradually falling in altitude as we pass northward to the pole, where the extreme limits, or that of the sea level and the line of perpetual snow, become coincident. Commencing at the sea level, the dimensions in altitude are—(1), the Campestral region, or that of the cultivated field and fruit trees, embracing the greatest varieties of soil and conditions of surface; (2), the Montane, or lower mountain region, marked at its upper limit by the disappearance of the beech; (3), the Sub-Alpine region, extending from the upper limit of the beech to the upper limit of the spruce fir; (4), the Alpine region, embraced between the commencement and termination of growth of the dwarf pine, and marked by the presence of dwarf birch; (5), the Supra-Alpine region, reaching above the limit of the trees named to the line of perpetual snow. A brief sketch was then given of the various *habitats* affected by mosses, and lists of the characteristic species given; these embraced the dwellers on walls, roofs, trees, heaths, bogs, and rocks. They were illustrated by a fine series of specimens of mosses and their associated flowering plants, prepared by the late Mr. N. B. Ward, who thus ingeniously attempted to work out the idea of representing the whole flora of a locality at one glance. Conspicuous among these were the sheets from Ben Lawers, Ben Voirlich, Heidelberg, Killarney, and Eridge Rocks.

Anthropological Society, January 18.—Annual General Meeting.—John Beddoe, Esq., M.D., president, in the chair. The report of the auditors showed the income of the society in 1869 to have been 1,091*l.* 9*s.* 5*d.*, the expenditure 964*l.* 9*s.* 8*d.*, and the balance in hand on the 31st December 126*l.* 19*s.* 9*d.* The report of the council was read and adopted. The president then delivered the annual address, including a full obituary notice of Dr. James Hunt, founder of the society. The ballot for the election of officers and council to serve in 1870 was taken with the following result:—President, John Beddoe, M.D.; vice-presidents, H. Beigel, M.D., Captain R. F. Burton, Dr. Charnock, J. Barnard Davis, M.D., F.R.S., Captain Bedford Pim, R.N., Dr. Berthold Seemann; director, Thos. Bendyshe, M.A.; treasurer, Rev. Dunbar I. Heath, M.A.; council, J. Gould Avery, J. Burford Carlill, M.D., S. E. Collingwood, Walter C. Dendy, George Harris, Jonathan Hutchinson, W. B. Kesteven, Kelburne King, M.D., Richard King, M.D., A. L. Lewis, St. George J. Mivart, F.R.S., Major S. R. I. Owen, Edward Peacock, F.S.A., J. Spence Ramskill, M.D., C. Robert Des Ruffières, John Thurnam, M.D., W. S. W. Vaux, F.R.S., C. Staniland Wake, Alfred Wiltshire, M.D., E. Villin.

Entomological Society, January 24.—Annual General Meeting, Mr. Frederick Smith, vice-president, in the chair. The Report of the Council for 1869, and an address by Mr. H. W. Bates, the retiring president, were read. The following thirteen members were chosen to form the council for 1870, viz: Messrs. Bates, Dallas, Dunning, Fry, Grut, M'Lachlan, Parry, Pascoe, Saunders, Stevens, Wallace, and Wormald. Mr. Alfred Russell Wallace was elected president for 1870; and the following officers were re-elected:—Mr. Stevens, treasurer; Messrs. Dunning and M'Lachlan, secretaries; Mr. Janson, librarian. The thanks of the society were voted to the officers and members of the council for their services during the previous year.

Glasgow

Philosophical Society of Glasgow, January 12.—Dr. Francis H. Thomson, vice-president, in the chair. The president, Dr. James Bryce, F.G.S., gave an account of the "Geological Structure of Skye and the West Highlands." The difficulty and danger of thoroughly studying the peculiar geological structure of Skye were so great that no geologist, in the author's opinion, should undertake it without the company of an associate; and as he considered that no such person should ascend the mountains for the first time unaccompanied, the author specially recommended Angus Nicholson as a reliable guide. Dr. Bryce dwelt at some length upon the wonderful peculiarities in the structure of the Cuchullin mountains, which form such a characteristic feature of the island in the vicinity of Glen Sligachan. They rise to a height of about 3,300 feet, the last 400 feet being absolutely inaccessible, owing to the peaked, spiry, or pinnacled structure. Thoroughly skilled Alpine climbers had been quite baffled by the Cuchullin mountains, unless they had gone to the ignominious extremity of using ladders to aid them in making the ascent. That structure was entirely due to the great abundance of one single mineral, a variety of augite known as *hypersthene*, the intense hardness of which was owing to the presence of large quantities of oxide of iron and oxide of manganese (*query*, silicate of iron and silicate of *magnesia?*). While referring to the rock-features of Skye, Dr. Bryce remarked that of late geologists have been too much led away by the attractiveness of palæontology as a means of geological research, overlooking the superior claims of mineralogy. He considered that in Skye there were two chains of mountains—one black, in which the hypersthene prevails, and the other red, owing to the presence of syenite—and that they had come up in two, if not even in four eruptions, through a liassic basin, the thickness of which is probably not less than 1,500 feet. Besides the lias, he found gneiss, sandstone, quartzite, marble, numerous whin dykes, and crystalline slates from 10,000 to 20,000 feet in depth. When the country was examined closely two syenites were found, one intrusive, the other disruptive. The granites and syenites of Skye were very closely approximated to each other, each rock shading off into the other. On the coasts there were beds of öolite and traps, but they were difficult of examination, and indeed there were many points in the geology of the island yet to be explored. Dr. Bryce referred to the separate examinations of Skye made by Sir Roderick Murchison and the late Prof. Edward Forbes, but he differed in opinion from some of the conclusions of those geologists on the geology of the West Coast, and he expressed himself inclined to support the crystalline schist view of Prof. Nicol, of Aberdeen, rather than the Silurian theory which Sir Roderick Murchison and Mr. Geikie had promulgated, although the latter was the popular theory. Dr. Young said he could not agree with Dr. Bryce in his remarks regarding the relative claims of mineralogy and palæontology in geological inquiries. He dissented from some of the conclusions arrived at by Dr. Bryce, and on other points he confessed and regretted his inability to understand him. Dr. Bryce briefly replied.

Chemical Section, January 17.—Alexander Whitelaw, Esq., vice-president, in the chair. Two papers were read,—the first by Mr. J. Wallace Young, on "Artificial Alizarine," recently obtained from anthracene, one of the coal-tar products. In reference to the question of price, a member having much experience, said that manufacturers felt quite satisfied that they could supply artificial alizarine in large quantities, in half tons if it was wanted, and at a price much under that of natural alizarine as extracted from madder.—The other paper read was, "On the estimation of iodine and bromine in the mother liquors from saltpetre and in kelp." By Dr. John Clark.

Berlin

German Chemical Society, January 24.—F. Rüdorff showed a simple experiment to prove the expansion of water when freezing. Cylindrical bombs cast in iron, of half an inch in thickness, and measuring three inches in length, and one in diameter, were entirely filled with water, previously freed from air by boiling, and then closed by a tightly fitting screw. They were then covered by a mixture of pounded ice and common salt. In from ten to twenty minutes' time they exploded with a loud report like that of a pistol, breaking in different directions.—Mr. Holbein exhibited animals, from mussels up to small mammalia, which had been preserved in a solution of creosote in water (one of creosote to twenty parts of water). This process appeared particularly suited to the preservation of fishes.—A. Baeyer spoke on a third isomeric form of hydromellithic acid, adding interesting considerations on the transformation of isomeric bodies one into the other, which will not bear abbreviation.—A. Horstmann reported on the vapour density of acetic acid, which he found to be normal at low temperatures, when the acid vapour was diluted with air.—Prof. Lieben (of Turin) sent in a paper published conjointly with Rossi on normal butylic alcohol produced by the reduction of butyric acid.—Prof. Rose reported on the first diamond found in Europe. A small diamond, recognised as such by Schafarik in Prague, has lately been discovered in an alluvial formation in Bohemia, in which garnets, hyacinths, and sapphires have been found for years.

Prague

National Museum of Bohemia, December 18, 1869.—Prof. Krejci continued his account of the Permian formation of the N.E. of Bohemia, and discussed the section of Stepanitz, near Paka, at Bélohrad. Three deposits are there distinguished. The lowest is schistose and rich in fossil fish; the next is composed of glauconitic grit, and contains trunks of auracaria *in situ*; the upper is calcareous, finely laminated, full of beautiful concretions of polished stones, of chalcedony and agate, often arranged in rows parallel to the stratification. This is the original deposit of the celebrated Psaronites (silicified trunks of *Marattiaceæ arborescentes*. M. Krejci calls this stratum the Kalva beds. This simple arrangement is disturbed by numerous faults and discolorations, united apparently by melaphyr. M. Krejci believes that all the numerous portions of melaphyr in this neighbourhood exhibited originally only a single level; he insists on the fact that in the sections frequently exposed of late in the course of railway operations; the melaphyr is intercalated conformably between the sedimentary deposits; thus leading to the supposition of a metamorphic change of schist or phyllite into melaphyr. He allows, moreover, that the mountain, Grand Levin, near Horka (Falgendorf) arose apparently through a cleft only one to two metres wide. As regards the band of melaphyr and red porphyry, which, at the southern foot of the superb basaltic mass of Mount Kozakov, rests against the very sloping beds of the cretaceous series, and extends towards Mount Jeschken for a distance of at least ten kilometres, M. Krejci prefers to the idea of an irruption, that of a fault into which the beds of porphyry and melaphyr have slid on the one side to reappear on the other.

January 17.—M. Schafarik announced the discovery of the diamond in Bohemia. A note on the subject will be found in another page. We may add here that the Dlaschkowitz diamond has been presented by Count Schönborn to the National Museum of Prague.—The Royal Society of Bohemia held no public meetings during the month of December.

Boston

Society of Natural History, November 17.—The president in the chair. Prof. N. S. Shaler read a note on the occurrence of the remains of *Tarandus rangifer* Gray, at Big Bone Lick, in Kentucky. At a previous meeting was presented the evidence in support of the conclusion that one of the large mammals of North America, the buffalo, had recently changed its limits, and had only ranged in the Ohio valley within the past few centuries. The same locality supplies us with evidence that the caribou existed in abundance in this river basin at a time anterior to the coming of the buffalo, and probably not very long after the disappearance of the *Elephas primigenius*. Since the coming of civilised man into America, the caribou has been confined to a narrow area in the north-east part of the continent; it is questionable whether it has ever ranged during this time south of the southern limit of the State of Maine. The position in which these remains were found leaves the precise relationship in time of this species to the mammoths and mastodons a little questionable. There is, however, little doubt in my mind that, if not in existence during the later part of the time of these pachyderms, it came immediately after them. Its bones are always found below the line of the buffalo and the Virginia deer. The remains of this latter species are found only among the most recent deposits of the swamp. The disappearance from this region of this eminently boreal animal immediately after the passing away of the ancient elephants from the Mississippi valley, goes to confirm the conclusion that the climatic change which closed the period of the mammoths was from cold to warmth, and not an alteration of the opposite character.

Section of Entomology, November 24.—Mr. Edward Burgess in the chair. The following paper was presented:—"American Lepidoptera. II. *Phalænidæ* Latr." by Charles S. Minot. At the June meeting of the section, I presented a paper entitled "American Lepidoptera, No. I." which contained descriptions of four new Geometridæ (*Phalænidæ* Latr.), and was published without further introduction. I should now like to say a few words on the intended purport of the series. I propose that it shall contain any papers of a miscellaneous nature which may aid in completing our knowledge of the natural history of the Lepidoptera; such as descriptions of new species, or of the metamorphoses and lists of insects found in particular localities or States, with their times of appearance, and perhaps ultimately anatomical communications. The descriptions of new species will, for the present, be principally, if not entirely, confined to the Phalænidæ. Mr. W. H. Dall remarked that while passing over the Portage to the Yukon River, in Alaska, when the temperature was below zero of Fahrenheit, he shot a Canada jay, which had in its mouth the caterpillar of an Arctian; afterwards, when the thermometer was sixteen degrees below zero, he found one of the same caterpillars crawling upon the snow. On the middle of the frozen river, whenever the sun shone for a short time upon the crust, he saw upon the snow a species of *Lepisma* or *Podura* in great abundance, although the cold was intense. The caterpillar of *Vanessa Antiopa* was twice noticed alive during the winter, and the perfect insect was seen at Nulato, May 20th, when the nightly temperature was below freezing.

December 3.—The president in the chair. Dr. C. T. Jackson presented, in the name of Mr. Daniel McCain, specimens of native carbonate of magnesia from Greece, California, Maryland, and Kansas. These minerals are used by the Union Stone Company in making calcined magnesia, which is one of the ingredients of their artificial stone, serving, when combined with chloride of magnesium, as the binding material. Dr. Jackson gave a detailed account of the method of making the artificial stones, and of casting bas-reliefs, busts, and ornamental mouldings. He said the processes had been so improved that now artificial grindstones made of quartz-sand and of emery had been constructed, which were as solid and durable as any natural stone. The emery wheels made of these materials are vastly better than those made with a paste of vulcanised indiarubber, since they do not glaze, but wear away in such a manner as to always expose fresh particles of emery. He regarded this new manufacture as of great value for architecture and the mechanic arts, and as showing the importance of the mineral native carbonate of magnesia, which had been before used only for the manufacture of Epsom salts, of which a limited supply only is wanted. Professor N. S. Shaler offered some remarks on the relation of the rocks in the vicinity of Boston.

PHILADELPHIA

American Philosophical Society, January 7.—Mr. Pliny E. Chase made some observations on the comparison of different mechanical equivalents. He stated that recent determinations, by the different methods of Thomson and Farmer, fix the mechanical equivalent of light, in a wax candle burning $126\frac{1}{2}$ grains per hour, at 13·1 foot-pounds per minute, the equivalent of one grain being 6·213 foot-pounds. According to Dubourg, the heat evolved during the combustion of one grain of olive oil in oxygen is sufficient to heat 9682 grains of water 1° C. According to Favre and Silbermann, one grain of oil of turpentine, burnt in oxygen, would heat 10,852 grains of water 1° C. It may therefore be presumed that the total heat given out by the combustion of one grain of wax is about sufficient to raise 10,000 grains of water 1° C., or 18,000 grains 1° F. This represents a mechanical equivalence of $(18{,}000 \times 772 \div 7{,}000 =)1985{\cdot}143$ foot-pounds, which is 319·5 times as great as the corresponding equivalent of the light given out during the combustion. Tyndall, in his lecture on Radiation, states that the visible rays of the electric light contain about one-tenth of the total radiated heat. The relative luminous intensity of an electric lamp would, therefore, appear to be about 31·95 times as great as that of a wax candle. This ratio resembles that of solar to terrestrial superficial attraction, and the connection of electric and magnetic currents with solar radiation is so evident, that additional experiments, to furnish materials for a great variety of similar comparisons, seem desirable. While it is possible that the resemblance in the present instance may be accidental, the numerous harmonies which exist between the manifestations of cosmical and molecular forces render it at least equally possible that it may have a weighty significance.

Academy of Natural Sciences, August 3, 1869.—Professor Cope called attention to a thin slab of shale containing foot impressions of vertebrate animals found some time ago by Professor Gabb, from the subcarboniferous slate in Schuylkill County. The position of the slab was about 300 feet above the conglomerate. The impressions found by Dr. Isaac Lea some years back were from a position about 700 feet below the conglomerate, and, therefore, more ancient. Professor Cope thought that the impressions found by Dr. Lea were neither reptiles nor fishes, but air-breathing vertebrates—*Batrachians.* But these tracks were different from most *Batrachia*, showing slender digits and long tarsus. The fore-feet are smaller than the hind. They are probably referable to a Salamandroid animal.

DIARY

THURSDAY, FEBRUARY 3.

ROYAL SOCIETY, at 8.30.—On the Fossil Mammals of Australia. Part III. Diprotodon Australis Ow.: Prof. Owen, F.R.S.—Note on an Extension of the Comparison of Magnetic Disturbances with Magnetic Effects, inferred from Observed Terrestrial Galvanic Currents, and Discussion of the Magnetic Effects Inferred from Galvanic Currents on Days of Tranquil Magnetism: The Astronomer Royal, F.R.S.

LINNEAN SOCIETY, at 8.—Revision of the genera and species of capsular gamophyllous *Liliaceæ*: J. G. Baker, F.L.S.—On a new form of Cephalopodous Ova: Dr. Collingwood, F.L.S.

ANTIQUARIES, at 8.30.—On some Ancient Oaken Coffins discovered in Northumberland: T. W. Snagge, Esq.

CHEMICAL SOCIETY, at 8.

FRIDAY, FEBRUARY 4.

PHILOLOGICAL SOCIETY, at 8.15.

ROYAL INSTITUTION, at 8.—Verona and its Rivers: Prof. Ruskin.

ARCHÆOLOGICAL INSTITUTE, at 8.

GEOLOGISTS' ASSOCIATION, at 8.

MONDAY, FEBRUARY 7

ROYAL INSTITUTION, at 2.—General Monthly Meeting.

ENTOMOLOGICAL SOCIETY, at 7.

MEDICAL SOCIETY, at 8.

LONDON INSTITUTION, at 4.

TUESDAY, FEBRUARY 8.

ROYAL INSTITUTION, at 3.—On the Architecture of the Human Body: Prof. Humphry.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY, at 8.30.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Discussion upon Mr. Harrison's Paper "On Railway Statistics and Expenditure."

PHOTOGRAPHICAL SOCIETY, at 8.—Anniversary Meeting.

ETHNOLOGICAL SOCIETY, at 8.—On the discovery of Flint Flakes under a Submerged Forest in West Somerset: W. Boyd Dawkins, F.R.S.—On Remains of Pre-historic man in the neighbourhood of the Crinan Canal, Argyleshire: Rev. R. J. Mapleton.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Anniversary Meeting.

ARCHÆOLOGICAL ASSOCIATION, at 8.

WEDNESDAY, FEBRUARY 9.

GEOLOGICAL SOCIETY, at 8.—The Fossil Corals of the South-Australian Tertiaries. Prof. P. Martin Duncan, F.R.S., Sec. G.S.—Note on a very large undescribed Wealden Vertebra: J. W. Hulke, F.R.S.—Additional Observations on the Neocomian Strata of Yorkshire and Lincolnshire, with Notes on their Relations to the Beds of the same Age throughout Northern Europe: J. W. Judd.

SOCIETY OF ARTS, at 8.—On Loss of Life at Sea: Mr. J. W. Wood.

THURSDAY, FEBRUARY 10.

MATHEMATICAL SOCIETY, at 8.—Quartic Surfaces: Prof. Cayley.

ZOOLOGICAL SOCIETY, at 8.30.—On a new Cervine Animal from the Yang-tze-Kiang: R. Swinhoe.—On the Size of the Red Corpuscles of the Blood of *Moschus, Tragulus, Orycteropus, Ailurus*, and some other mammalia, with historical notices: G. Gulliver.

THURSDAY, FEBRUARY 10, 1870

THE ROYAL COMMISSION ON SCIENCE

THE Council of the British Association for the Advancement of Science was received on Friday last by Earl de Grey, Lord President of the Council, as a deputation to urge on the Government the issuing of a Royal Commission to inquire into the state of Science in England.

That such a body, representing as it does, not only the science but the intellect of the nation, more fully than, perhaps, any other association in the kingdom, should take so decided a step is sufficient proof that in the judgment of those best qualified to guide public opinion on the subject, our scientific system needs reform.

The truth is that we have no scientific system, properly so called. Nothing can be more distinct than Prof. Stokes's statement to Earl de Grey as to the incompleteness of our arrangements. We have it on his authority that a certain class of Astronomical observations is carried on at the Royal Observatory and that natural objects are displayed at the British Museum; but that experimental research receives "little or no support" from the State. It is not easy to frame a plausible distinction between these branches of science, which shall justify support in one case and neglect in the other. The existing anomaly may be explained by the facts that astronomy and natural history have engaged the attention of man from the earliest ages and that they appeal palpably to his senses; whilst chemistry and physics are comparatively recent studies, whose aims and processes and even many of their results are understood and appreciated only by the few, though ministering to the welfare of all. Chemistry, in the modern sense of the word, is not a century old; electricity and electro-magnetism are younger still. Mainly by private means, these and cognate branches of science have been advanced in England to their present stage; "but," says Prof. Stokes, "it was perfectly obvious that there were many investigations which it was desirable to carry out and which would require the main part of a man's time; but which involved appliances on so large a scale as to be beyond the power and scope of a private establishment." The plain inference from this pregnant statement is that these desirable investigations cannot be carried on for want of means. It is notorious, indeed, that progress is stayed in many important directions for want of those "appliances and establishments" and that "time" which it is hopeless to expect from private sources.

Still, it may be urged that there is not so much need for these investigations as to demand that the State should undertake them; or, that the help of the State has something noxious about it which tends to paralyse the spirit of philosophical inquiry. Let us examine these two very different objections. The simple answer to the first is given by the very proposal of the deputation. They do not, on their sole representation, weighty though that must be admitted to be, demand that Government physical laboratories shall be established. They say, "We think such things are wanted; but do not take our word for it. Inquire; constitute a commission composed of persons of station, independence and statescraft, to receive our statements and to sift from them our interested enthusiasm, reducing what may be our too soaring aspirations to practical and business-like proportions. Inquire first and then act, if you see fit; but do not persist in neglecting, without inquiry, things that ought to be done."

With regard to the second objection, namely the paralysing effect of State aid, we can only treat it as a purely sentimental notion. Does Mr. Airy's salary paralyse astronomy? Does Sir Henry James's salary paralyse Geodesy? Does the money spent on art at South Kensington, on pictures for the National Gallery and on collections at the British Museum, paralyse those establishments? Is there something so peculiar in experimental labours as to place them in a category by themselves, subjecting them to malign influences from which the whole of the rest of the business of life is exempt? Are such labours so exceptional in their nature that whilst a public body like the Royal Institution shall purchase apparatus and pay salaries and thus stimulate the genius of Davy, Faraday and Tyndall, the same apparatus and stipends given to them by the State must have reduced these men to torpor?

But to return to practical matters. The main points for a Royal Commission to throw light upon are these. First, is it right that science should be aided at all by the State? Secondly, is the aid now given exactly what is needed—neither too much nor too little? Thirdly, the degree and direction in which science should become a State business having been settled, what will be the best organisation for the purpose? Not one of these points has ever yet been thoroughly considered in England. At present all is arbitrary, inconsistent and incomplete: or, to use Prof. Huxley's comprehensive word, "chaotic." The British Association wishes naturally to reduce chaos to order and they wisely begin—not by definite requisitions for things which few out of their charmed circle know the value of; but by a moderate demand for inquiry. This cannot possibly be refused to them. The nation is thoroughly awakened to a sense of its shortcomings as to education and it will be quite prepared to further those ends to which education is merely a means. The outlay which it will be called upon to provide need not be great; indeed, at first we shall have to deal more with the utilisation of what we already possess, than with the creation of new means. The great point is first to establish a sound principle of working and then to apply it by degrees, with caution and economy.

The word education reminds us of its occurrence in the course of the proceedings before Lord de Grey. Education and Science so naturally associate themselves in the mind that it is hardly possible to discuss the latter as independent of the former. Almost all the great continental scientific endowments include instruction in some form or other. And in this country the greater number of our most distinguished men of science are professors and teachers. The question of scientific instruction must, therefore, necessarily be considered by those who inquire into the question of scientific research. This will be by no means the easiest part of their labour. The complaint now is that men eminently qualified for research have too much of their time occupied in teaching. It will be difficult so to apportion the two functions that they shall reinforce and not obstruct each other. And again, there are some departments of science which experience has shown may be safely dissociated from instruction. Astronomy furnishes an example. Mr. Airy would probably not consider that the teaching of a class would aid him much in his peculiar duties.

We have said that this part of the inquiry will be difficult. The whole inquiry is indeed fraught with difficulty. It means nothing less than the constituting of a department of the State of which even the nucleus cannot be said, as yet, to exist. To do this liberally and efficiently and yet, with such regard to economy as shall make the result visibly beneficial to the community on whom the cost will fall, will be an achievement worthy of any statesman's ambition; but beyond no real statesman's reach.

We do not doubt that the Commission will be granted. Lord de Grey and Mr. Forster are too experienced to attach undue importance to the apparent want of harmony between some of the opinions expressed, or to suppose that all the grounds on which the Commission was asked for could be given in an hour's conversation. They will rather be swayed by the representative character of those who asked for it.

PETROLEUM AND ITS ALLIES

CONSIDERABLE anxiety has for some time past prevailed as to the existence of danger attending the use, storage and transport of the mineral oil now used for illuminating purposes and, as the questions involved are not only of great importance in many respects; but likely to be soon brought prominently before the public, some account of the sources of mineral oil and of its characteristics will probably be acceptable to our readers.

Thirty years ago, or less, the materials which form the subject of this article were almost unknown to either commerce or manufacturing industry. With some few exceptions, such as the use of the petroleum of Miano, in Italy, for lighting the streets of Parma and Genoa in 1800, natural mineral oil was only in scanty demand, under the name of Persian naphtha, for some few minor purposes and it was generally rare, even as a curiosity, in mineralogical collections. The analogous oils obtained artificially, by the distillation of coal and other bituminous materials, were even less familiar; for no material was then known that would yield them in sufficiently abundant proportion to admit of their being manufactured on a commercial scale. For this reason mainly, the various attempts to produce such oil were a succession of failures commercially and it was not until about the year 1840 that Mr. James Young, of Glasgow, had the good fortune to meet with a peculiar bituminous mineral—the precise character of which has been the occasion of much controversy—capable of yielding a very much larger proportion of oil by distillation than any other material of a similar kind. The discovery of this material and the recognition of its oil-yielding capability, were speedily turned to account by Mr. Young and his colleagues, forming the basis of a manufacture that has now assumed gigantic proportions and furnishing a commodity which is, for many thousands of people, a daily necessary.

But scarcely had this paraffin oil, now so well known, begun to come into general use as an illuminating material, than a formidable competitor appeared in the market in the shape of natural mineral oil, derived, at first and for a brief period, from Burmah and subsequently, in overwhelming abundance, from certain districts of North America, chiefly Pennsylvania and Canada. Since the first working of the petroleum deposits of America—about the year 1860, the exportation of this material, or of products manufactured from it, has increased rapidly and it now amounts to little less than one hundred million gallons a year.

The character of the refined petroleum imported from America has had much influence in extending its use; for, its pleasing appearance and comparative freedom from disagreeable smell, have gained for it a popular preference that so far is not unfounded.

American petroleum, however, contains a large proportion of a very volatile oil or spirit and, consequently, since the introduction of American refined petroleum into the market, the greater part of the oil derived from that source has been characterised by a greater degree of inflammability than the oil manufactured from Rangoon petroleum and from coal or shale; this difference being due to the fact that the volatile spirit, so abundant in American petroleum, is not completely separated in the process of refining. By leaving this spirit in the refined oil, a larger produce is obtained by the manufacturer and there is a further advantage gained in this way, owing to the fact that the volatile spirit, when separated, generally sells for only half the price of lamp oil.

The practical question in regard to the safety of mineral oil and its fitness for domestic use, is as to the extent to which the more volatile portions of the crude materials should be separated in the refining operation. Although in reference to this question, the possibility of careless and improper usage of the oil cannot reasonably be regarded as justifying any considerable restrictions in the application of a material so useful; still some allowance requires to be made even for that possibility, taking into account the conditions under which mineral oil is carried, stored and used in a general way. The point to be ascertained is not merely what oil may be used without necessary danger; but what description of oil will best answer the purposes for which it is intended, without requiring a greater degree of caution in its use than can fairly be expected, or any unreasonable restriction on the trade. Hence it would seem to be desirable for the convenience of those engaged in the mineral oil trade, as well as for ensuring public safety, that every branch of this trade should be subject to appropriate regulation: that the degree of inflammability of mineral oil should be limited; a definite standard established and, a mode of testing the oil adopted, which would not admit of discrepant results being obtained, either by accident or otherwise.

With this general object an Act of Parliament "for the Safe Keeping of Petroleum" was passed in 1862, prohibiting the storage of more than forty gallons of petroleum within fifty yards of a dwelling-house or building in which goods were stored, except in virtue of a license granted by local authorities who had the power to annex to their licenses any conditions thought necessary for diminishing risk of damage by fire or explosion. The application of the term "petroleum" in this Act was specially limited to crude petroleum, or any product of it giving off inflammable vapour at a temperature less than 100° Fahr. This Act may be said to have been entirely without effect on the refined petroleum sold for use in lamps and, another Act, passed in 1868 to amend it, has been but little more effective in this respect; so that the facts as to the storage and sale of mineral oil, of all degrees of inflammability, remain much the same as they were before.

The abortive character of this Act is probably to be ascribed, in great measure, to a conflict of interests, supposed to be opposite, when the bill was before Parliament and a further reason for its inoperative character, consists in the absence of any sufficient or fitting organisation for carrying out its provisions and regulating the trade in mineral oil. Strange to say, the licensing bodies have, generally speaking, no power under the Act to inspect and test mineral oil, except as a condition of licenses granted by them and the persons who are specially authorised by the Act to inspect and test, are not in most cases under the control of the licensing bodies. Of still greater influence in nullifying the provisions of the Petroleum Acts, is the want of any properly-constituted authority for instituting proceedings in cases where those provisions have been infringed. Any person may prosecute; but, as is generally the case with a duty so general, everyone leaves it for some one else to do so.

But perhaps one of the chief reasons why the Petroleum Act of 1868, has proved inoperative, is to be found in the unsatisfactory nature of the test by which the fitness of mineral oil for domestic use is directed to be ascertained and in the vague terms by which the operation of testing is described in the schedule appended to the Act. The point to be ascertained is the temperature at which mineral oil gives off inflammable vapour and, since any danger that may arise in this way, would exist chiefly in the ordinary use of the oil in lamps, it would seem to be an obvious necessity that the test, applied to ascertain that point, should be conducted under conditions as nearly resembling those obtaining in the actual use of the oil as could possibly be devised. The Act, however, prescribes a test under conditions which are the direct opposite of these. In using a mineral oil lamp, the oil is heated in a closed vessel partly filled with air; in testing the oil it is directed to be heated in an open vessel with the surface of the oil freely exposed to the atmosphere. In the test, any vapour that is given off from the oil is liable to be blown away by draughts and by diffusing into the surrounding air, to become so much diluted as to lose its inflammable character; while, in the lamp, any vapour given off is confined and forms an explosive mixture with the limited quantity of air contained in the oil reservoir. There is indeed, generally speaking, little real danger attending such a result as this, for the quantity of inflammable vapour produced in the reservoir of a lamp would rarely be sufficient to cause any dangerous explosion; but the flash resulting from the ignition of this vapour, would certainly be enough to startle almost any persons and cause them to drop the lamp. It is probably in this way that many of the accidents with mineral oil have taken place, since the lamps are very generally made of glass and since the oil readily takes fire when spilt upon linen, paper, or any such material.

Besides this cardinal defect in the prescribed test of mineral oil, the various directions given for conducting it are so vague and general, that they leave much to the fancy and option of the operator. Moreover, it is to be doubted whether inspectors of weights and measures, who are the persons authorised under the Act to test mineral oil, are generally competent to conduct these tests in a satisfactory manner.

Although the Act has been in operation only a few months, it has already given rise to much difficulty and inconvenience, without being productive of any benefit. Within the last few weeks, a series of trials of mineral oil, purchased indiscriminately at shops in various parts of the metropolis, has brought to light the fact that, out of 75 samples thus obtained, 39 of them were below the legal standard in regard to inflammability, when tested in strict accord with the directions of the Act.

These facts are sufficient to show that there is great need of further legislative action in this matter; this need has long been felt by those engaged in the mineral oil trade and there is every reason to believe that a well-digested enactment, providing for the safe transport, storage and use of mineral oil, would be of great benefit, not only to the public at large; but also to those engaged in all branches of the trade connected with this useful commodity.

HOSPITAL CONSTRUCTION

An Address on the General Principles which should be Observed in the Construction of Hospitals. Delivered to the British Medical Association at Leeds, by Douglas Galton, C.B., F.R.S. (London: Macmillan and Co., 1869.)

THIS able address with the discussion which followed it, brings fully before us the question of hospital construction. The Address itself is exclusively practical: it goes direct to its object and, by appealing to the results of every day's experience of the benefit of cleanliness, space and fresh air; it points out how these essential elements in the management of the sick, have been embodied in recent hospitals and it indicates by implication, what errors should be avoided.

After stating briefly the work done in this matter by different Sanitary commissions in this country, Mr. Galton gives the following enumeration of objects which must be attained in hospital buildings:—

"1. Pure air, that is to say, there should be no appreciable difference between the air inside the ward and that outside the building.

"2. The air supplied to the ward should be capable of being warmed to any required extent.

"3. Pure water, so supplied as to ensure the removal of all impurities to a distance from the hospital.

"4. The most perfect cleanliness within and around the building."

To realise these conditions the first step in hospital improvement is to select healthy sites, away from irremovable sources of air impurity and, having by this means obtained a pure moving atmosphere, the author proceeds to show how the site is to be used so that the pure atmosphere may not become a disease generator in the wards. The building must be so arranged as to interfere as little as possible with the free, natural movement of the outer air and this free outside movement should be kept up, as far as practicable, within the wards. "Stagnant air is foul air," especially in a hospital.

It has been experimentally shown that ward-air moves most readily when care is taken to combine as far as possible the following requirements:—1st, To let the prevailing outer air currents strike the *sides* of the wards; 2nd, To provide that the sun shall shine on the opposite sides of the wards every day he shines: 3rd, To have windows on opposite sides of the wards, with the beds arranged between them. A proper use of these opposite windows is the *sine qua non* of ward ventilation and of ward healthiness. But, in cold variable climates, provision has to be made for graduating the ventilation and for warming a portion of the air.

The subsidiary means which have been found to answer in practice are foul air shafts, fresh air inlets close to the ceiling, and warm air stoves—of a peculiar construction described in detail—so contrived that, while the ward is heated by radiant heat, the air warmed is not ward air but fresh air.

The cubic space per patient is determined primarily by the superficial area per bed, which, in its turn, is determined by the area required for efficient nursing. From 90 to 100 square feet per bed is sufficient, except in hospitals where there are medical schools. The cubic space per bed hence depends on the height of the ward.

There is but one test of ventilation and that is freshness of the ward air. No quantity test is of any avail, hence ventilation, that is, the proper use of the means of ventilation, is an essential part of ward administration. No man or woman who has not a sensitive nose and who has not also a perfect horror of bad smells or closeness, should ever take office in a hospital.

The central point in hospital construction is the ward itself and the following figure shows the usual arrangement of the ward and its offices, in the new class of hospitals.

FIG. 1.

On one side of the entrance is placed a nurses' room; on the other side of the entrance is placed a small scullery. In the ward itself the beds are arranged two and two along the wall spaces between the windows, with a bed at each corner. At the further end of the ward is a large end window. On one side of this window there is a building, thrown out from the corner, in which are placed the water-closets. The other building, at the opposite corner, contains the lavatory and bath-room.

The next figure shows the simplest arrangement of these ward units in a regimental hospital. Such a building can be constructed on one or two floors. The administrative portion, together with two or four small wards for special cases, occupies the centre of the block and the kitchen is detached. The larger wards project at either end. (A, fig. 2.)

A very important question, raised by Mr. Galton, is the manner in which hospital accommodation should be provided for recurring epidemics, fevers, cholera and the like. He shows that the cheapest and most effectual provision consists of temporary huts, a result which we commend to those who consider that large, costly, permanent fever hospitals are necessary for London.

With this general statement of the principles we must refer our readers to the address itself for the numerous points of detail which require to be attended to for securing due care and prompt attendance on the sick. They are all in strict accordance with scientific requirements and, if intelligently applied, will save many valuable lives.

We wish we could say as much of some portions of the discussion which followed the address. We allude to the obtrusion of the "germ" disease hypothesis into the hospital question. This theory, it is true, met with little countenance from the meeting; but there it was. In one sense its introduction was useful as showing what the final results of such a doctrine are. Of disease itself we know little scientifically as yet; nevertheless, it has become a fashion of late to supplement lack of knowledge by assuming that certain diseases are separate specific existences like animal or vegetable species, each springing from a "germ" or seed introduced from without; hence in the discussion it was averred that the supposed destructive influence of carbolic acid on these "germs" can be made to supply the place of fresh air in hospital wards, and, as a consequence, that the danger has to be encountered, not in foul air but in disease "germs."

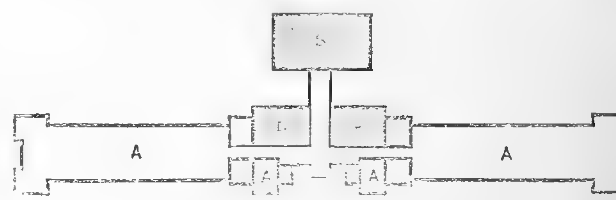

FIG. 2.

There may be disease "germs" for anything we know; but, until their existence is proved physically and until it is shown that there are germs with different distinctive specific characters, each of which germs can be shown to produce always the same group of symptoms in the human body, which symptoms can arise from no other cause; we can in no sense recognise the existence of disease germs. In scientific questions of this kind, "*de non apparentibus et de non existentibus eadem est ratio.*"

To neglect the ventilation and other sanitary arrangements of hospitals for a mere theory, would be to undo all that has been done in hospital improvements in Europe, with the inevitable result of destroying life.

Mr. Galton concludes his paper with some pertinent remarks on the cost of useless ornament in hospitals, which we commend to the consideration of hospital architects. Hospital resources are limited, patients are many—too many we should say.

Miss Nightingale begins her admirable "Notes on Hospitals"—a book which has done great good—with this startling passage:—"The very first requirement of a hospital is that it should do the sick no harm." Have hospitals, then, done harm to the sick? We are sorry to say that there are few of the older, badly constructed, ill-ventilated hospitals in any country which have not their calamitous records of immense death rates at all times and, especially, during epidemic seasons.

No one can read Mr. Galton's address without recognising that, from first to last, it is a protest against hospitals. Why are all these precautions and costly appliances necessary, unless it be to enable the sick poor to be grouped together in hospitals without destroying their lives?

Are not all these precautions a tacit admission that in breaking the family tie, in sickness, we are acting against Nature? She has bestowed the "family" with its common joys, sorrows and duties, on the human race. If, in order to aid the poor in sickness, it is necessary to break up the family tie and to expose the sufferers to risks in hospitals which they might escape at home, we would suggest whether there be not a prior question—namely, whether we cannot improve the dwellings of the people, make them better adapted for sickness as well as for health and thus look forward to the abolition of hospitals altogether.

We are, as yet, far from this consummation and, if we must have hospitals, we are bound to make them not only harmless, but useful. Mr. Galton has added a valuable contribution to the literature of hospitals in showing how this may be done.

ENTOMOLOGY IN AMERICA

A Guide to the Study of Insects and a Treatise on those Injurious and Beneficial to Crops: for the Use of Colleges, Farm-Schools and Agriculturists. By A. J. Packard, Jun., M.D. With upwards of 500 Engravings. Parts I.-VIII. (Salem: published by the Essex Institute, 1868-69. London: Trübner and Co.)

IT must be confessed that our American brethren are inclined in the present day to advance in the study of natural history, as in everything else. We can call to mind a dozen or more thriving institutions for the advancement of Science, especially natural history, in various towns in the United States, some of the names of which are hardly known to us, except by their scientific publications.

The Governments, both of the whole Confederation and of the different States, show a liberality in patronising scientific researches and in diffusing the results of those carried on under their auspices, which we should be glad to see imitated nearer home. A great number of American naturalists enter boldly upon investigations which but few of their distant relations on this side of the Atlantic, seem inclined to take up: their papers are generally of interest, and, not unfrequently, of great value.

In no department of zoology are the zeal and energy of the American naturalists more clearly shown than in the study of entomology. Doubtless, in the United States, as elsewhere, there are a great many amateurs, who rush into print with crude notions and write perhaps too hastily; but amongst the American entomologists there are several who are doing excellent work in the elucidation of this branch of the natural history of their country and even attacking groups, such as the *Ichneumonidæ*, in face of which German or Scandinavian pertinacity recoils baffled, or makes but little way.

Dr. Packard, the author of the "Guide to Entomology," of which eight parts (out of ten) are now before us, is well known as a writer on American insects, chiefly Hymenoptera and Lepidoptera,—he has also made some original investigations upon the anatomy and physiology of insects. The first portion of his book, occupying nearly two parts, is devoted to general entomology and furnishes an admirable, though necessarily brief, account of their organisation, of their reproduction and development in the egg and of their metamorphoses. The most recent memoirs connected with these subjects, have been made use of by the author and this part of his work is certainly the best manual of entomology which the English reader can at present obtain. The author concludes the general section of his work with directions for collecting and preserving insects, followed by a short bibliography and then proceeds to discuss the classification of insects.

In his classification, Dr. Packard departs somewhat from the generally received views, especially in regarding the class of insects as including, along with the true six-footed and generally winged forms, the Spiders and Myriapods, which have either eight or many feet. It is true that the Myriapods approach the true insects very closely; but the passage indicated by Dr. Packard from the Diptera to the Spiders appears to be founded solely on superficial resemblances and it by no means warrants the union of the *Arachnida* with the Insecta, although that of the *Myriapoda* may perhaps be accepted. Of course, as the boundaries of the class of insects are thus enlarged, the true insects of other authors have to occupy a lower rank in the system and Dr. Packard treats them as forming a single order of his class insects. He then adops the usual seven ordinal divisions as "sub-orders" and indicates their arrangement in two slightly divergent series as follows:—The Neuroptera, or lace-winged flies, form a common starting point, from which issue, on the one hand, the Orthoptera, Hemiptera and Coleoptera; on the other, the Diptera, Lepidoptera, and Hymenoptera, the latter series being the highest. The author does not state that he regards this as a genealogical tree, or as expressing the course of evolution of the groups; in any case the relationship of the Hemiptera to the Coleoptera does not seem very clear.

These slight objections to some of our author's theoretical views of classification do not, however, apply in the least to his exposition of the classification itself, which is admirably clear and complete. Under each order he gives a general account of the structure and habits of its members, followed and illustrated by a more detailed description of the characters and mode of life of particular species, arranged under their respective families. The examples selected by the author consist, for the most part, of the commonest species inhabiting the United States, a circumstance which will necessarily form a little drawback to its usefulness in this country; although, from the fact that great numbers of the North American insects have their allies, if not representatives, in Britain, the descriptions of habits, at any rate, will be generally applicable.

The study of economic entomology, especially with reference to insects injurious or beneficial to agriculture, has long been zealously followed in the United States, and the writings of Harris and Fitch are well known on this side the Atlantic.

OUR BOOK SHELF

The Sun. By Amédée Guillemin. Translated by T. L. Phipson, Ph. D. Pp. 296. 58 illustrations. (Bentley.)

MONSIEUR GUILLEMIN is favourably known among us by his beautiful book "The Heavens" and the present volume may be regarded as a considerable expansion of his chapters on the sun in that work, with additional matter, giving an account of the recent solar discoveries. The expansion has been very judiciously done; but the new matter introduced has been added, in too much haste and consequently the recent conquests of Science do not come out so satisfactorily as they might otherwise have done. In "The Heavens," M. Guillemin did what Frenchmen very rarely do—he took the trouble to inform himself on what was done in England, America and Germany. In the present instance he has taken his information from French sources exclusively and the result is poor.

Still, for those whose purpose it is to inform themselves on the sun generally, the book fills a gap and may be safely recommended. Mr. Phipson has done his part well—except where he has added notes and the book in its English dress is pleasant to the eye.

Handbook of Physical Geography. By Keith Johnston, Jun., F.R.G.S. Pp. 220. (W. and A. K. Johnston, Edinburgh and London. 1870.)

THIS is the text to accompany the altogether satisfactory half-a-crown atlas we noticed some time ago and in saying that the text is as good as the maps, we intend to convey high praise. Within the limits of somewhere about 200 pages, Mr. Johnston has contrived to give a very admirable account of the various natural phenomena with which physical geography has to deal; the facts are well and widely chosen. The style is clear and the arrangement a very model.

Of the four divisions of the book—Topography, Hydrography, Meteorology and Natural History, the two central ones possibly present evidences of the greatest care; for instance in Map 18 (the Mediterranean basin), the contour lines both of height and depth have been investigated by Mr. Johnston expressly for this work and in Map 13 (Physical Geography of Palestine) the isotherms have been worked out from observations at Alexandria, Cairo, Jerusalem, Beirut, Damascus, Aleppo and other places.

We heartily commend this book both to teachers and students.

The Advanced Atlas: consisting of Thirty-two Maps, containing all the Latest Discoveries and Changes in Boundaries; *The Progressive Atlas:* consisting of Thirty-two Maps—and *The Primary Atlas:* consisting of Sixteen Maps. All constructed and engraved by J. Bartholomew, F.R.G.S. (William Collins, Sons, & Co. Glasgow, Edinburgh and London.)

ALL these maps, even including the sixteen in the "Primary Atlas" which sells for sixpence, are printed in colours; their engraving is of a high order, the maps being rendered clear by a judicious omission of names. It would have been better for the young student if the boundaries between States, *e.g.*, Turkey and Greece, had been made more decided in the "Advanced Atlas." Great care has been taken in many cases, Africa for instance, to introduce the most recent discoveries.

Echoes in Plant and Flower Life. By Leo H. Grindon, Lecturer on Botany at the Royal School of Medicine, Manchester. (London: Pitman, 1869.)

WE opened this little book in the hope of finding some new light thrown on the fascinating subject of Mimetism. The writings of Mr. Darwin, Mr. Wallace, and Mr. Bates have made even the non-scientific reading public familiar with the existence of wonderful external resemblances between animals belonging often to widely different natural orders; resemblances which those writers have sought to explain on the theory of Natural Selection. Though the most remarkable instances of Mimetism to which attention has been drawn, are chiefly to be found in the tropics, scarcely less interesting examples are furnished by certain families of our own native Hymenoptera and Diptera: even in the vegetable kingdom we need not seek far for superficial resemblances which are not underlain by any corresponding similarity of organic structure. To trace these "echoes" in plant life (why "Plant *and* Flower Life" we do not know), is Mr. Grindon's hobby and to say that he rides his hobby too hard is only what might perhaps be expected. There is only a very limited number of ways in which anthers can open to discharge the pollen and to call the dehiscence by recurved valves of the bay tree, an "echo" of the same method in the barberry, seems to us an instance of decidedly hard riding. Nevertheless the writer has collected together a large number of very interesting facts which will be of service to anyone who hereafter attempts a scientific explanation of these phenomena. The writer does not; we hope some one else will and he will then find this little book of some value. The style in which it is written, is not such as to commend it to the man of science. In his preface the writer says, "to be a philosophical treatise, the treatment must be æsthetic." When we find the flowers of plants described as "those sweet harp-strings which, vibrating for ever, preserve to us the melodies of ancient Eden and by which they will be floated down the ages yet to come," the treatment of the subject may be æsthetic; we can hardly admit it to be philosophical. Would Prof. Huxley or Dr. Hooker recognise the following description? "Every true naturalist enjoys a renewed puberty of the soul. While other people are young but once, he, like the cicada, in age recovers his spring-time. In this respect he is abreast of the man of genius, whose privilege, like that of the sunshine, is to weave as lovely a sky for the evening as for the morning."

A. W. B.

British Lichens—Lichenes Britannici; scripsit Rev. Jacobus M. Crombie, M.A. (London: L. Reeve and Co 1870.)

MR. CROMBIE is well-known as an indefatigable hunter after lichens and one who has added a considerable number of new species to the British flora. This little book contains a record of the habitat and distribution of the 658 species of lichens at present known as inhabitants of Great Britain and Ireland, together with references to the authorities where descriptions are to be found and the synonymy. The classification followed is that of the veteran lichenologist Nylander, to whom the work is dedicated and the whole is written in Latin. It ought to be in the hands of everyone interested in this branch of our cryptogamic flora. A. W. B.

Chimie Organique en 1868.—*Rapport méthodique sur les progrès de la Chimie organique pure en* 1868. Par L. Micé. Large 8vo. pp. 446. (Paris: Baillière. 1869.)

WHEN we opened this work and found that the author had attempted, for the first time, what he truly designates as "neither an easy nor a glorious task" and that he intends his book to be a sufficiently concise and yet detailed annual report, a suitable "vade-mecum for a professor of high-class instruction," we formed expectations which were not quite realised on further perusal. M. Micé wrote this report at the request of the *Société des Sciences Physiques et Naturelles*, who purpose publishing similar reports annually. The title, it will be perceived, is perfectly general and it might have attracted any student of organic chemistry. But the author informs us (p. 1) that his book "can only be useful on condition of being methodical and *containing no more than a Faculty professor can deliver, from memory, in his lectures*." We should strongly recommend M. Micé, especially as he proposes to extend this plan to the entire domain of chemistry, to alter his title-page before again proceeding to publication. "Lecture Notes for Professors of Chemistry" would be a much more appropriate designation; less pretentious, certainly, but having the great advantage of accuracy. Undoubtedly, the author has succeeded in producing a *rapport méthodique*; but it is decidedly not a *rapport sur les progrès de la Chimie organique pure*, nor has it that nice adjustment between details and conciseness which is the essential requirement of such a treatise. The only work which fulfils and ably fulfils these conditions, is the German "Jahresbericht der Chemie," a model of patient and deliberate composition. M. Micé will find prefixed to it a list of some sixty or seventy periodicals, containing the various original papers to which it refers. We may fairly ask him whether many French professors (*du haut enseignement*) will be satisfied with the basis he has selected, viz., five French journals and the 3rd edition of MM. Pelouze and Frémy's "Traité de Chimie." Considering that the author has had recourse to such a method of shortening his labours, it is not surprising that the performance should exhibit a generally hasty character. At p. 117, for example, we find the following passage:—"Théine gives up a quarter of its nitrogen, creatine a third, the other natural and artificial alkaloids one-half." It so happens that the experiments in this particular case, instead of being carried out with *all* nitrogenous organic bodies, were pardonably limited to nineteen instances. We regret we cannot commend this work, as fulfilling either the promise held out on its title-page, or the more limited intention expressed in its opening paragraphs.

History of Creation.—*La Création d'après la Géologie et la Philosophie Naturelle.* Par J. B. Rames. (Paris: Hachette.)

THIS is an odd book. Even in these days of sensational works on science we are not sure that, in his own style, M. Rames has been surpassed. His purpose is to describe in a kind of prose epic, the history of our planet and its inhabitants, from the nebulous condition of the solar system down to the present day. Apostrophising sun, moon and stars by turns, he tells them how they have been fashioned and of what uses they are. Tyrants and philosophers come in for appropriate addresses and then the writer plunges into the depths of the primeval ocean in which the Laurentian rocks were formed. He finds its waters hot, charged with silica and in the act of depositing crystalline rocks in the form of gneiss and schist. One day—whether in the depths of the thermal ocean, or in the lakes that dotted the lonely islets, he cannot tell—"Life, one of the special forms of solar heat pervading the universe like all the other natural forces, finds, for the first time upon our globe in little aggregations of inert matter, the conditions which allow of its manifestation, and thus rises dimly the dawn of an organic kingdom." The subsequent development of these primal germs into the complex genera and species of the animal and vegetable world, through its succeeding geological formations, forms the subject of the remaining portions of the book, of which, however, only the first part, reaching into the Permian period, is published. M. Rames seeks no adventitious aid from sensational pictures: not a single illustration occurs in his book. He trusts wholly to the powers of his pen and has certainly produced a lively, if not very trustworthy, narrative.—A.G.

THE WORK OF THE SEA

THE work done by the Sea is infinitely various, immeasurable in quantity and of inexpressible value to the inhabitants of the earth. It is the one ceaseless worker, never resting and ever accomplishing the tasks it has to perform. The land and the sea may appear to some to be for ever fixed and unalterable, and the map of the world represents to them the geography of the globe of 6,000, or 60,000 years ago, the geography of to-day, and the geography of 60,000 years hence. Still not only does Geology show by the testimony of the far-distant past the impossibility of this being so; but it has been given to man to see and record the constant rising and falling of the land, within the periods of history and even to measure the movement with sufficient accuracy and such certainty as to enable him to venture predicting, to some extent, on the probable geography of the future.

The Earth is born of the Ocean. Continents and islands rise out of the sea, new, luxuriant and vigorous; and like ourselves they grow, mature and do their appointed work; then wane and seem to die, though they do *not* die. They sink beneath the waves, apparently for ever; but only to be regenerated, renewed, quickened into life and born again remodelled. And the sea—the invigorating and ever-toiling Mother—works this wonder.

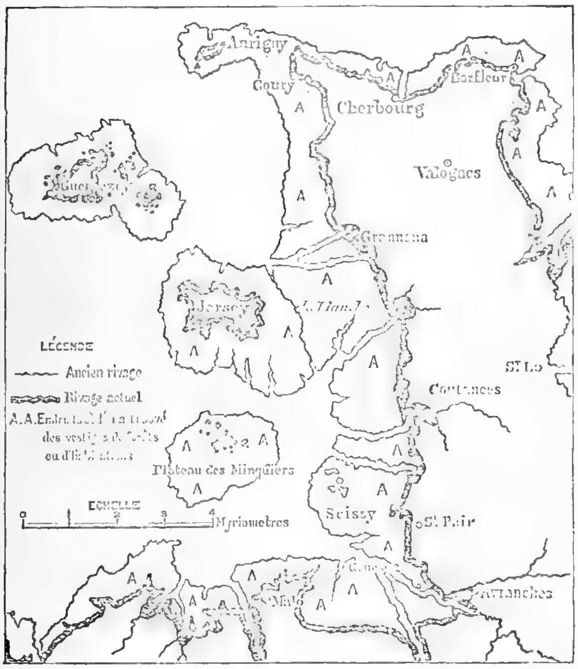
Mons. Quenault, Sous-Préfet de Coutances, in a little book called "Les Mouvements de la Mer," has lately given us some exceedingly interesting facts, which he has gathered from old records, as well as from his own observation and other sources, respecting the sinking of the land and the encroachments of the sea on the coasts of Brittany, Normandy and other places on the western borders of France. Thus, in the Gulf of Cordouan at the mouth of the Gironde, the sea has advanced 730 metres, within twenty-eight years; the buildings on the Pointe de Grave have often been destroyed and rebuilt and the lighthouse is now removed, for the third time, more inland. The sea flows more than ten metres deep over what a short time since was a sandy beach. Twenty-five more years and the Atlantic will flow over the marshes of Soulac and Verdun; the Gironde will enter the sea by a second embouchure and the Isle of Cordouan, detached from the continent, will gradually become a mere rock.

The legends which are recounted among the population of Brittany lead one to think that many places in the neighbourhood of the coast—to-day immersed—were formerly above the level of the sea. In their native poetry and with their passion for the marvellous, the country people refer these facts to supernatural agency, where the Devil plays a prominent part. The bay of Douarnenez, where at high water the depth is considerable, is the site of a once flourishing city, the town of Ys, the capital of Cornouaille. At the south side, when the tide is low, are distinguished clearly, five or six metres under water, Druidical remains, altars, portions of walls and ruins of various monuments. Again, on the opposite side, near Cape Chèvre, they are to be found, though not so easily seen and not so numerous; but that they can be seen under favourable circumstances there is no doubt whatever. The fishermen there believe all the reefs and rocks in the bay to be portions of the ruins. In the 16th century, when the water in the bay was not so deep as now, the Canon Moreau was able then to follow the lines of a vast enclosure (enceinte) of masonry, and above the sand, in the shallower places, he discovered funeral urns, stone sarcophagi, &c. The traveller Comby also adds, that after a storm which excavated and scooped out portions of the sands, one could perceive traces of elm trees, disposed with a regularity which shows that a plantation existed at this spot.

Submerged forests have been found on the coasts of Brittany and particularly in Finisterre, in the neighbourhood of Morlaix. There are historical documents to prove that at the bay of Mont Saint-Michel the coast has been submerged within a period subsequent to the Roman domination. Rouault, Curé de Saint-Pair, says:—"About the year 400 there was in the Basse Normandie towards the west a large forest named Sciey, extending from the rocks of Chausey to the Mont de Tomba"—now Mont Saint-Michel. In the twelfth century the troubadour Guillaume de Saint-Pari referred to this submerged forest in a quaint bit of old French, which may be freely translated thus:—

"Not far from Avranches, on Brittany's shore,
Quokelonde forest spread out of yore;
But that famous stretch of fertile land
Is hidden now by the sea and the sand,
No more will its venison grace the dish—
The ancient forest yields nought but fish."

This forest of Sciey, or Scissiacum, was said to have been full of wild beasts—"præbens altissima latibula ferarum"—and peopled by half-savage natives, to whom succeeded, in Christian times, a number of Anchorites who sought retirement there, far from the tumult of the



world. The parishes of St. Louis, Mauny and La Feuillette have disappeared beneath the waves since the 13th century. A story is told of a priest of the diocese of Dol, that, having in 1685, learned by tradition that there was formerly, in the place then (and now) occupied by the sea, a parish named St. Louis, informed the Court of Rome that this living was vacant "*per obitum.*" Upon this they consulted the registers and found actually that there had been presentations to this living by former Popes. A priest of Basse-Bretagne was therefore appointed and he departed at once to take possession. But on arriving in sight of Mont Saint-Michel, what was his surprise when he was shown on the sands and in the sea, the place where was formerly situated his pretended parish.

There is every reason to believe that the whole of the Channel Islands were, at one time, part of the mainland of France and there is positive proof of the island of Jersey having been so. There are certain existing manuscripts belonging to the monastery of Mont Saint-Michel, which tell us that, in the sixth century, the district of Jersey was separated from the mainland of Coutances by only a narrow rivulet, bridged by a single plank which the inhabitants were bound to keep in repair for the Archdeacon of the mother church to pass over on his periodical visitations. In the register of the taxes of the island, there is an entry referring to rents received from various persons for the privilege of allowing pigs to feed on the acorns in the forest of St. Ouen—now the bay of that name—but, M. Quenault's informant adds rather unnecessarily, "elles ne sont plus payées aujourd'hui!" There are also many other manuscripts quoted and instances given of the great alteration that has taken place in the outline of the Channel Islands and the coasts of France, of which there is given an exceedingly interesting map by M. Deschamps-Vadeville—a *fac-simile* of a chart copied in the year 1406 from one of a much older date. This map, which we reproduce in miniature, shows the coast line from Cape Finisterre down to St. Malo to have been, at that time, from six to twelve miles farther west than at present. The island of Jersey is part of a peninsula, ten or twelve miles wide, stretching out from the French coast to a point some three or four miles west of that island as it at present exists. Guernsey also is shown to have then been considerably larger than the Isle of Man now is. Throughout the whole area of this departed coast, are depicted the positions of some score of places where evidences of the existence of submerged forests have been discovered.

The sinking of the land which has taken place within the periods of history, has occurred only between the parallels of 10° S. and 55° N. lat. North of this, it is gradually becoming more and more elevated. Of this phenomenon M. Quenault gives an equally interesting and detailed account, with numerous facts and voluminous evidence which cannot be recounted within the limits of the present article. M. Quenault concludes—with regard to the depression of the land—"One gathers from all these evidences, that the movement, since the eighth century, has been about two metres a century. If it continues at the same rate for ten centuries more, the peninsula of Cotentin will be an island and all the ports of La Manche will be destroyed. Some centuries later and Paris will be a seaport, waiting only to be submerged in a score of centuries. Thus in a period, less than half as long as that during which the pyramids of Egypt have braved the ravages of time, Paris itself—if it is not burned down during one of the revolutions of its inhabitants, as amiable and *spirituel* as they are inconsistent—Paris will probably be engulphed in the Atlantic, a master before whom the intractable Parisian must haul down his flag. Let him take warning!"

CHARLES W. WHITAKER

MICROSCOPICAL INVESTIGATION OF METEORITES

A PAPER on the above subject, forming part of an investigation commenced two-and-a-half years ago by its author, Prof. Maskelyne, of the British Museum, was read at a recent meeting of the Royal Society. We are indebted to the author for enabling us to lay before our readers the following full abstract of the paper:—

With a view to obtain some more satisfactory means of dealing with the aggregates of mixed and minute minerals, which constitute meteoric rock, the author sought the aid of the microscope, having in the first place sections of small fragments cut from the meteorites so as to be transparent. By studying and comparing such sections, one learns that a meteorite has passed through changes and that it has had a history of which some of the facts are written in legible characters on the meteorite itself and, one finds, that it is not difficult roughly to classify meteorites according to the varieties of their structure. One also recognises constantly recurring minerals; but the method affords no means of determining what these are. Even the employment of polarised light, so invaluable where a crystal of which the crystallographic orientation is at all known, is examined by it, fails, except in rare cases, to be a certain guide to even the system to which such minute crystals belong. It was found that the only satisfactory way of dealing with the problem, was by employing the microscope chiefly as a means of selecting and assorting out of the bruised débris of a part of the meteorite, the various minerals that compose it and then investigating each separately by means of the goniometer and by analysis—finally recurring to the microscopic sections to identify and recognise the minerals so investigated. The present memoir is concerned with the former part of this inquiry. Obviously the amount of each mineral that can be so obtained is necessarily small, as only very small amounts of a meteorite can be spared for the purpose. On this account one has to operate with the greatest caution in performing the analysis of such minerals and the desirableness of determining the silica with more precision than usually is the case in operations on such minute quantities of a silicate, suggested the process which, after several experiments in perfecting it, assumed the following form. After the separation, by alternate treatment with hydrogen chloride and potash, of all silicate that gelatinises with acid, the pounded and weighed mineral was placed in a small retort of platinum with a little ball of the same metal and digested with an excess of pure hydrogen fluoride, containing some 32 per cent. of absolute acid, for two hours, at 100° C. By little platinum delivery tubes with which the retort was provided, a current of hydrogen was allowed to traverse the apparatus and afterwards to bubble through some concentrated aqueous solution of ammonia. After the lapse of the two hours the retort was placed in a bath of paraffin and its temperatuie slowly raised till 132° C. was reached, at which point the silicium difluoride is evolved and is carried by the current of gas into the ammonia. In a few minutes the operation is complete and it must be repeated with fresh charges of acid and ammonia, till all silicium has been driven into the receiver. This done, a little hydrogen sulphate is introduced into the retort and the retort once again heated in paraffin. If 0·2 gramme of silicate be taken, twice charging of the retort with hydrogen fluoride will suffice; if half a gramme, the process may have to be repeated three or four times. The greater portion of silicium is removed by the first operation and the ammonia becomes semi-solid with deposited gelatinous silica. This is slowly evaporated together with the later ammoniacal charges and the washings of delivery tube and receiver in a platinum dish, and, as the excess of ammonia passes off, a point is reached where the last flock of suspended silica is taken up by the hot solution; the dish is now removed from the water-bath and to its contents, when cold, are added a slight excess of potassium chloride and the requisite volume of absolute alcohol. After 24 hours have elapsed, the precipitated potassium hydro-fluosilicate is filtered off and weighed in the usual manner. The metallic oxides present in the mineral, remain in the retort as sulphates.

The Busti Meteorite.—This meteorite fell on the 2nd of December, 1852, about six miles south of Busti, a station half-way between Goruckpoor and Fyzabad, in India. The fall was attended by an explosion louder than a thunder-clap and lasting from three to five minutes. The explosion that shattered the meteorite, must have occurred soon after its passing the longitude of Goruckpoor. There was no cloud in the sky at the time. The stone, which weighed about 3lb., was presented to the collection at the British Museum by the Secretary of State for India. The Busti aërolite bears a great resemblance to the stone that fell on the 25th of March, 1843, at Bishopsville, South Carolina, U.S.

The meteorite consists for the most part of the mineral enstatite; at one end, however, were embedded a number of small chesnut-brown spherules, in which again one detected minute octahedral crystals, having the lustre and colour of gold. These two minerals seem scarcely to have been affected by the heat that fused the silicates which surround and encrust them. The brown spherules are sulphide of calcium (named by the author Oldhamite) and they also occur sparsely in the Bishopsville aërolite. This mineral forms small, nearly round spherules, whose outer surface is generally coated with calcium sulphate. It cleaves with equal facility in three directions, which give normal angles averaging 89° 57′ and are no doubt really 90°. Its system, therefore, is cubic; indeed, in polarised light it is seen to be devoid of double refraction. Its specific gravity is 2·58 and its hardness 3·5 to 4. With boiling water it yields calcium polysulphides and in acids it easily dissolves with evolution of hydrogen sulphide. Chemical analysis indicated the following as the composition of the spherules:—

		I.	II.
Oldhamite	Calcium monosulphide	89·369	90·244
	Magnesium monosulphide	3·246	3·264
Gypsum		3·951	4·189
Calcium carbonate		3·434	——
Troilite		——	2·303
		100·000	100 000

The presence of such a sulphide in a meteorite, shows that the conditions under which the ingredients of the rock took their present form, aie unlike those met with in our globe. Water and oxygen must have alike been absent. The existence of iron in a state of minute division, as often found in meteorites, leads to a similar conclusion. But, if we bear in mind the conditions necessary for the formation of pure calcium sulphide, the evidence imported into this inquiry by the Busti aërolite seems further to point to the presence of a reducing agent during the formation of its constituent minerals; whilst the crystalline structure of the Oldhamite and of the Osbornite next described must certainly have been the result of fusion at an enormous temperature. The detection of hydrogen in meteoric iron by Professor Graham tends to confirm the probability of the presence of such a reducing agent. Osbornite is the name given by the author to the golden-yellow microscopic octahedra imbedded in the Oldhamite, in honour of Mr. Osborne and in commemoration of the important service that gentleman rendered to science in preserving and transmitting to London, in its entirety, the stone which his zeal saved at the time of its fall. These minute octahedra gave the angles of the regular octahedron; but the amount, about 0·002 gramme, was too small for anything but qualitative experiments. These showed the little metallic-looking crystals to contain calcium, sulphur and a metal which gives the reactions of titanium in some singularly stable state of combination. The next mineral described was an augite, of which the measurements and analyses were given in detail. Its formula was ($\frac{2}{3}$ Mg, $\frac{1}{3}$ Ca) Si O_3. The greater part of the meteorite, however, consisted of enstatite, which presents itself in three apparently different characters: in each, however, the mineral is nearly pure magnesium monosilicate. Of this mineral, the measurements and analyses were recorded. The iron contained in small amount in this remarkable meteorite, gave as the result of its analysis 79·069 per cent. iron, 3·205 nickel, and 1·00 per cent. schreibersite.

The Manegaum Meteorite of 1843 was next described and was shown to consist almost entirely of an enstatite, with the formula ($\frac{2}{3}$ Mg, $\frac{1}{3}$ Fe) Si O_3, associated with small quantities of Chromite and of meteoric iron. In publishing the results obtained in the attempt, so far as this memoir goes, to treat exhaustively of the mineralogy of two important meteorites, the author wished to record his obligations to Dr. Flight, assistant in his department at the British Museum, for his valuable aid in the chemical portion of the inquiry.

In March, last year, Prof. Maskelyne recorded in a preliminary note, read before the Society, his discovery in the Meteorite of Breitenbach, of silica in *the rhombic system* with the specific gravity of *fused* quartz. It was associated with enstatite with the formula ($\frac{4}{5}$ Mg, $\frac{1}{5}$ Fe) Si O_3. It is singular that the measurements of the crystals of this enstatite, made at the British Museum and published by Prof. Viktor von Lang (Sitzungsb. Akad. Wien, vol. lix., 1869, p. 848), accord closely with those recently published by Von Rath as the crystallographic constants of a kind of enstatite to which he has given the name Amblystegite.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Japanese Sea Shells

SINCE writing the notice of Dr. Lischke's work which appeared in No. 13 of NATURE, I have received from Dr. Lea of Philadelphia a typical specimen of his genus *Hippagus* and the volume of his "Contributions to Geology." For such a valuable communication I would publicly acknowledge my obligation to that veteran conchologist. I was misled by Philippi and Searles Wood, in considering *Hippagus* and *Verticordia* the same genus. *Hippagus* is closely allied to *Crenella*, as the latter is represented by *C. glandula* of Totten and, indeed, I cannot detect any character to distinguish them generically. These agree in shape, sculpture, hinge, muscular impressions and inflexion of the beaks. The genus *Verticordia* of S. Wood is very different and belongs to another family, viz. that of *Lyonsia*.

Mr. Arthur Adams informs me that he has several Japanese species, which he believes are also found in the Mediterranean, and I have identified many British species with those of North Japan. J. GWYN JEFFREYS

An Oversight by Faraday

IT is not often that Faraday committed an oversight; but such I think he must have done in his well-known paper concerning the existence of a limit to vaporisation. ("Experimental Researches in Chemistry and Physics," p. 119.*) Faraday showed experimentally, that mercury emitted no appreciable vapour below 20° F. and accounted for this on the ground that "the elastic force of any vapour which the mercury could have produced at that temperature, was less than the force of gravity upon it and that, consequently, the mercury was then perfectly fixed." He adds, "I think we can hardly doubt that such is the case, at common temperatures, with respect to silver and with all bodies which bear a high temperature without appreciable loss by volatilisation, as platina, gold, iron, nickel, silica, alumina, charcoal, &c., and that, consequently, at common temperatures, no portion of vapour rises from these bodies or surrounds them."

Has not Faraday overlooked the fact that though gravity might prevent the *rise* of vapour, it would assist the *fall* of vapour from the sides or under surface of a body suspended *in vacuo?* If Faraday's theory had any grounds in truth, it would be possible to distil a substance from above downwards by the sole force of gravity, but I know of no experiment to support the idea. Were all the other forces which could act upon the molecules, exactly balanced in unstable equilibrium, the force of gravity might undoubtedly upset this equilibrium, so that vapour would be produced from the under surface of a suspended solid when it could not be produced from the upper surface. But a very slight estimation of the forces which may enter into such a problem, shows how unlikely it is that the case could ever happen.

I do not mean to say that the force of tenacity of solid substance, is identical with that which is opposed to volatilisation; but it is possibly comparable with it in amount. Now a copper wire, having a section of one square millimetre, will bear a weight of 90 lbs. and this force of tenacity only acts between portions of metal in absolute contact and continuity. Compare now the weight of a film of copper, say $\frac{1}{100}$ part of a millimetre thick, with the force by which it adheres to the remainder of the mass of copper with which it is continuous. Taking the specific gravity at 8·9, the weight will be, per square millimetre, 0·000089 gramme; the force which would be required to tear it from the remainder of the mass would be, for the same surface, 40819· grammes. The force of tenacity, therefore, exceeds the weight rather more than 450,000,000 (450 million) times. This seems to show that the molecular forces which tend to maintain the integrity of a solid metal, are almost infinitely greater than the gravitation of the same molecules towards the earth. To cause these molecules to fly off in free vapours, we must call in the aid of forces of heat, electricity, or chemical affinity which can cope with the prodigious force of solid cohesion. It is practically impossible that we should ever meet with a case, where these forces were so exactly balanced that the exterior force of gravity, many million times less in amount, should produce a perceptible disturbance.

These considerations do not, however, appear to affect the validity of Wollaston's speculations concerning a definite limit to the earth's atmosphere as caused by the gravity of the aërial particles. J.

* Phil. Trans. 1826, p. 484.

Where are the Nebulæ?

I AM unaffectedly glad to find that one whose opinion has such weight as Mr. Spencer's must have, should have anticipated me in the matters to which he directs your attention in his interesting letter. There can be no question as to his priority; since in 1863 I had not only formed no views respecting the nebulæ; but had no further knowledge of astronomy than I derived from a very faint recollection of what I had learned in a hasty two hours' perusal of Goodwin's Astronomy (Course of Mathematics) the night before our examination on the subject in the "Three days" at Cambridge.

In considering the subject of the nebulæ recently, however, the points touched on by Mr. Spencer had not escaped me. In five papers in the *Intellectual Observer and Student* called "Notes on Nebulæ," "Notes on Star-streams," and "A New Theory of the Universe" (three parts), I touched on these and many other proofs that the nebulæ are not external galaxies; but part and parcel of the sidereal system.

I have since found that Dr. Whewell, in his "Plurality of Worlds," had adopted the same view. But as a matter of fact, we owe the enunciation of clearly convincing evidence respecting the true nature of the nebulæ to Sir John Herschel; while Sir W. Herschel, when as yet the available evidence was incomplete, indicated his belief that the Orion nebula (amongst others) is within the sidereal system.

Strangely enough, the point first dwelt on by Mr. Spencer was boldly quoted by the Rev. C. Pritchard (V.P.R.A.S.) as a proof that the nebulæ are external galaxies, immediately after I had read my communication on the distribution of the nebulæ to the Astronomical Society. I asked at once if we were to regard those vacant spaces as the spy-holes, so to speak, of the sidereal system, through which alone the nebulæ could be hopefully looked for and Mr. Pritchard said "*Yes.*" Mr. Stone, also, pointed out subsequently, that the glare from the stars might elsewhere obliterate the nebulæ (at least the fainter ones) from view. This would be a point to be attentively considered were it not that in the Nubeculæ we have evidence that the glare from many stars does not obliterate faint nebulæ.

The second point dwelt on by Mr. Spencer affords a remarkable instance of the way in which considerations that should be perfectly obvious, escape even practised astronomers. Strangely enough, I dwelt on this point, only three days ago, in a letter I addressed (not for publication) to the editor of the *Spectator*. It is commonly understood and stated that telescopes which are only just able to show stars of the tenth, twelfth, or fourteenth magnitude as the case may be, are able to exhibit the component stars of certain external galaxies, which must (according to the theory) be thousands of times farther from us than the fourteenth magnitude stars. Not a thought has been given to the obvious conclusion that these component stars, to be thus visible, must be millions of times larger than the members of our galaxy.

In a letter addressed last August to Sir John Herschel (a portion of the answer to which was quoted in my article in NATURE for January 27), I pointed out half-a-century of reasons for believing that the sidereal system is differently constituted than has been supposed and that the nebulæ are not external to it. (This would have involved an egregiously long letter had I been writing to an ordinary correspondent, but in the actual case a few words served sufficiently to indicate each reason.) These reasons were not interdependent—each afforded good and most afforded perfectly sufficient ground for rejecting the accepted theory. In his reply, Sir John (always kind, courteous and encouraging) was good enough to speak of the "number and variety of the striking facts brought together and the evident bearing of a large proportion of them on the great problem offered by the sidereal system to man's contemplation." Amongst the facts which afford the strongest evidence of all, are two I left unnoticed in my late paper, viz., (1) the relatively large proper motion of the fainter stars and (2) the drift of whole groups of stars in a definite direction. These facts apply to the structure of the sidereal system, rather than to the position of the nebulæ; but, as a matter of fact, the two matters are so closely related, that evidence bearing on one carries with it conclusions affecting the other also. RICHD. A. PROCTOR

February 4

Analogy of Colour and Music

I FIND in your number of January 13 an interesting paper by Mr. Barrett on the Correlation of Colour and Sound. It seems to me that Mr. Barrett depreciates the phenomenon of Newton's rings by saying that the "connection between the relative spaces occupied by each colour and the relative vibrations of the notes of the scale" .... "cannot be more than a coincidence." The diameters of the rings are functions of the wave-lengths and, therefore, expressions of a physical condition. Mr. Barrett's own process is, to say the least, very rough and, after taking "the mean of two limits," rather wide apart for the length of the waves of each colour, he obtains a series of numbers which differ not inconsiderably from those which belong to the musical scale and he is obliged, after all, to place blue and indigo together, taking their "mean rates" as corresponding with G. I do not know how far Newton's measurements are correct; but I find that Professor Zannotti, of Naples, gives for the diameters of the rings from red to red the cube-roots of the numbers 1, $\frac{8}{9}$, $\frac{5}{6}$, $\frac{3}{4}$, $\frac{2}{3}$, $\frac{3}{5}$, $\frac{9}{16}$, $\frac{1}{2}$. The intervals between these, taken successively, are $\frac{9}{8}$, $\frac{16}{15}$, $\frac{10}{9}$, $\frac{9}{8}$, $\frac{10}{9}$, $\frac{16}{15}$, $\frac{9}{8}$; that is—major-tone, semi-tone, minor-tone, major-tone, minor-tone, $\frac{1}{2}$-tone, major-tone. Calling the major-tone *M*, the minor tone *m*, and the semi-tone ×, for the sake of brevity. I will give the five different forms of which the musical scale is capable—expressed by the succession of intervals—and show that the above series of intervals is one of them:—

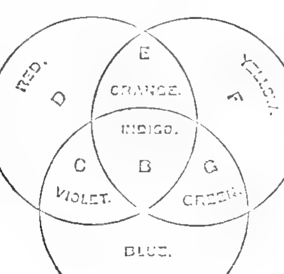
	D,		E,		F,		G,		A,		B,		C,		D	
(1)		m		×		M		m		M		×		M,		or Sintono.
(2)		M		×		m		M		m		×		M,		or Newton's scale of colours.
(3)		M		×		M		m		M		×		m		
(4)		m		×		M		M		m		×		M		
(5)		M		×		m		M		M		×		m		

Varieties depending upon the permutation of the quantities M, m, and ×. The 1st contains the imperfect fifth, DA; the 2nd two such fifths, EB and FC; the 3rd GD; the 4th A_2E_2; and the 5th the imperfect fifth, C_2G,—all of course with their corresponding augmented fourths.

Thus, Newton's scale of colour is one of a series of five scales of sound, all requiring modification by a *comma* of one, or at the most two-fifths; but all are found of perfect major and minor tones and major semitones. If the correlation between colour and sound exists, I think it will be found here. If this be admitted, the colours and notes corresponding are as follows:—

D, E, F, G, A, B, C, D

Red, Orange, Yellow, Green, Blue, Indigo, Violet, Red; or better according to the figure—



Thus the series of colours corresponds with the Gregorian Scale of the *first mode* and not with the modern scale of C. I may remark, by the way, that the ancient Greek *plain chant* is said sometimes to have a notation in which the notes are distinguished by different colours. It would be interesting to know whether such a notation has any scientific foundation.

In conclusion, I would say, that Newton's rings give a far more clear division of the colours that we get in the spectrum and the distinction between blue and indigo is too well defined to warrant them to be treated as Mr. Barrett has done. No doubt the neighbourhood of indigo is a difficult one and to make the correlation with sound complete, this colour itself ought to be divided into two; indigo-blue and indigo-violet corresponding to the notes B♭ and B♮, both of which are required to obtain the fourths and fifths all perfect. Allow me to inquire if there be any marked line in the red, dividing it into two reds separated by the interval $\frac{81}{80}$? I ask this question because the Sintono Scale (1) requires two D's differing by this interval, to complete its intervals of fourths and fifths. Also, would the correction of the fifths, &c., in the other four scales given above, by the introduction of one or two new notes, be such that these notes can be made to correspond to marked divisions in the spectrum or to like divisions in the series of colours determined by Newton's method?

W. S. OKELY

THE supposed analogy between the spectrum and the musical scale is not strictly accurate, because in the former the colours blend into one another imperceptibly, while the notes of the latter are separated by distinct intervals.

Yet it is precisely on this blending of the colours that the pleasing effect of the spectrum depends. If we place red, orange, yellow, &c., in their order, in immediate juxtaposition, as distinctly defined bands, we obtain precisely that arrangement which is admittedly distasteful.

The chromatic scale, as its name implies, approaches more nearly to the spectrum than does the diatonic; but the spectrum would be still better represented by the sliding tones produced by running the finger up the sounding string of a violin.

But leaving this objection, which may be thought too critical, I would remark, that the analogy which Mr. Barrett points to is rather one of melody than of harmony.

In the case of a musical concord, the two notes fall simultaneously on the ear and are perceived as one compound sound, the effect of which is very different from that produced by sounding the notes in succession, however rapid; yet this last is what rather seems to correspond to the sensation produced by two colours placed in juxtaposition, the eye passing rapidly from the one to the other. To obtain the optical analogue of a musical concord, the colours ought to be received simultaneously on the retina—in other words, should be blended. Could not this be accomplished by producing two distinct spectra by means of two prisms and causing the so-called harmonious colours in either to overlap one another on the screen? Blending thus, for example, those rays of the two spectra whose vibrations are to one another in the ratio of 100 to 75, their resultant (a purple of some sort, I suppose) would give us the true analogue of the fifth in music.

Similar experiments, I am aware, have been made by causing patches of colours to rotate upon a disc so rapidly that they are in effect blended upon the retina; but some modification of the method above suggested would seem to have the immense advantage of enabling the experimenter to combine colours whose wave-lengths would be in any desired ratio.

I should be curious to know whether the result of such an experiment would be that the compound tint produced by the two rays would be more or less agreeable, the more or less nearly its component parts were in the exact musical ratio; also whether, when the two colours were slightly "out of tune," we should have the phenomena of "interference" presenting themselves analogous to the "beats" in music.

A curious speculation here suggests itself. It is well known that what are called complementary colours—red and green, for instance—produce, if combined in due proportions, white.

Proceeding by the above method, then, should we find that the particular tints of red and green necessary to produce white, are those whose ratio is exactly that of the musical fourth? If so, white is as much entitled to a place in our catalogue of colours as purple or any other harmonised compound.

If white is not the optical representative of the musical fourth, where shall we look for its analogue in the latter science? Can any of your readers suggest a method of producing a *white sound?* "White," we know, is the resultant of the blending of the whole rays of the spectrum—*i. e.*, of the same part of the retina simultaneously receiving rays whose wave-lengths pass imperceptibly through every conceivable shade of difference.

If it were possible for a violinist to slide his finger up the string of his instrument in such a way that, instead of producing a sound varying in pitch, every part of the string passed over should continue to sound simultaneously with every other part; or, if we can suppose some millions of violinists each sounding a note inappreciably higher than his neighbour, but comprehending among them every conceivable shade of pitch within the octave, we might possibly obtain the purest and most ætherial of tones, a "White Sound!"

Edinburgh, Jan. 24 FRANCIS DEAS

Government Aid to Science

WILL you allow me, with the utmost respect, to remind your able correspondent, that *every individual* in the state pays taxes for ignorance and inefficiency; while so interwoven are the interests of man with man—so often does inquiry after the most abstract principles lead to valuable practical results, that it is impossible to predict in which department of Science discoveries may be made that shall materially lighten these unsatisfactory imposts. Hence the field of research should be open to all and every facility afforded. If this be not the duty of the State it is difficult to explain its *raison d'être*.

The question from the economical point of view is—Shall we pay heavy rates for prisons and workhouses, or shall we try to lighten them by the spread of education? It is well to remember that the law of supply and demand will not avail here, for they who most want it are the least likely to ask for instruction. Perhaps, Mr. Wallace's chief objection is to the unsatisfactory way the money raised by rating, is expended. And here is room for large reforms, if not retrenchment. His proposal regarding the British Museum seems admirable. It is painful to see what excellent opportunities for teaching those who really require it, are lost in that magnificent collection, for want of a little, a *very little*, more expense and trouble.

These remarks are made from the very lowest stand-point, the principle of self-interest—a principle, I believe, your correspondant would heartily despise; for the man of science is essentially liberal, essentially averse to huckstering calculations of profit and loss, essentially unqualified for scrambling after loaves and fishes. E. G. A.

Kant's View of Space

I AM quite willing to leave the readers of NATURE and the students of Kant to decide on the propriety, in English philosophical discourse, of calling Space and Time "forms of Thought," the more so as Sir W. Hamilton—a great stickler for philosophic precision—uses the term in that sense and would have been surprised to hear that he had misrepresented Kant in so doing. My opponents persist in limiting the term Thought to the restricted meaning given to it in Kant's terminology, which, in English, is restricting it to Conception or Judgment: on this ground they might deny that Imagination or Recollection could be properly spoken of as Thought. Throughout I have accepted Thought as equivalent to mental activity in general and the "forms of Thought" as the conditions of such activity. The "forms of Thought" are the forms which the thinking principle (Kant's *pure* Reason) brings with it, antecedent to all experience. The thinking principle acts through three distinct faculties: Sensibility (Intuition), Understanding (Conception), and Reason (Ratiocination): to suppose Thought absent from Intuition, is to reduce Intuition to mere sensuous impression. Therefore, whatever is a form of Intuition must be a form of Thought.

The following passage from Mr. Mahaffy's valuable translation of Kuno Fischer's work on Kant, may here be useful: "Sensibility and understanding are cognitive faculties differing not in degree but in kind, and form the *two original faculties of the human mind*" . . . . The general problem of a Critick of the Reason "is subdivided into two particular objects, as human Reason is into two particular faculties of knowledge. The first object is the investigation of the sensibility; the second, that of the understanding. The first question is, How is rational knowledge possible through sensibility? The second question, How is the same knowledge possible through the understanding?" (pp. 4, 5.)

Those who maintain that it is improper to speak of Space and Time as forms of Thought, must either maintain that Kant held Sensibility *not* to be a faculty of the Mind (thinking principle); or that the term Thought is *not*, in English discourse, a correct expression for the activity of the thinking principle. I believe that the student will agree with me in saying that, although Kant restricted the term Thought to what we call Conception or Judgment, he understood by the activity of the mental faculties (Pure Reason) what we understand by Thought.

It is not, however, to continue this discussion that I again trespass on your space; but to reply to the personal part of Mr. Sylvester's letter. He charges me with misquoting myself and with misquoting him. I said that, in my exposition, Space and Time were uniformly spoken of as forms of Intuition and I say so still. Mr. Sylvester has taken the trouble of reading that exposition without taking the trouble of understanding it; he declares that he "has marked the word intuition as occurring once and forms of sensibility several times; but forms of intuition never." His *carefulness* may be estimated by the fact that the word intuition occurs *four* times on the two pages: his *comprehension* by the fact that it is perfectly indifferent whether Sensibility or Intuition be the term employed, since sensibility is the faculty and Intuition the action of that faculty. Mr. Sylvester, not understanding this, says "If form of sensibility is as good to use as form of intuition, form of understanding ought to be as good as form of thought; but Mr. Lewes owns that the former is indefensible, whilst he avers that the latter is correct." Considering that this passage occurs in a letter which charges me with unfair misquotation, it is curious. So far from owning that the former is "indefensible," it is what I declare to be true; and, with regard to the latter, though I do think a form of Understanding is a form of Thought, my statement was altogether *away* from it, namely, that Space and Time as forms of Sensibility, would be incorrectly spoken of as forms of the Understanding.

With regard to the alleged misquotation of his own words, which he characterises as unfair and as "too much like fighting with poisoned weapons," it was a charge which both astonished and pained me. There are few things for which I have a bitterer contempt than taking such unfair advantages of an adversary. I beg to apologise to Professor Sylvester for any misrepresentation which, unintentionally, I may have been guilty of. But, in accepting his denial of the construction I placed upon his language, I must still say that, after re-reading his letter, I am at a loss to see what other construction it admits of, that has any bearing on the dispute, and that he has not expressed his meaning with sufficient clearness. Intuition and Thought are there compared with Force and Energy as terms "not convertible"; Force is detached from Energy as potential from actual and Intuition without Thought, is made to hold an analogous position. Here is the passage; let the reader judge:—

"Can Mr. Lewes point to any passage in Kant where Space and Time are designated *forms of Thought?* I shall indeed be surprised if he can do so—as much surprised as if Mr. Todhunter or Mr. Routh in their Mechanical Treatises were to treat *energy* and *force* as convertible terms. To such a misuse of the word energy it would be little to the point to urge that *force without energy is a mere potential tendency*. It is just as little to the point, in the matter at issue, for Mr. Lewes to inform the readers of NATURE that *intuition without thought is mere sensuous impression*."

Is it to use "poisoned weapons" to interpret this as assuming that Intuition and Thought differ as potential and actual? I repeat that, since Mr. Sylvester disclaims the interpretation, my only course is to apologise for it; but, after his own misinterpretations of me, he will not, I hope, persist in attributing mine to a desire to take an unfair advantage. If I make no reply to the other points roused in the various letters it is in order not to prolong the discussion.

GEORGE HENRY LEWES

I DO not know whether Mr. Sylvester and Dr. Ingleby will be satisfied with Mr. Lewes' letter in yours of the 27th. I am not and I think, in defending his former mistake, Mr. Lewes has fallen into additional errors.

It is undoubtedly fair to translate an author into your own language before criticising him, provided you found no criticism on the language that you have put into his mouth. But this I think Mr. Lewes has done. He accuses Kant of inconsistency in speaking of pure *à priori* cognitions, when, on his own system, pure thought only supplies one element to these cognitions, the other being derived from sense or intuition. Now (not to insist here that Kant constantly uses the term cognition in a wider sense than that which Mr. Lewes insists on fastening upon him), this criticism is evidently invalidated by the simple remark that Kant admits pure intuitions, as well as pure concepts and explains the nature of mathematics, as a system of *à priori* cognitions, by the fact that its object-matter consists of nothing but pure intuitions.

Mr. Lewes now informs us that Kant's Intuition and Thought "differ as species and genus." According to Kant they differ in kind; and Liebnitz was as wrong in making sensibility a species of thought as Locke was in making Thought a species of sensibility. Space and Time, Mr. Lewes adds, are forms of "mental activity" and, therefore, are properly termed "forms of Thought," in the meaning of the latter term which is usually current in this country. If they were forms of mental activity they would be forms of Thought, according to Kant, likewise; for the criterion by which Kant distinguishes between Intuition and Thought (under which term he includes both the understanding proper and the reason proper) is that, in the former, the mind is passive (receptive) while, in the latter, it is spontaneously active; and it is precisely on this ground—the passive reception of them by the mind—that he refers Space and Time to Sensibility rather than Thought. This is repeatedly brought out in the Transcendental Deduction of the Categories. See in particular Sections 11 (Meiklejohn, p. 80) and 18 (Meiklejohn, p. 90).

I think if Mr. Lewes will turn to the preface to the first edition of the "Critick," he will see that the transcendental logic only (and perhaps I might limit it to the transcendental dialectic) grapples *directly* with the problem indicated by the title of the book. The Æsthetic is a preliminary inquiry, which proves afterwards of great use; but is not to be considered as a Critick of Pure Reason in this particular department. His using the term "concept" of space, is certainly confusing; but its explanation, I think, is to be found in a passage in the "Transcendental Exposition" of this "concept" (Meiklejohn, p. 25), where he says, "It must be *originally* intuition, for from a *mere* conception no propositions can be deducted which go out beyond the conception and this happens in geometry." In the preceding page he similarly qualifies his statement that Space is an intuition. "No conception *as such*," he says, "can be so conceived as if it contained, within itself, an infinite multitude of representations." We may *now* have a concept as well as an intuition of Space and Time; but the intuition was the original form of the idea and it is to the intuition that we must always have recourse in mathematics when we wish to discover a new truth.

I think, if Mr. Lewes will again read over the Transcendental Æsthetic and the parts of the Transcendental Analytic which are closely related to it, he will see that Kant never designates the *original* representations of space and time "concepts," or refers their origin to "pure reason." W. H. STANLEY MONCK

Trinity College, Dublin, Jan. 29

[This correspondence must now cease.—ED.]

NOTES

THE Gold Medal of the Royal Astronomical Society will be presented to M. Delaunay, the president of the Paris Academy of Sciences, to-morrow. It is to be regretted that the stay of the distinguished French savant in England is but short.

WE referred last week to the "situation" at the Paris Observatory. The action of the French Government has been of the promptest and M. Le Verrier is no longer Director. This step indicates very clearly—too clearly we fear—the strength of the case put before the Minister of Public Instruction, in the memorial, of which a copy has been sent to us. This document, which is signed by all the *chefs de service*—Villarceau, Marié-Davy, Wolf, and Loewy—and the *astronomes adjoints* without exception, discusses all points connected with the administration of the Observatory, scientific and otherwise. It is to be sincerely hoped that M. Le Verrier may be able yet to do service to astronomy, in some other capacity, some position where his great talents alone will be called into play. His is a name that will never die, let us hope it is but momentarily eclipsed.

THE Trustees of the Johnson Memorial Prize for the encouragement of the study of astronomy and meteorology propose "the laws of wind" as the subject for the next essay:—1. With regard to storms; 2. With regard to average periodical phenomena at given places on the earth's surface. The prize is open to all members of the University of Oxford and consists of a gold medal of the value of ten guineas, together with so much of the dividends, for four years, on 338*l.* Reduced Annuities as shall remain after the cost of the medal and other expenses have been defrayed. Candidates are to send their essays to the registrar of the university under a sealed cover, marked "Johnson Memorial Prize Essay," on or before the 31st day of March, 1871, each candidate concealing his name, distinguishing his essay by a motto and sending at the same time his name, sealed up under another cover, with the same motto written upon it. No essay will be received after the 31st day of March, 1871.

A NEW office has been constituted under the Public Works Department and Mr. Douglas Galton, C.B., F.R.S., has been appointed to it with the title of Director of Works and Buildings. We may congratulate ourselves that our public building will be looked after by one so eminently qualified by his high scientific attainments and great experience in such matters.

AT the meeting of the French Academy on January 31, the two candidates recommended for the vacancy in the Bureau des Longitudes were M. de la Roche-Poncié and M. Gaussin. The former received 40 votes out of 43. At the same meeting the mineralogical section presented a list of candidates for the vacancy in the list of correspondents to replace Sir Roderick Murchison, who has recently been nominated a foreign associate. The candidates were, in the first rank, Prof. C. F. Naumann; in the second, in alphabetical order, MM. Abich, Gustav Bischoff, Ami Boué, Dana, von Dechen, Domeyko, James Hall, von Hauer, von Helmersen, C. T. Jackson, Kjerulf, von Kokscharow, W. E. Logan, W. H. Miller, Ferdinand Römer, Scacchi, A. Sismonda, and Studer.

THE *Goloss*, of St. Petersburg, says that a special commission will shortly be appointed by the Academy of Sciences there, for the purpose of observing the transit of Venus on the 26th of November, 1874 (old style). The members of the commission are to be Messrs. Struve, Savitch and Wild, of the Russian Academy; Messrs. Döllen and Wagner, superintendents of the Observatory at Pulkova; Vice-Admiral S. J. Seleny and Major-General Forsch. The *Goloss* adds that the reason the commission will be appointed so early, is that much time will be required for making the necessary preparations and that similar commissions have been already appointed in England, France and Germany.

PROF. W. H. FLOWER, who has recently been appointed Hunterian Professor of Comparative Anatomy and Physiology, will commence a course of eighteen lectures introductory to the study of the anatomy of the class Mammalia, on Monday, February 14, 1870, in the Theatre of the Royal College of Surgeons. The lectures are to be delivered on succeeding Mondays, Wednesdays and Fridays, at four o'clock and will treat of methods and aims in the study of morphology: classification of the mammalia; osseous system of the mammalia: Axial skeleton—vertebral column; modifications of the characters of the vertebræ in the cervical, thoracic, lumbar, sacral and caudal regions in different mammals; sternum, cranium, hyoid arch. Appendicular skeleton—essential structure and modifications of the bones composing the shoulder-girdle and anterior extremity; structure and modifications of the pelvic girdle and posterior extremity; comparison between the structure and the functions of the anterior and the posterior extremities. Tegumentary system and its appendages: the dermis; modifications of the integument mainly due to peculiar conditions of the dermis; ossifications in the integument; the epidermis and its modifications; callosities, scales, nails, claws, hoofs, horns, hairs, spines, antlers, glandular organs connected with the integument, or opening on the external surface of the body; scent glands; mammary glands. Dental system: structure and essential characters of teeth; classification and nomenclature of teeth; development and succession of teeth; modifications of the characters of the teeth in the different groups of the Mammalia; horny structures taking the place of teeth in certain mammals. Baleen, &c. These lectures are open to Fellows and Members of the College of Surgeons and of learned and scientific bodies in the United Kingdom.

THE death is announced of E. W. Brayley, many years connected with the London Institution, and a frequent lecturer on scientific subjects. Mr. Brayley was well known for his scientific attainments and has contributed to scientific literature, some valuable papers on geology, astronomy and other subjects.

THE second course of Cantor Lectures for the present Session will be given by Dr. Benjamin Paul, F.C.S. The course will consist of four lectures, "On the Phenomena of Combustion and the Chemical and Physical Principles involved in the Use of Fuel and in the Production of Artificial Light," to be delivered on Monday evenings, the 7th, 14th, 21st, and 28th of March, at 8 o'clock.

THE third part of the nineteenth volume of the *Jahrbuch der kais.-kön. geologischen Reichsanstalt*, including the more important papers communicated to the Austrian Geological Institute during the months of July, August, and September, 1869, has just reached us. It contains some valuable memoirs for the students of general geology. M. D. Stur describes the characters and mode of occurrence of the brown-coal in the district of Budafa, in Hungary. He has ascertained the existence of two layers of useful coal, the upper one varying from two to three feet in thickness, the second being usually from four to six feet and sometimes as much as eleven feet thick. Borings indicate a third horizon having coal from eight-and-a-half to ten feet thick; but the quality of this coal has not been ascertained. Dr. M. Neumayr's contributions to the knowledge of the fossil fauna of the Austrian dominions consist of lists and numerous descriptions of fossil shells, from the late Tertiary freshwater marl of Dalmatia and from the Congerian beds of Croatia and West Sclavonia. This paper is illustrated with four plates. M. D. Stur reports upon the geological survey of the environs of Schmöllnitz and Göllnitz, in Hungary, including especially the mountain-mosses of the Volovec and Branisko. It includes an "Eozoonal" rock and deposits belonging to the Carboniferous, Permian, Triassic and Liassic formations. The other papers are: A description of the Amphibole-Trachyte of the Mátra in Central Hungary, by Dr. Joseph Szabó; an account of mineralogical investigations in the chemical laboratory of the Institute, communicated by Karl Ritter von Hauer and a translation, by Dr. E. Bunzel, of the account given by Drs. Carpenter and Wyville Thomson of their dredging operations on board the *Lightning*, in 1868.

THE *Canadian Entomologist* for January announces that the Council of the Agricultural and Arts Association of Ontario has appropriated the sum of four hundred dollars to aid the Entomological Society during the present year in forming a cabinet of insects useful or prejudicial to agriculture and horticulture, for continuing the journal and making an annual report. It contains also notes on some of the common species of *Carabidæ* found in temperate North America, by P. S. Sprague; on the currant worm, by W. Saunders; remarks on the history and architecture of wood paper-making wasps, by W. Cowper; a list of *Coleoptera* taken at Grimsby, Ont., by J. Pettit and miscellaneous notes.

THE Nederlandsche Maatschappij ter bevordering van Nijverheid—that is, The Netherlands Society for the Promotion of Industry—offer, for the year 1871, a prize of a gold medal worth 150 florins and three hundred florins in money, for the best method of illuminating floating buoys so that they can be seen at night. The contrivance, whatever its form, is to be self-lighting, for obvious reasons. Here, then, is another task for those who are skilful in sending sparks through long wires. We remember that Mr. Siemens had some project of the sort a year or two ago. Is this a fitting opportunity for trying to work it out? If Dutch mariners feel it desirable that their buoys should be lighted at night, so do those of all other nations. Competitors for the prize are to send their documents and models to the general secretary of the society, M. F. W. Van Eeden, at Haarlem, before September 30, 1871.

WE learn from the *Athenæum* that Dr. Andrews, Vice Principal of Queen's College, Belfast, has been elected an Honorary Fellow of the Royal Society of Edinburgh, in the room of the late Master of the Mint.

A CONTROVERSY is going on in the *Medical Times and Gazette* as to the sufficiency of a test for Morphia, involving serious considerations as regards toxicological inquiries. The point is, whether the production of a blueish purple tint on mixing a substance with a molybdate and sulphuric acid, is sufficient proof of the presence of morphia, or whether the same colours may not be produced by other substances which are quite innocuous.

NEWS has this week been received from Mr. C. F. Tyrwhitt Drake of Trinity College, to whom, last autumn, the University of Cambridge granted a sum of money out of the Worts Travelling Bachelors' Fund, to enable him to collect zoological specimens while accompanying Mr. E. W. Palmer of St. John's College, the distinguished orientalist, in exploring the Tîh country—the "Wilderness of the Wanderings." The Arabs were by no means prepared to find Englishmen travelling without the luxuries to which they are accustomed and, in consequence, were suspicious of their object in visiting the country. It is to be hoped, however, that nothing will hinder our adventurous explorers from accomplishing their wish of reaching the Jordan by the route traditionally followed by the Israelites. Mr. Drake's journal and collections can scarcely fail to be of much interest.

WE understand that one of the two zenith sectors, constructed by Messrs. Troughton and Simms from the designs of Lieut.-Col. Strange, for the Great Trigonometrical Survey of India, has reached its destination—Bangalore, in the Madras Presidency. This instrument differs entirely from all of its class. Ramsden's and Graham's cumbrous though most ingenious structures of timber were superseded by the far more efficient sector designed some years ago for the Ordnance Survey by the Astronomer Royal. But even Airy's zenith sector was too heavy for transit over the rugged and pathless mountain chains of Hindustan. It weighed, without its packing-cases, upwards of 1,100 lbs. The instrument of which we now speak has been reduced to 600 lbs., without loss of power. The telescope has an aperture of 4 inches with a focal length of 4 feet and the sectors are portions of a circle 3 feet in diameter, read by means of 4 micrometer microscopes. This class of instrument is intended solely for the determination of latitude. Hitherto it has been used for this purpose, in measuring the zenith distances of known stars, as its name implies, which we may call the absolute method. But of late years another mode of determining latitude has come much into favour,—this we will call the differential method. It consists in measuring, with a micrometer attached to the eye-end of the telescope, the difference of zenith distance of two stars nearly equidistant from the zenith, one north, the other south. Its merit consists chiefly in the simplicity of the means necessary for the purpose, namely, a telescope firmly mounted with a good micrometer and a good level, no circle or sector being required. Colonel Strange has, we hear, adapted his instrument to both methods, which may therefore be thus submitted to a comparative trial under circumstances equally fair to each. The instrument is in the hands of Capt. J. Herschel, R.E., who is about to employ it for the twofold purpose of furnishing data for improving our knowledge of the figure of the Earth and of throwing light on the interesting physical problem of local attraction. It will be remembered that some years ago the operations of the Russian Survey indicated the presence, in a particular locality, of a huge subterranean cavity, the existence of which would never have been suspected, had not anomalies in observed latitudes established the fact. We may expect to hear of similar phenomena being discovered by the same means in India when observations are multiplied by a more portable instrument than any hitherto used of equal power. The facts that cavities may exist where least suspected and that hidden masses of higher specific gravity than the surrounding rocks are known to occur, render it imperative that in geodetic operations the latitude, which is affected by such irregularities, should be more frequently observed than was formerly thought necessary. It is satisfactory to find that such scientific desiderata are appreciated and so liberally provided for, by the Indian Administration.

THE purity of the metropolitan water supply has been seriously affected by the winter floods. Professor Frankland, in his last monthly report, states that the water supplied by the East London Company was very turbid and contained vibrios. This is the first occasion in which Dr. Frankland has detected these organisms, which are abundant in putrid sewage, in the London water.

A VERY interesting paper on the Pearl, Coral and Amber Fisheries, was read at the meeting of the Society of Arts held on the 19th inst. The chair was occupied by Professor Owen, who in proposing a vote of thanks to the lecturer, Mr. T. L. Simmonds, made some instructive remarks on the origin of pearl, coral and amber. Both the paper of Mr. Simmonds and the observations of Professor Owen, will be found at full length in the last number of the Society's Journal.

WE are glad to know that an "Athenæum" has been established in Belfast. It contains a large reading-room, provided with most of the daily and weekly papers and the monthly and quarterly reviews. There is also a commercial, literary and scientific reference library and all the usual accessories of a club. Such an undertaking deserves every support. A series of lectures on scientific and literary subjects has already been commenced in connection with this institution.

THE Lowndean Professor of Astronomy in the University of Cambridge intends to give a course of lectures on the Lunar Theory, with special reference to M. Delaunay's method of treating the subject.

Land and Water announces that the Prince Pless, who has large possessions in Siberia, has succeeded in crossing the common Red Deer with the Wapiti (*Cervus Canadensis*) and the perfect fecundity of the hybrids appears to be well established.

ACCORDING to *Les Mondes*, the Mont Cenis tunnel will certainly be finished during the present year. On the 1st ult., the galleries opened measured 10,598 metres and there only remained 1,621 metres to be excavated.

THE *Photographic News* announces that a Photographic Society has just been formed at Dresden. Among the members are the names of Krone, president, Hahn, Hanfstængl, &c. The society publishes a monthly journal entitled *Helios*, this being the sixth photographic journal published in Germany.

IS Sicily about to lose the monopoly of sulphur which she has so long enjoyed? By recent intelligence from America, we learn that a bed of pure sulphur, 135 feet in thickness and about 530 feet below the surface, has been discovered on an island in Bayou Choupique, in the delta of the Mississippi. The place is within ten miles of the sea, from which it may be anticipated that shipment of the mineral will be comparatively easy. The extent of the deposit has not yet been ascertained; but the local formations are such as to lead to the inference that it is "immense." Besides the sulphur, there is a deposit of gypsum, of perhaps equal extent; hence we may anticipate that the company formed to work the one, will also turn the other to profit. Sulphur is so much in demand for the manufacture of sulphuric acid and for many other purposes in the arts, that this discovery of a deposit in a country teeming with energy and enterprise, seems opportune. When in full work it will most likely occasion a fall in the price of sulphur and a corresponding falling off in the use of pyrites. This sulphur bed was discovered during the sinking of a well in search for petroleum. But instead of "oil" the boring discharges a copious stream of water, which is described as a saturated solution of sulphuretted hydrogen, combined with a small amount of gypsum and common salt. It is clear that the company which is about to explore the sulphur, will have to provide for an abundant drainage, as well as for ventilation. The locality may be found on a good map, near Lake Calcasieu, on the western border of the Mississippi delta.

SCIENTIFIC SERIALS

THE new number of Pflüger's Archiv. (III. i.) contains a paper by Prof. L. Hermann "On the absence of currents in uninjured inactive muscle." Munk's views are criticised and a new experiment described, in which the gastrocnemius of a frog is prepared for investigation, in such a way that no contact between the cutaneous secretion and the surface of the muscle (a source of currents in previous observations) takes place. With a galvanometer of 1,600 windings, giving a deviation of 300 sc. for an ordinary nerve current, the muscle so prepared gave only a deviation of 10 to 20 sc. "We are hereby justified," says the author, "in supposing that with a still more careful method of preparation, by the avoidance of yet other unknown causes of injury, we shall at last get a muscle *perfectly* free from currents."

In another paper "On the course of the development of currents in dying muscle," Prof. Hermann shows that when part of a muscle is killed and rendered rigid by exposure to a temperature of 40° C., the development of the current takes place just at the moment when *rigor mortis* makes its appearance.

The same author has also a paper "On the danger of drinking cold water when the body is heated," in which an attempt is made to submit the matter to an experimental inquiry. The only result obtained, however, was that in curarized animals, the injection of ice-cold water into the stomach caused a sudden and great rise in the arterial tension in the carotid and crural arteries, apparently from spasm of the visceral arteries in the neighbourhood of the stomach. Such a sudden increase of tension would prove dangerous in the case of unsound vessels. When the animals, however, were not curarized, very little rise of tension was observed, suggesting the idea that some compensating mechanism was at work, *e.g.* respiratory movements.

There are also papers "On acute phosphorous poisoning," "On convulsions due to disturbances of the cerebal circulation (venous obstruction)" and "On simultaneous contrasts" by Prof. Hermann and his pupils; "On the action of Hydrocyanic acid on the red blood corpuscles" by Geinitz; "On the interference of the bile with gastric indigestion" by Hammarsten; and, "On serum-albumin" by Zahn.

Revue des Cours Scientifiques, February 5.—This number contains an interesting paper read by M. P. I. Van Beneden, of Louvain, at the Belgian Academy of Sciences, on what he terms "commensalism" in the animal kingdom, or certain associations of animals for feeding purposes, which are not, in the ordinary sense, cases of parasitism. The author gives several illustrations of this fact, and he defines the parasite as an animal which lives upon another, while the commensal or messmate is merely a feeding companion. He distinguishes free and fixed commensals. Of the former there are numerous instances in the class Crustacea. The most interesting examples of the latter are the *Tubicinella diadema* or *coronula* covering the skin of whales; the *Remora*, found in the Mediterranean, and made use of, in fishing, by the inhabitants of Mozambique after the manner of a falcon on land. This number also contains a lecture by M. Ch. Robin, on Histology, delivered at the Faculté de Médicine in Paris.

In *Silliman's Journal* for January, Professor B. Silliman has a paper on the relation between the intensity of light produced by the combustion of coal gas and the volume of gas consumed, read at the Salem meeting of the American Association for the Advancement of Science last year, in which he gives as the result of many trials the theorem that, within ordinary limits of consumption, the intensity or illuminating power of gas flames increases as the square of the volume of gas consumed, according to which the method of computation hitherto adopted in photometry, would involve an error amounting to 40 per cent., in the case of rich gas, burning at the rate of $3\frac{1}{2}$ feet an hour with an observed effect of 20 candles—the illuminating power reduced to the standard consumption of 5 cubic feet an hour, being in this case equal to 40 candles instead of 28·57 candles. Hence it follows that all photometric determinations obtained by computation from volumes greater or less than the standard of 5 cubic feet an hour, in the simple ratio of the volumes consumed, must be considered as absolutely worthless. This applies also to the case of sperm candles burnt at a rate different from the standard of 120 grains per hour. As a consequence of these observations it would appear to be essential for photometric observers, in their determinations, to bring the rates of consumption both of gas and sperm to the agreed standards. For the consumer of gas it is evident, also, that where it is important to obtain the maximum economical effect from gas, this result is best attained with burners of ample flow. Prof. W. D. Alexander describes, in a letter to the editor, the results of a careful survey of the crater of Haleakala in the island of Maui. F. W. Clarke gives a new method of separating tin from arsenic, antimony and molybdenum, based on the solubility of the sulphides of tin in oxalic acid solution. E. Billings, paleontologist of the Canadian Geological Survey, continues his notes on the *Crinoidea*, *Cystidea* and *Blastoidea*. A paper on a new spectroscope, with contributions to the spectral analysis of the stars, by Dr. Zöllner, is translated from the Proceedings of the Royal Society of Saxony. H. J. Clark has a paper on Polarity and Polycephalism, extracted from a forthcoming memoir on the anatomy and physiology of *Lucernariæ*, in which he treats of the discussion that has of late years prevailed as to whether the lower compound denizens of water are individuals or organs forming only a part of an individual. Dr. Sterry Hunt contributes a paper on Laurentian rocks in Eastern Massachusetts, in which he announces the discovery of Eozoön in the limestone of that district, by Mr. Bicknell. In a paper on the chemistry of common salt, Dr. Goessmann treats of the origin, occurrence and manufacture of salt. J. Lawrence Smith gives an account of the fall of meteoric stones in Alabama, with analyses, and points out the importance of a thorough re-examination of the mineral nature of meteoric stones. A. E. Verrill continues his contributions to zoology, from the Museum of Yale College, by describing Echinoderms and Corals from the Gulf of California and gives also a note on the generic relations and synonymy of the Common Sea-Urchin of New England (*Euryechinus Drobachiensis*) in which he replies to a criticism by M. Agassiz upon the author's classification of the species here referred to. E. S. Morse has a paper on the early stages of Brachiapods, describing the development of *Terebratulina Septentrionalis*, abundant in the waters of Eastport (Maine) and Dr. Jeffries Wyman has a paper on the existence of a Crocodile in Florida, said to have been killed near the mouth of the Miami river and considered by the author, as belonging to the sharp-nosed species (*C. acutus*).

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 3.—The following papers were read:—"Note on an Extension of the Comparison of Magnetic Disturbances with Magnetic Effects inferred from observed Terrestrial Galvanic Currents—and Discussion of the Magnetic Effects inferred from Galvanic Currents on days of tranquil magnetism." By George Biddell Airy, Astronomer Royal. (Received December 22, 1869.) The author, referring to his paper in the Philosophical Transactions for 1868, stated that he had examined the whole of the galvanic currents recorded during the establishment of the Croydon and Dartford wires (from 1865 April 1, to 1867 October 24). The days of observation were divided into three groups: No. 1 comprising days of considerable magnetic disturbance; No. 2, days of moderate disturbance, of which no further use was made and No. 3, days of tranquil magnetism. The points most worthy of notice are, that the general agreement of the strong irregularities, galvanic and magnetic, is very close; that the galvanic irregularities usually precede the magnetic, in time and that the northerly magnetic force appears to be increased. The author remarks that no records appeared open to doubt as regards instrumental error, except those of western declination; and to remove this he had compared the Greenwich curves with the Kew curves and had found them absolutely identical. In the discussion of the galvanic current-curves, on days of tranquil magnetism, for independent examination of the galvanic laws, the author explained the method of measuring the ordinates and connecting the measures into expressions for magnetic action, at every hour, grouping the measures, at the same nominal hour, by months and taking their monthly means for each hour. As these exhibited sensible discordance, they were smoothed by taking the means of adjacent numbers, taking the means of the adjacent numbers of the new series and so on, repeating the operation six times. The author explained the theory of this process and the way in which it tends to degrade the periodical terms of higher orders. He then explained an easy method of resolving the numbers so smoothed, into periodical terms recurring once or twice, or thrice in the day, &c. and applies the method to the numbers for every month. When these quantities (which from month to month are perfectly independent) are brought together in tables, they present such an agreement, with gradual change accompanying the change of seasons, as to leave no doubt of their representing a real law of the diurnal changes of the galvanic currents. They also show the existence of a constant turn towards the north (explaining the apparent increase of force to the north observed in the results for days of great disturbance), and a still larger force towards the west (also well marked on the days of great disturbance). No light is obtained as to the origin of these turns; but they appear to be probably pure galvanic accidents, depending on the nature of the earth-connections. The author then exhibited, in curves, the diurnal inequalities of magnetism which the galvanic currents must produce. The form generally consists of two parallel lobes, making with the magnetic meridian an angle of nearly 60° from the north towards the west. The greatest east-and-west difference of ordinates, in the month of April, is 0·0004½ of total horizontal magnetic force; it corresponds in the hours to which those ordinates relate, nearly with the ordinary diurnal inequality. But it is much smaller than the ordinary diurnal inequality and the daily law of the galvano-magnetic inequality differs greatly from that of diurnal inequality. For the greater part, therefore, of diurnal inequality the cause is yet to be found.

"On the fossil mammals of Australia.—Part III. *Diprotodon australis*, Owen." By Prof. Owen, F.R.S., &c. Received December 10, 1869. In this paper the author communicated his descriptions of *Diprotodon australis*, with figures of the fossil remains at his command, which have been received from various localities in Australia, since the first announcement of this genus founded on a fragment of lower jaw and tusk described and figured in the "Appendix" to Sir Thos. Mitchell's "Three Expeditions into the Interior of Eastern Australia," 8vo, 1838. The fossils in question include the entire cranium and lower jaw, with most of the teeth, showing the dental formula of:—$i\,\frac{3-3}{1-1}$, $c\,\frac{0\cdot0}{0\cdot0}$, $m\,\frac{5-5}{5-5}=28$; portions of jaws and teeth exemplifying characteristics of age and sex; many bones of the trunk and extremities. The author described the skull and teeth and the result of the comparisons, establishing the marsupial characters of *Diprotodon* and its combination of characters of *Macropus* and *Phascolomys* with special modifications of its own, which are more fully and strongly manifested in the bones of the trunk and limbs, subsequently described. The pelvis and femora present resemblances to those in *Proboscidea*, not hitherto observed in any other remains of large extinct quadrupeds of Australia. But in all the bones described, essentially marsupial characteristics are more or less determinable. A summary of the characters of *Diprotodon* illustrated the conditions of its extinction, its analogies with the *Megatherium*, its affinities to existing forms of *Marsupialia* and the more generalised condition which it manifests of that mammalian type. A table of the localities, in Australia, from which remains of *Diprotodon* have been obtained and a table of the principal admeasurements of the skeleton, are appended to the text.

Royal Astronomical Society, January 16.—Third meeting of the Session.—Mr. De la Rue, vice-president, in the chair. The chairman announced that the president, though he was recovering his health, was not able to take the chair. Thirty-one presents were announced and the thanks of the society voted to their respective donors. The first paper read was a communication from Sir John Herschel, having reference to a supplementary list of eighty-four double stars observed at Slough since the year 1820. Amongst these were many observed by the elder Struve and an interesting portion of the communication referred to the relation between Sir John Herschel's estimate of the magnitudes of stars and Struve's. It appeared from the comparison that Herschel's magnitude 3·0 corresponded to Struve's 2·6 and the difference gradually widened from successive magnitudes until from the lowest orders the two lists were altogether discordant. A similar relation was observed (we believe by Mr. Knott) between the magnitudes in Admiral Smyth's Bedford catalogue and Argelander's estimates.—A communication from Mr. Joynson, having reference to observations made on occultations and on phenomena of Jupiter's satellites, was then read.—In a paper containing a list of occultations, Captain Noble referred to an estimate, by Mr. Penrose, of the latitude of the former's observatory as deduced from an occultation of ζ Ceti.—The next paper, by Commander Davison, on the November meteors as seen at Santa Barbara, California, contained several interesting diagrams.—The annual statement of the observations made on the sun at Kew was then read. It appeared from this that sun-spots have scarcely been so numerous as was to have been expected so near the epoch of maximum spot-frequency. The sun was observed on 96 days during the year 1869; there were no days when the sun was without spots and 224 new groups made their appearance.—Mr. Browning then read an account of a new method of measuring the position of lines in the spectrum. In this arrangement an illuminated cross is made to traverse the spectrum by turning a micrometer screw. Mr. Browning mentioned that he had found it perfectly impossible, by the ordinary mode of measurement, to deal with the faint spectrum of the planet Jupiter. The spectrum itself was nearly obliterated and the lines in it were rendered altogether invisible. He remarked that though Jupiter is so bright, its spectrum is fainter than that of a second magnitude star, even when the latter spectrum is made as wide as that of the planet (a peculiarity obviously depending on the fact that we use but a portion of a planet's light in observing its spectrum, while the linear image of a star includes the whole of the star's light). Mr. Bidder, referring to Mr. Browning's method of bringing the illuminated cross upon the spectrum, said that he had often thought Sir W. Herschel's plan of comparing double stars with movable lights placed at some distance from the observer might, with modifications, be applied to the micrometrical measurement of double stars. He described an arrangement he had tried for this purpose. Messrs. Huggins and Lockyer made some suggestions on the mode of measuring the plan of lines in the spectrum, the former pointing out the necessity of having the cross differently coloured for measuring lines in different parts of the spectrum and showing how this might be done by means of a small prism: the latter remarking that some arrangement was desirable by which the lantern might be so shifted, while the micrometer screw was turned, as not to alter the conditions under which the spectrum was observed. At the chairman's request, Mr. Lockyer then gave an account of Mr. Newall's great telescope, a Cooke refractor, 25 inches in clear aperture, remarking that it was a noteworthy circumstance, that a telescope of this size should have been mounted in the so-called German manner; that is, not on a long polar axis; but on the Fraünhofer stand, familiar to his hearers. He said that Mr. Newall proposed to devote the powers of this instrument in the most generous manner to the interests of science and that when it had been erected in a suitable climate, astronomical workers would be invited to avail themselves of its powers. The chairman then asked if any information could be given respecting Mr. Buckingham's 21-inch refractor, from whose performance so much had been expected. Mr. Buckingham, who was present, said that he had only that evening been observing Jupiter with it; and he had to remark, with reference to the ruddy colours of the equatorial belt which had recently been attracting so much attention, that in his powerful instrument he could clearly discern red masses resembling clouds in shape, on a white background. One band, in the red part of the spectrum, was at present invisible. The chairman invited Mr. Buckingham to make some frequent communications respecting the great telescope's performance. He also confirmed the statements made by Mr. Buckingham respecting the present aspect of the planet. Colonel Strange then gave a most interesting account of a transit instrument constructed by the late Mr. Cooke on the Russian plan (so called) and Mr. Carrington mentioned that the instrument should properly be called the Harris transit, after a countryman of our own who devised the method. The instrument, which is intended to be used by those engaged in the survey of India, was exhibited at the meeting. Instead of the ordinary arrangement, the optical axis of the instrument is divided into two halves at right angles to each other, one corresponding to the object half of an ordinary transit, the other being in the horizontal axis of the instrument; so that the eye-piece is placed at one end of the horizontal axis and the observer stands on one side of the instrument. The advantages of the arrangements are obvious: the eye is always at the same height and the vision always directed horizontally. On the other hand, Colonel Strange remarked that he could not altogether get rid of his dislike to the plan. He thought all who had been engaged in actual observation would agree with him that the less the cone of light forming the object-glass was tampered with the better. But passing over that and minor objections, there remained this important point to be considered. In the ordinary arrangement, any disturbance of the collimation, whether taking place at the object-end or at the eye-end of the instrument, produced effects varying inversely as the distance separating the object-glass from the eye-glass. In the new arrangement, if the prism by which the rays from the object-glass were reflected towards the eye-glass were disturbed, the effects would be increased in precisely the same proportion that the distance between the prism and the object-glass is less than that between the eye-piece and the object-glass in the ordinary arrangement. The answer to this was, that the prism in effect never does get disturbed; but, for his own part, he thought this could hardly be looked upon as established. There was this further objection (first pointed out by Captain Clarke) to be considered, that there was a variation in the collimation—errors according to the position of the instrument. An interesting discussion ensued, during the course of which the possible disturbances resulting from the heat, or from the weight of the observer, were discussed and the performance of the instrument compared with that of such an instrument as Mr. Carrington is about to employ, in which the whole of the telescope's axis is always horizontal. Mr. Stone was then invited to give an account of his researches into the heating powers of the stars, which he did in a most interesting and lucid manner. The substance of his remarks has already appeared in these columns under another heading.

Zoological Society, January 27.—Prof. Newton, V. P., in the chair.—A letter was read from Mr. R. B. White, concerning the hairy tapir (*Tapirus roulini*) of the Andes of New Granada, of which he was endeavouring to obtain specimens for the Society's menagerie.—Dr. Cobbold, F.R.S., exhibited specimens of, and made remarks upon, the new entozoön from the Aard-wolf, described at the last meeting of the society, and proposed to be called *Acanthocheilonema dracunculoides*.—Mr. G. D. Rowley, exhibited and made remarks upon a specimen of the Siberian lark (*Alauda sibirica*), recently taken at Brighton, and believed to be the first example of this species that had occurred in the British Islands. He also exhibited some other rare birds from the same locality.—Prof. Newton, in exhibiting a specimen of the North American *Zonotrichia albicollis*, shot near Aberdeen, and sent to him for that purpose by Mr. W. C. Angus, called attention to the injudicious practice of many ornithologists who are prone to give the name of "British Birds" to all such foreign species as occasional stray to this country.—A communication was read from Professor Owen, containing a letter received from Dr. Haast, F.R.S., on the discovery of cooking-pits and kitchen-middens containing remains of various species of *Dinornis*, in the province of Canterbury, New Zealand.—Mr. P. L. Sclater read a paper on some new or little-known birds from the Rio Paranà, collected during the second survey of the river by Captain Page, U.S.N. and submitted to him for examination by the Smithsonian Institution. — Dr. W. Baird communicated a description of a new genus and species of shells from Whydah, on the West Coast of Africa, proposed to be called *Pretoma*, together with some remarks on the genus *Proto* of Defrance.—Mr. R. B. Sharpe read a paper on the genus *Pelargopsis* of the family *Alcedinidæ* and pointed out the geographical distribution of the eight species of this genus in the Indian and Australian regions.—Mr. Sharpe also exhibited and pointed out the characters of a new species of *Campephaga* from Damara-land, which he proposed to call *Campephaga Anderssoni*, after the late Mr. C. J. Andersson, its discoverer.—Dr. J. E. Gray communicated some notes on the skulls of the whales of the genus *Orca* in the British Museum, and a notice of a specimen of the same genus from the Seychelles.—A communication was read from Dr. J. C. Cox, containing descriptions of seventeen new species of land shells from the South Sea Islands. The original specimens were stated to be in the cabinet of Mr. John Brazier, of Sydney.—A communication was read from Lieut.-Col. Playfair, containing an account of a fresh-water fish recently discovered in the vicinity of Aden, which appeared to referable to the widely-distributed Cyprinoid, *Discognathus lamta*.—Dr. J. Murie read a note upon a larval æstrus found in the orbit of the hippopotamus, to which was added a list of the species of mammals in which æstri-larvæ have hitherto been found.—Dr. Murie also read a note on a specimen of the so-called *Aquila Barthelemyi* recently living in the Society's Gardens, which appeared to be nothing more than a variety of the Golden eagle *Aquila fulva*.

Chemical Society, February 3.—Prof. Williamson, F.R.S., President, in the chair. Mr. Chapman read a note on the organic matters contained in the air. Some time ago the author in connection with Mr. Wanklyn and Mr. Smith, found that the smallest traces of nitrogenous organic matter in water could be detected by converting the nitrogen of the organic matter into ammonia and estimating the latter with the Nessler test. It occurred to the experimentors that the process might be extended to the investigation of the air by washing it with water. But Mr. Chapman found the operation of washing the air more difficult than he had expected. It seemed the most obvious method to draw air through water, or through some other medium which would have afterwards to be washed with water. The absorption by water alone proved insufficient. Filters of cotton wool and gun cotton acted very well; but neither of the two materials could be obtained free from traces of nitrogenous substances. Asbestos seemed to be sufficiently good; but the preparatory treatment it has to undergo before its use in the experiment, is too troublesome. Lastly, finely powdered pumice-stone was tried as a filtering medium and was found satisfactory in all respects. It has to be heated to redness before it is employed and is then moistened with some water spread over coarser pieces of pumice, which rest on wire gauze fitted into a funnel. The funnel is connected with one neck of a Wolfe's bottle, whilst the other neck is joined to an aspirator. When a sufficient quantity of air—say 100 litres—has been drawn through the apparatus, then a pumice is transferred to a retort which contains water freed from ammonia and organic matters and the operation is now proceeded with exactly as if it were an estimation of nitrogenous organic matter in a sample of water. By this method Mr. Chapman found that the air of crowded rooms contains suspended fixed organic particles, as well as volatile bases. The first can be removed by filtration through cotton wool, the latter pass through the filter and when conducted into water can be detected therein. Air collected from the neighbourhood of a sewer contained notable quantities of those volatile bases. The author thinks it would be of interest to investigate by the above-described method the air in hospitals, fever wards and the like places. With respect to the examination of the volatile bases occurring in the air, Dr. Mills suggested that the charcoal out of the "Stenhouse air filter" might furnish a good means for collecting those bases.—In another paper Mr. Chapman communicated some new reactions of alcohols. Amylic alcohol, as commonly obtained, consists of two liquids, one rotating the polarised ray, the other not. The two may be separated by distilling the mixture from soda, calcic chloride, &c. The non-rotating alcohol is retained, the rotating distills over. But by repeated distillations it was found that the rotating alcohol is converted into the non-rotating by the very treatment employed to separate the two. No difference in the physical properties of the two alcohols is perceptible. The compounds of the non-rotating liquid do not turn the ray of polarised light; those of the rotating do and that in an opposite direction to the original alcohol. These facts seem to indicate that the internal structure of organic compounds is not so permanent as the habit is of thinking them. Another observation Mr. Chapman made whilst pursuing these experiments was, that caustic soda is not merely unable to dry alcohol, as is well known, but that it actually moistens it. On proper investigation, it turned out that the sodium replaces the hydrogen of the alcohol, whilst the displaced hydrogen takes the place of the sodium in the caustic soda and thus produces water. Referring to this latter observation, the president remarked that it confirmed the idea of a double decomposition taking place when potassic hydrate is dissolved in alcohol, an idea derived from the well-known reaction of carbonic action on a solution of potassic hydrate in alcohol, whereby ethylo-potassic carbonate as well as potassic carbonate is formed.—Mr. Perkin exhibited a modification of Berthelot's method for the synthesis of hydric cyanide (prussic acid) by direct union of acetylene and nitrogen under the influence of the electric spark. Mr. Perkin takes advantage of the fact that nearly all the hydro-carbons, when submitted in the state of vapour to the action of the spark, yield more or less acetylene. Nitrogen was caused to bubble through benzole, then to pass through a globe in which the spark was discharged and thence into a solution of silver. Even after a few seconds, abundant evidence of the formation of hydric cyanide was obtained. Hydric cyanide is further produced when the spark is discharged in a mixture of ammonia-gas and ether vapour. If, however, nitrogen instead of ammonia is employed, no prussic acid is formed. Mr. Perkin's modification of Berthelot's method is well adapted for purposes of lecture demonstration.

Royal Geographical Society, January 24.—Sir R. Murchison, president, in the chair. A letter from Mr. Hayward detailing his plans of reaching the Pamir Steppe, by way of Ghilghit, was read. He expected to winter in Ghilghit and hoped to be at Lake Karakol next May; he proposed to thoroughly lay down the positions of the Pamir Steppe and the basin of the Jaxartes. An account of Easter Island, or Rapa Nui, by Mr. Palmer, R.N., was then read. The island lies in 27° 8′ 46″ S., long. 109° 24′ 36″ W., about 1,000 miles from Pitcairn. It is volcanic and contains several extinct craters, the highest point being 1,100 to 1,200 feet high. The principal craters are Te Rana Kau, the depth of which is 700 feet; Te Rano Hau, whence came the tufa of which the hats or crowns of the images are made; and Te Rana Otu Iti, where the images were sculptured of grey lava. There is no water, save in pools, which are 26 feet deep and one spring, mineral, but potable. The coast is ironbound, without harbours. The character of the natives has been much improved by the teaching of the Jesuit Fathers and they now are scrupulously honest. They are perfectly idle, content to starve rather than work; number about 900—600 women to 300 men and will probably, ere long, die out. They make and sell well-carved wooden figures, with eyeballs of obsidian, ornamented with double-headed "aronies," or birds—and other figures. They are described by all visitors as a tall, almost white, race; the women handsomer than those of the Marquesas. They are not idolatrous, but believe in a Great Spirit. The dead, swathed in grass, are laid on platforms, heads to seaward. They have a tradition that they came from Oparo. The platform for the images faced the sea, supported by a stone wall seven or eight yards high, built of dry stones six feet in length; the platform was 100 paces long and thirty feet deep, terminating landwards in a step three feet high. It was strewn with bones; all the images had been thrown down. Near that, on an area paved with large stones, stood a pillar of red tufa, six feet high, on which were two skulls, apparently twelve or fourteen years old. A place of cremation was near this. The images amount to several hundreds, some unfinished. In the crater of Otu Iti they vary in size from thirty feet (of which the head measures two-thirds) to five feet. They are marked by excessive shortness of the upper lip; the eyeballs, of obsidian, are lost; the ears display very long pendant lobes; each image has its own name; some have "hats" or crowns, some have the heads cut flat to receive them; the tools seem to have been long boulders ground down with obsidian—only one specimen was found. The paper was illustrated by numerous drawings made on the spot and enlarged pictures taken from them. Mr. Markham pointed out the resemblance between these remains and the Imarra works in the vicinity of Lake Titicaca, in Peru and advocated the theory that this island had been a stepping-stone for the successive arrivals of immigrants into Peru and perhaps revered as a holy isle whither the Incas sent ships. The Peruvian images were dispersed like those of Easter Island, as though walking through the country; the present islanders were simply Polynesians and probably not descendants of the sculptor-race. Mr. Franks pointed out the resemblance of some peculiarities in the wooden figures now made and the stone images; at the same time the wooden figures brought home by Cook and now in the Museum, differed materially from those brought in 1840—the change of style, therefore, would not imply a change of race. The want of forest timber might have occasioned the employment of the soft volcanic tufa and a long lapse of time would account for the numbers of images found. Sir G. Grey stated that all Polynesians were addicted to carving—if the wooden figures carved in New Zealand had not decayed there would be now thousands of them; there were in these islands traditions of stone figures brought from other islands. Mr. Palmer said, in reply, that he had not formed any theories on the subject; but only recorded what he saw; the people had all been withdrawn to the settlement in consequence of the Peruvians having kidnapped some hundreds to work the guano deposits.

Anthropological Society of London, February 1.—Captain Bedford Pim, R.N., V.P., in the chair, "On the negro slaves in Turkey," by Major Frederick Millengen, F.R.G.S. The author exposed first the particulars connected with the sale of negro slaves in Mussulman countries, then described the condition of negroes in Turkey and concluded by some general observations. The negroes imported into the Sultan's dominions come from the countries situated on the higher basin of the Nile; and though that valley is the route followed by the cargoes of slaves on their way to the markets, numbers of secondary channels exist, through which slave-dealers convey their merchandise. The causes of the supply are the feuds of the negro races, the causes of demand are that slavery is inherent in the religious system of Mussulman nations, inherent in their social system and congenial to their ideas and manners. The author considered that Sir Samuel Baker's expedition to put a stop to the slave trade must end in failure; and he quoted the speech of Lord Houghton plainly avowing the disappointment felt by his friend Sir Samuel Baker on seeing the Mussulmans hostile to his scheme. In conclusion, the author said that, if the Sultan and Khédive really intend doing away with slavery, they have nothing else to do but to open wide the gates of their harems.

DUBLIN

Natural History Society, February 2.—Mr. R. P. Williams in the chair. Dr. A. W. Foot exhibited a young bitch terrier suffering from goitre and made a few remarks on the subject of goitre in animals. The list of animals affected with this complaint includes the lion, hyæna, racoon, monkey, cat, dog, horse, mule, pig, cow, sheep and mouse. The geological conditions which appear to be connected with the occurrence of this disorder in animals were discussed and commented upon. —Prof. Macalister read a paper "On some points in the anatomy of the sartorius muscle." - Dr. A. W. Foot exhibited thirteen species of dragon flies, collected during the past summer in the county of Wicklow: *Agrion elegans, minium, pulla, cyathigerum; Lestes nympha, Calypteryx virgo, splendens, Æschna pratensis, juncea, grandis, Libellula quadrimaculata, striolata* and *cærulescens.*

MANCHESTER

Literary and Philosophical Society, January 25—J. P. Joule, LL.D., F.R.S., &c., president, in the chair.

"On organic matter in the air." By Dr. R. Angus Smith, F.R.S., &c. In referring to the new experiments by Prof. Tyndall on this subject, the author mentioned that he had long ago proved the existence not only of inorganic and organic material; but also of organised bodies in the atmosphere. He did not claim to have originated the idea that this is the case; but rather to have furnished proof and quantitative demonstration of the fact, as far back as 1846, when he brought a notice of the subject before the Chemical Society and, in 1848, in a report to the British Association; having also followed up the inquiry since then, in conjunction with Mr. Dancer and published his results at various times. In conclusion he says we must not be panic-stricken because of the presence of organised germs in the air. Some are hurtful; but it may be that others are required for the maintenance of healthy animal life exactly as in vegetable fermentation.

Prof. Williamson exhibited some specimens affording additional information as to the organisation of calamites. Through Mr. Butterworth he had succeeded in obtaining examples whose structure was intermediate between calamodendron and calamopitus. In the general arrangement of separate parts the new specimens corresponded closely with the type figured by Mr. Binney; but they differ in two important particulars. All the fibro-vascular tissues are of the reticulate type seen in calamopitus and dictyoxylon, with a few scalariform vessels here and there. The cellular laminæ separating the vascular wedges exhibit remarkable variations even in the same specimen; the cells being sometimes elongated into vertical forms of prodenchyma—sometimes extended transversely and still more frequently they consist of ordinary parenchyma. In some the fibro-vascular tissues of the wedges are separated by masses of cellular tissue, both at the nodes and internodes. These tissues, or modified medullary rays, are so numerous in one example, that more than two vertical vessels can scarcely be found in contact without the intervention of one of these vertical rows of mural cellular tissue. In other specimens these medullary rays are much more scanty, as if connecting the type under consideration with that figured by Mr. Binney. In these new examples, the verticillate medullary radii of calamopitus are wholly wanting. Additional proof is thus afforded that all three of the types may be only variations of the common calamodendron and it thus becomes more demonstrable that in the Lancashire coal-field, at least, we have no evidence of the existence of an equisetiform type of calamite distinct from the calamodendroid one. The author further announced the discovery by Mr. Butterworth of a young calamite in which the vertical layer is well preserved, presenting a parenchyma of somewhat remarkable structure and of a thickness equal to the ligneous zone which it invests. Its further description will be given after investigation.

"On the so-called molecular movements of microscopic particles." By Professor Stanley Jevons, M.A. In studying the phenomenon first pointed out by Robert Brown in 1827, the author found that silicates appeared to be generally the most active substances in this respect, pure quartz crystal in fine powder maintaining rapid oscillation: but charcoal, red phosphorus, antimony and sulphur were also very active. Metallic oxides and earthy salts, such as carbonate of lime, appeared to be less active; but it cannot be said any substance is free from such motion. On varying the liquid, however, by dissolving salts in it, the fact became apparent that pure distilled water gave rise to the greatest activity. The motion appeared to be closely connected with the suspension of fine powder in water, a fact already noticed by Dujardin.* All acids, alkalis, or salts which checked the motion were found to facilitate the subsidence of suspended material. Gum arabic, on the contrary, prevents subsidence and it has a remarkable power of exciting the molecular motion. The author was soon convinced that the motion was due to electrical action, by the close analogy with the circumstances under which electricity is produced by the hydro electric machine, pure water alone producing much electricity, while almost any salt, acid, or alkali prevented the action by rendering the water a conductor. Ammonia, however, is a remarkable exception in this respect and it does not stop the molecular motion or facilitate subsidence of suspended material. Boracic acid, likewise, is a non-conductor and does not cause subsidence.

However, acetic acid, which Faraday stated did not render water a conductor, does, in common with other vegetable acids, occasion subsidence. It is probable that silicic acid does not render water a conductor, since silicate of soda tends to increase the molecular motion rather than otherwise and this is another exception to the general influence of soluble substances in causing subsidence.

The author is of opinion that this motion of suspended particles is closely connected with the phenomena of osmose as a case of action and reaction; for, if a liquid be capable of impelling a particle in a given direction, the particle, if fixed, would be capable of impelling the liquid in an opposite direction with an equal force. The earthenware jars used by Graham were composed of a substance highly active under the microscope, and the fact that osmose is chiefly an affair of very dilute solutions, certainly accords with the electric origin of the molecular motion, which the author considered to be established experimentally, pointing to the experiments of Wiedemann on electric osmose as suggesting a speculative explanation. Solid particles of organic substances also exhibit the motion; albumen, distrin, sugar, starch-solution, alcohol, &c., have little power to arrest the motion. The author thinks it not unlikely that, when these phenomena are fully investigated, they will give strong support to the theory lately put forward by Becquerel, that the movements of liquids in animals and plants are really due to electric action. Mr. Dancer stated that particles approaching to a spherical form showed the greatest activity with some few exceptions, as in the case of sublimed mercury and sulphur. He did not regard electric action as a satisfactory explanation of the phenomenon, and thought the results of many experiments pointed to heat as a probable cause.—"On a general system of numerically definite reasoning," by Prof. W. Stanley Jevons, M.A. The substance of this paper was given in the report of the Royal Society's proceedings for January 20.

LIVERPOOL

Naturalists' Field Club, January 14.—The Rev. H. H. Higgins, president, in the chair. The President informed the members that Mr. H. S. Fisher was in communication with some botanists in the south of England, with the view of obtaining exchanges of specially local plants and that he had been successful in supplying a gentleman in Cornwall with fifty or sixty specimens of plants, placed in a list of desiderata forwarded by him—among them *Centaurea latifolia*—a plant peculiar to Crosby in this neighbourhood. He also mentioned that he had witnessed the phenomenon known as the Zodiacal Light at Rainhill on the 19th of December last, at 4.25 P.M. In substance, but not in form, it resembled the tail of a comet.—Mr. Gibson then read a

* Manuel Complet de l'Observateur au Microscope. Paris: 1843, p. 60.

short paper on the Parasitic character of *Pyrola rotundifolia*—Wintergreen—and stated his belief, founded on minute personal investigation, that it *is* Parasitic on the root of the dwarf willow, *Salix repens*. He never found Pyrola where the willow was absent and in some cases he detected the fibrous roots of the Pyrola apparently growing on those of the willow.

BRIGHTON

Brighton and Sussex Natural History Society, January 13.—The president, Mr. T. H. Hennah, in the chair. The receipt of a copy of a paper by Mr. C. Roper, on the Decapod Crustacea found at Eastbourne, was announced.—Mr. J. E. Mayall communicated a note on what he believed to be a new fact in connection with coal gas. While engaged in the spectrum analysis of organic bodies, he had found his results interfered with by the presence of copper. Examining the solutions and no trace of copper being found, it occurred to him that it might be present in the common coal gas used in the Bunsen lamp, in which the incandescence of the organic matter was produced. Having candles with wicks dipped in the chlorides of various metals always at hand as standard spectra, on comparing the flame of a copper candle with that of the gas under examination, their spectra were found to be identical. From this he inferred the copper was generated from pyrites contained in the coal. Mr. J. E. Mayall then read a paper on Volcanic Theories.

PARIS

Academy of Sciences, January 24.—M. Lecoq de Boisbandeau communicated a note on the continuity of luminous spectra, in which he developed his theory of the production of spectra by inequalities in the luminous molecules, and referred especially to the phenomena presented by rubidium, cæsium, and potassium.—At this meeting there were no other papers on subjects of any special importance.

January 31.—M. Vérard de Sainte-Anne read a Memoir on a project for establishing a communication between France and England. The author proposes the establishment of a railway bridge, either open or tubular, across the Straits of Dover. A continuation of M. J. Boussineq's memoir on the theory of the flow of a liquid through an orifice in a thin partition was presented by M. de Saint-Venant.—M. Gaiffe communicated a letter containing remarks on the process employed by Mr. Adams to produce deposits of nickel by electrolytric action, in which he maintained that the neutral chloride and sulphide of nickel and ammonia with no trace of free fixed alkali can alone furnish workable baths.—M M. Becquerel maintained that the presence of soda and potash does not hinder the deposition of the nickel.—M. A. Lallemand stated that when a solution of sulphur in sulphide of carbon is exposed to solar light concentrated by a lens, insoluble sulphur is produced: the spectrum of the emergent light is deficient in all the rays between G and H and the ultra-violet spectrum has entirely disappeared. A solution of phosphorus in sulphide of carbon is similarly acted upon.—M. Cahours presented a note by M. L. Daniel, giving an account of some interesting experiments with vacuum-tubes under the influence of magnetism. — A note on the heat of combination of boron with chlorine and with oxygen, by MM. L. Troost and P. Hauteville, was presented by Mr. H. Sainte-Claire Deville, who also communicated a paper by Mr. Landrin on the division of a limited quantity of acid between two bases employed in excess. From his experiments it appears that the oxides are dissolved in simple equivalent proportions, *i.e.*, 1 to 2, 3, 4, 5, &c.—A note by M. E. Bourgoin on the cause of the unequal loss of oxalic acid at the positive and negative poles and on the nature of oxalic acid when dissolved in water, was presented by M. Bussy. The loss by decomposition is three times as great at the positive as at the negative pole; the gas disengaged at the former is pure carbonic acid, at the latter hydrogen. The author concludes that the composition of oxalic acid in solution in water, is $C^4 H^2 O^8$, 2 H^2, O^2.—M. C. Dareste read a paper on the convolutions of the brain.—M. P. Gervais presented a reply to the observations of M. Balbiani on the ova of the *Sacculinæ*, by M. E. Van Beneden and M. A. L. Donnadieu noticed a case of monstrosity (hemiterism) in a carp.—M. A. Chatin communicated a note on the cause of the dehiscence of the anthers of plants, in which he denies that this phenomenon is due exclusively to the fibrous cells of the endothecium as supposed by Purkinje and shows that in some cases certainly and in many others probably, the exothecium or epidermic layer plays an important part in it.

DIARY

THURSDAY, FEBRUARY 10.

ROYAL SOCIETY, at 8.30.—On some remarkable Spectra of Compounds of Zirconia and the Oxides of Uranium: H. C. Sorby, F.R.S.—On the Mathematical Theory of Stream Lines, especially those with four foci and upwards: Professor Rankine.—On Linear Differential Equations: W. H. L. Russell, F.R.S.
MATHEMATICAL SOCIETY, at 8.—Quartic Surfaces: Prof. Cayley.
ZOOLOGICAL SOCIETY, at 8.30.—On a new Cervine Animal from the Yang-tze-Kiang: R. Swinhoe.—On the Size of the Red Corpuscles of the Blood of *Moschus, Tragulus, Orycteropus, Ailurus* and some other mammalia, with historical notices: G. Gulliver.
ANTIQUARIES, at 8.30.
LONDON INSTITUTION, at 7 30.

FRIDAY, FEBRUARY 11.

QUEKETT MICROSCOPICAL CLUB, at 8.—For exhibition of objects and microscopic gossip.
ROYAL INSTITUTION, at 9.—The Deep Sea: Dr. Carpenter.
ASTRONOMICAL SOCIETY, at 3.—Anniversary Meeting.

SATURDAY, FEBRUARY 12.

ROYAL BOTANIC, at 3.30.

MONDAY, FEBRUARY 14.

MEDICAL SOCIETY, at 8.
ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.

TUESDAY, FEBRUARY 15.

ANTHROPOLOGICAL SOCIETY, at 8.—On the Aborigines of the Chatham Islands: Dr. Barnard Davis and A. Welch.—Polygamy: Dr. John Campbell.—Inscribed Stone from Venezuela: R. Tate.
PATHOLOGICAL SOCIETY, at 8.
STATISTICAL SOCIETY, at 8.—On International Coinage and the Variations of Foreign Exchanges during recent years: E. Seyd.
INSTITUTION OF CIVIL ENGINEERS, at 8.
ROYAL INSTITUTION, at 3.—On the Architecture of the Human Body: Prof. Humphry.

WEDNESDAY, FEBRUARY 16.

SOCIETY OF ARTS, at 8.—On Emigration: T. Plummer.
METEOROLOGICAL SOCIETY, at 7.

THURSDAY, FEBRUARY 17.

ROYAL INSTITUTION, at 3—Chemistry: Prof. Odling.
LINNEAN SOCIETY, at 8.—On the Tree Ferns of British Sikkim: Mr. Scott.
CHEMICAL SOCIETY, at 8.
ZOOLOGICAL SOCIETY, at 4.
ANTIQUARIES, at 8.30.
ROYAL SOCIETY, at 8.30.

THE MEASUREMENT OF GEOLOGICAL TIME

I.

MODERN geological research has rendered it almost certain, that the same causes which produced the various formations with their imbedded fossils, have continued to act down to the present day. It has therefore become possible that, by means of changes which are known to have occurred in a given number of years, some measurement of the time represented by the whole series of geological formations might be obtained. It is true, that changes in the earth's surface, the records of which constitute the materials for geological research, occur very slowly, yet not so slowly as to be quite imperceptible in historical time. Land has risen or sunk beneath the sea, rivers have deepened their channels and have brought down sediment which has converted water into land, cliffs have been eaten away and the surface of the earth has been, in many ways, perceptibly and measurably altered during an ascertained number of centuries. But it is found that these changes are too minute, too limited and too uncertain, to afford the basis of even an approximate measurement of the time required for those grand mutations of sea and land, those contortions of rocky strata many thousands of feet thick, those upheavals of mountain-chains and that elaborate modelling of the surface into countless hills and valleys, with long inland escarpments and deep rock-bound gorges, which form the most prominent and most universal characteristics of the earth's superficial structure. Another deficiency in this mode of measurement arises from the fact, now universally admitted, that the record of past changes is excessively imperfect, so that even if we could estimate with tolerable accuracy the time required to deposit and upheave the series of strata of which we have any knowledge; still that estimate would only represent an unknown proportion, perhaps a minute fraction of the whole time which has elapsed since the strata began to be formed.

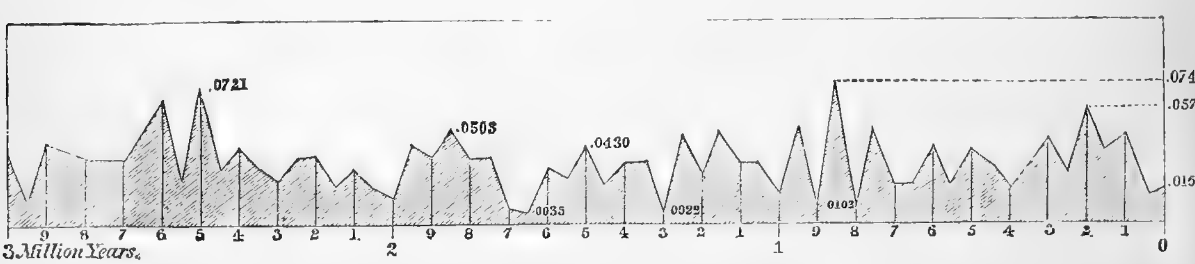
But there is another class of geological phenomena which enable us to measure those very gaps in the record of which we have just spoken, and it is now generally admitted that the continual change of the forms of animal and vegetable life which each succeeding formation presents to us, affords the best means of estimating the proportionate length of geological epochs. Though we have no reason to think that this change was at all times effected by a uniform and regular process; yet believing, as we now do, that it was due to the action of a vast number and variety of natural causes acting and reacting on each other, according to fixed general laws, it seems probable that, with much local and temporary irregularity, there has been on the whole a considerable degree of uniformity in the rate at which organic forms have become modified. It may indeed be the case that this rate of variation has continually increased or diminished from the first appearance of life upon the earth until the present day, or has been subject to temporary changes; but so long as we have no proof that such was the case, we shall be safer in considering that the change has been tolerably uniform.

To measure geological time, therefore, all we require is a trustworthy unit of measurement for the change of species: but this is exactly what we have not yet been able to get; for the whole length of the historical period has not produced the slightest perceptible change in any living thing in a state of nature. Moreover, though, the much longer time that has elapsed since the Neolithic or Newer Stone age, has been sufficient for some changes of physical geography and has, to some extent, altered the distribution of animals and plants, it has not effected any alteration in their form. It is only when we get back to the Palæolithic or Older Stone age, when men used chipped flints for weapons and Europe was, probably, either just emerging from the severity of the glacial epoch, or in some of the intercalated milder periods, that we meet with a decided change in the forms of life. Elephants and rhinoceroses, bears, lions and hyenas then inhabited Europe; but they were nearly all of species slightly different from any now existing, while the reindeer, the musk-sheep, the lemming and some other animals, were the same as those that still live in the Arctic regions: all the mollusca, however, were identical with living species. In the newer Pliocene Crag, on the other hand, which seems to have been deposited just as the glacial epoch was coming on, there are 11 per cent. of extinct species of shells and about 55 per cent. of extinct mammalia. What we want, therefore, is to be able to estimate, by means of the physical changes before alluded to, the time since the beginning or the end of the glacial epoch. Then we should have the unit we require for measuring geological time by the repeated changes in the forms of life as we go further and further back into the past; but before showing how this may perhaps be done, something must be said about physical and astronomical determinations of the age of our globe.

A few years ago, Sir W. Thomson startled geologists by placing a limit to the time at their disposal, which they had been in the habit of regarding as practically infinite. He showed, from the known laws of heat and the conservation of energy, that there are determinable limits to the age of the sun. Then, applying the same principles to the earth, he showed that, from the known increase of heat towards its interior and from experiments on the rate of cooling of various rocks, it cannot have existed in a habitable state for more than about one hundred million years. It is within that time, therefore, that the whole series of geological changes, the origin and development of all forms of life, must be comprised. But, geologists had been accustomed to demand a much vaster period than this for the production of the series of fossiliferous deposits in the crust of the earth; while the researches of Mr. Darwin render it almost certain that, however vast the time since the Silurian and Cambrian epochs, yet anterior to these, at least an equal, and probably a much longer, series of ages must have elapsed since life first appeared upon the earth, in order to allow for the slow development of the varied and highly organised forms which we find in existence at those early epochs. Sir Charles Lyell is not disposed to admit the accuracy of these calculations, and Professor Huxley has criticised them in detail, with a view of showing that they are, in many respects, unsound; while Mr. Croll as strenuously maintains that they are sound in principle and accurate within certain limits.

We have now to consider the bearing of Astronomy upon the problem. In a series of admirable papers in the *Philosophical Magazine*, Mr. Croll has fully discussed the question, how far variations in the excentricity of the earth's orbit, together with the precession of the equinoxes, have produced variations of climate in past ages. He has endeavoured to show that the date of the last glacial epoch and those preceding, may be determined by such considerations. With this view he has laboriously calculated tables showing the amount of excentricity for a period of three million years, at intervals of 10,000 years for a large portion of that time, and 50,000 for the remainder. These tables show that the amount of excentricity is alternately great and small at intervals of 50,000 or 100,000 years, as represented with sufficient accuracy in the diagram, which I have constructed by means of his figures. Owing to the precession of the equinoxes, combined with the revolution of the apsides, either pole will be presented towards the sun (constituting summer in that hemisphere and winter in the opposite one) at a different point in the earth's orbit on each succeeding year, the motion being such as to cause a complete revolution in 21,000 years. If, therefore, at any one period, winter in the northern hemisphere occurs when the earth is nearest the sun or in *perihelion* (as is the case now), in 10,500 years it will occur in *aphelion*; at the one period the winters will be shorter and warmer, at the other longer and colder. When the excentricity is great (say two, three, or four times what it is now), million years probably includes a large portion of the tertiary period, which therefore should have mainly consisted of alternations of warm and cold climates in each hemisphere, the latter generally forming true glacial epochs. This seems the legitimate deduction from Mr. Croll's reasoning and from the tables of excentricity with which he has furnished us; but, as he very justly argues, we cannot expect to find geological evidence of all these changes of climate. The warm and temperate periods will naturally leave the best records, while the cold epochs will generally be characterised only by an absence of organic remains. Besides, we must consider 10,500 years as a very small fragment of time in geology and we have good reason for thinking that several such periods might pass away without the occurrence of those exceptional conditions which Mr. Darwin and Sir C. Lyell have shown to be necessary for the preservation of any geological record. As to physical proofs of ice-action, very few could survive the repeated denudations, upheavals and subsidencies, which the surface must have undergone since any of the earlier glacial epochs; so that it may be fairly argued that these repeated changes of climate may have occurred and yet have left no distinct record by which the geologist could interpret their history.

Throughout the whole of his argument, Mr. Croll considers astronomical causes to be the most important



Mr. Croll shows that, from the known laws of heat in reference to air and water, winter in *aphelion* will lead to an accumulation of snow, in the polar regions, which the summer will not be able to melt. This will go on increasing for many thousand years, till winter occurs near the *perihelion*, when the snow will be melted and transferred to the opposite pole. When the excentricity was very great a glacial epoch would occur in each hemisphere for more or less than 10,500 years, the other portion of the period of 21,000 years being occupied by an almost perpetual spring, with two transition periods from that to the glacial epoch. By examining the diagram of excentricity, we see that during the last three million years there have been more than twelve periods of great excentricity, each long enough to admit two or three, and several of them eight or ten, complete revolutions of the equinoctial points, thus sufficing for the production of not less than fifty or sixty glacial epochs in each hemisphere, with intervening phases of perpetual spring or summer.

The diagram also shows us (and this is of very great importance) that the present amount of excentricity is exceptionally small. During the last three million years there have only been five occasions, always of very short duration, when it has been less than it is now, while periods of high excentricity have often lasted for two hundred thousand years at a time. This period of three and effective agents in modifying climate, while Sir Charles Lyell maintains that the distribution of land and water, with their action on each other by influencing marine and aerial currents, are of prepondering importance. He has certainly shown that these causes have an immense influence at the present time. The effects which, on Mr. Croll's theory, ought to be produced by the existing phase of precession combined with even the small amount of excentricity that now exists, is not only neutralised, but actually reversed by terrestrial causes. Dove has shown that the whole earth is really warmer when it is furthest from the sun in June, than when it is nearest in December, a fact which is to be explained by the northern hemisphere (turned toward the sun in June) having so much more land than the southern. So, the northern hemisphere being three millions of miles nearer the sun in winter than in summer, while the southern hemisphere is the reverse, the northern winter ought to be warmer and the northern summer cooler than the southern; but this, too, is the opposite of the fact, for the southern summer is more than 11° Fahr. cooler than ours, while its winter is nearly 5° Fahr. warmer. The immense differences of temperature of places in the same latitude, sometimes amounting to nearly 30° Fahr., can also be traced, in almost every instance, to the distribution of land and water and of winds and currents. Sir Charles Lyell further argues that the existing distribution of land is so extremely irregular—such an undue proportion being near the poles, while there is such a deficiency at the equator and in the south temperate zone—that whatever differences may have occurred in past time, they can hardly fail to have often been such as to cause a more uniform climate. Therefore he believes that if the poles were tolerably free from land, so as to admit of the uninterrupted circulation of the warmer equatorial waters and to afford no lodgment for great accumulations of snow and ice, a glacial epoch would be impossible even during the most extreme phases of excentricity.

We have now much evidence to show that three distinct modifications in physical geography occurred just before or during the Glacial epoch, which would each tend to lower the temperature. The first is the submergence of the Sahara, which would have caused the southerly winds to be charged with aqueous vapour, condensing on the Alps into snow instead of being, as now, dry and heated and acting powerfully to melt the glaciers. The second is the submergence of Lapland, which would have admitted the cold iceberg-laden waters of the Arctic Sea into the very heart of Europe. The third is the probable submergence of part of Central America, causing the Gulf Stream to be diverted into the Pacific. The only proof of this is the fact that one-third of the known species of marine fishes are absolutely identical on the two sides of the isthmus of Panama; but it is impossible to conceive any means by which such an amount of identity could have been brought about except by a recent, if only a temporary, communication. A subsidence and elevation no greater than what occurred in Wales about the same time—as proved by Arctic shells of existing species in drift 1,300 feet above the sea—would have effected the communication by a broad and deep channel. Now if any two of these changes of physical geography occurred together, we may be sure that a very small increase of excentricity would have led to a more severe glacial epoch than would be possible, under existing conditions, with a much larger excentricity. We must keep this in mind when attempting to fix the most probable date for the last glacial epoch. A. R. WALLACE

FARADAY

The Life and Letters of Faraday. By Dr. Bence Jones. Two vols. 8vo. (Longmans, 1869.)

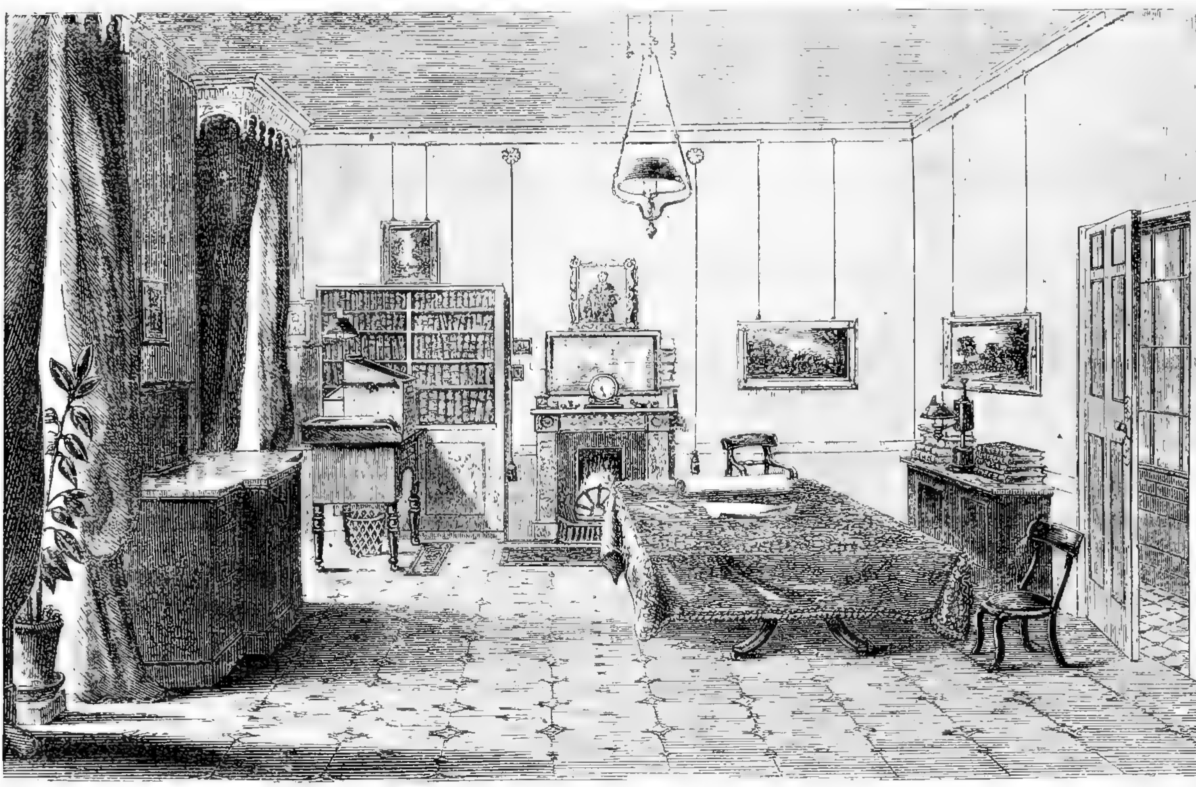
IF none but Apelles was fit to paint Alexander, where shall we find a biographer worthy of Faraday? Shortly after his death, many sketches of his character and work appeared, among which that of De la Rive may be specially mentioned. These were succeeded by Tyndall's two Friday evening discourses on "Faraday as a Discoverer," which were afterwards embodied in an admirable little book. But a more complete biography was wanted, and the question was frequently asked, "Who understood him sufficiently well to draw his portrait?" Eventually it was rumoured that the materials had been placed in the hands of Dr. Bence Jones. First there appeared an unusually long obituary notice in the Proceedings of the Royal Society, consisting of little else than a catalogue of the papers published, lectures delivered, reports written and honours won by the great philosopher in each year during half a century; showing that Dr. Jones had a rare collection of interesting documents, so as to whet our appetite for the coming work. Now it is before us—"The Life and Letters of Faraday"—in two goodly octavo volumes.

The preface tells us what we are to expect: not a complete likeness either of the man or of the philosopher; but a kind of "autobiography"—for, as the author truly says, "from his letters, his laboratory note-books, his lecture-books, his Trinity-house and other manuscripts, I have arranged the materials for a memorial of Faraday in the simplest order, with the least connecting matter." The very abundance of that material was a source of embarrassment, and the necessity for omissions seems to have been felt more strongly as the work advanced; so that while very nearly half the first volume is devoted to three years of Faraday's life—when he was between twenty and twenty-three years of age and before his "earlier scientific education at the Royal Institution" commenced—the latter years of his life are so rapidly passed over, that some of his latest scientific work—for instance, the adjustment of apparatus in lighthouses—is not even alluded to.

An autobiography has great advantages, especially when it is, as in this instance, an unconscious one; but it is not without its defects. It gives a picture only from one point of view, and Faraday was too modest always to do himself justice. We want to know what impressions other people formed of him, and those who have enjoyed his company would wish to find, in the book, some reflex of his own brightness, some of those characteristic anecdotes which are told in scientific circles. The best, almost the only sketch of this kind in the book, is by one of his nieces, Miss Reid, who gives charming details of her uncle's treatment of her when a little girl, and of his habits both at work and play. Tyndall's book, though professing to describe Faraday only as a discoverer, gives a far more vivid impression of the man. I propose at some time to write down my own reminiscences of him; but at present there is not room to deal with more than the way in which he is presented to the world in the "Life and Letters."

The career of Michael Faraday was marked by steady progress rather than by striking events; there were few changes in his life save such as rose naturally from his increasing knowledge and ever-growing fame. We find him born in London in 1791, of poor parents, taught little more than the rudiments of reading, writing, and arithmetic; beginning active life as an errand-boy at a bookseller's in Blandford Street, and shortly afterwards apprenticed to a bookbinder. Here, however, we see him taking every opportunity of gaining knowledge, making experiments in natural science, and presently, on introducing himself to the notice of Davy, obtaining the post of assistant in the laboratory of the Royal Institution. That was in March 1813. His travels with Sir Humphrey about the Continent, for a year and a half, are minutely described in copious extracts from his diary and his letters home: we see here how he came into contact with many other bright intellects, and learned what to copy and what to avoid. In 1816, at the City Philosophical Society, he gave his first lecture, and, in the *Quarterly Journal of Science*, he published his first paper—on native caustic lime—the beginning, in each case, of a series which for many years delighted and instructed his contemporaries. In 1821 commenced his happy domestic life, through his marriage with Miss Sarah

Barnard. Immediately afterwards he became a member of the Sandemanian Church, in which eventually he held the office of elder, and frequently preached. When he was appointed Director of the Laboratory at the Royal Institution, in 1825, his first act was to invite the members to evening meetings with experimental demonstrations, thus commencing the Friday evening discourses, while in the same year he started the juvenile lectures at Christmas. Eight years afterwards he was appointed Fullerian Professor of Chemistry. He continued to discharge these various duties at Albemarle Street till failing health rendered it impossible. During this time we see Faraday working often for the Government and regularly for the Trinity House, while the researches in his laboratory were never intermitted, except through illness. To enumerate his investigations here would be out of the question, but all students of science will remember something of what he accomplished in the liquefaction of gases, the preparation of steel and optical glass, the ventilation of lighthouses, and, especially, that magnificent series of researches in electricity which extended from 1831 to 1855, comprising the induction of electric currents, the evolution of electricity from magnetism, the explanation of the voltaic pile, with the definiteness of electro-chemical decomposition, the influence of magnetism on a ray of polarised light, diamagnetism, the polarity of bismuth and other crystalline bodies, the effect of heat on magnetic force, as well as the mutual relation of these various powers of nature.



FARADAY'S ROOM AT THE ROYAL INSTITUTION

These discoveries were made known principally in the "Philosophical Transactions," extending his reputation so much that, though living in great simplicity, his friendship was desired by the great as well as by the wise of the earth. He received unsought no fewer than ninety-five honorary titles and marks of merit, while both the Royal Society and the Royal Institution in vain requested him to become their president.

The book consists in a great measure of Faraday's own words; to a few intimate friends, as Mr. B. Abbott, Huxtable, his wife, Schönbein, and De la Rive, both father and son, he poured out his thoughts in a rich stream. From these various writings it is very tempting to make extracts. Here are two or three:—

"The philosopher should be a man willing to listen to every suggestion, but determined to judge for himself. He should not be biassed by appearances; have no favourite hypothesis; be of no school and, in doctrine, have no master. He should not be a respecter of persons, but of things. Truth should be his primary object. If to these qualities be added industry, he may indeed hope to walk within the veil of the Temple of Nature."

"When a mathematician engaged in investigating physical actions and results, has arrived at his own conclusions, may they not be expressed in common language as fully, clearly, and definitely as in mathematical formulæ? If so, would it not be a great boon to such as we to express them so—translating them out of their hieroglyphics that we also might work upon them by experiment? I think it must be so, because I have always found that you could convey to me a perfectly clear idea of your conclusions, which, though they may give me no full understanding of the steps of your process, gave me the results, neither above nor below the truth, and so clear in character that I can think and work for them."

"I do think that the study of natural science is so glorious a school for the mind, that with the laws impressed on all created things by the Creator and the wonderful unity and stability of matter and the forces of matter, there cannot be a better school for the education of the mind."

his imagination,—as a man, truthfulness, kindness, and energy. He speaks also of the great influence of religion on his character.

To form a complete conception of Faraday we must picture him calmly, patiently, and honestly asking questions of nature in his laboratory, and following up the intuitions of his genius; now chatting with his friends in a strain of kindly sympathy or genial playfulness, then giving forth the results of his own or others' discoveries to large and rivetted audiences with perfect simplicity of thought and language; experimenting before them with marvellous dexterity; writing learned papers and inventing useful applications; but ever enriching mankind both by the wealth of his discoveries and the beauty of his example.

BOOKSELLER'S SHOP IN BLANDFORD STREET WHERE FARADAY WAS APPRENTICED

For giving us this correspondence we owe no small debt of gratitude to Dr. Bence Jones, who has also enriched the biography by letters which Faraday received on various occasions from many eminent men. In conclusion he enumerates what he conceives to be the chief characteristics of the subject of his memoir: as a philosopher, the trust which he put in facts, and the power of

OUR BOOK SHELF

Sorghum and its Products.—*An Account of recent Investigations concerning the Value of Sorghum in Sugar Production, &c. &c.* By F. L. Stewart. (Lippencott: Philadelphia. 8vo. 1869. London: Trübner.)

Mr. STEWART informs us that sorghum was introduced in 1854 into the United States from France, whither it had been carried from China. It is now grown on a large scale and quite successfully, in North America. The little treatise now before us is intended as a manual for the manufacture of syrup and sugar from this plant: the author has divided his work into thirty chapters, treating consecutively of the history and cultivation of the sorghum, the extraction of sugar from it and the mode of utilising the various waste products obtained.

Mr. Stewart's manual may be read with interest, not only by manufacturers—who will find it most practically written—but by all who feel a pleasure in the success of economic chemistry. The author does not, however, carry his description so far as the final stage of a finished process. He seems to have contented himself with writing merely for farmers of about 75 acres, and instructing them how to prepare on their own land "a golden syrup, unexcelled either in colour or flavour by the best products of the refineries" (p. 153), or "a fair yellow sugar." This is not the proper condition of a great national industry. The successful manufacture of sugar, indeed, can hardly be attained without the concentrated effort of a large capital, aided, even then, by considerable special knowledge. The class of cultivators described by the author would consult their own advantage by contenting themselves with the humbler office of contributing the raw material.

Vegetable Essences.—*Die Pflanzenstoffe* in chemischer physiologischer, pharmakologischer, and toxicologischer Hinsicht. Bearbeitet von Dr. Aug. Husemann und Dr. Theod. Husemann. Erste Lieferung; Bogen 1—16. (Berlin: Springer, 1870. London: Williams and Norgate.)

THE first section of an important work on those products of the vegetable kingdom which are of importance to the chemist, the physiologist, and the physician. These substances the MM. Husemann classify as follows:—A, Simple combinations; (1) Bases or alkaloids; (2) Acids, both those of general distribution and those of special development; (3) Neutral substances, with the same distinction. B, Compound substances; (1) Volatile oils; (2) Resins; (3) Fats. In each section the substances are arranged under the natural orders to which the plants belong; and we have an account of their discovery, mode of preparation, properties, composition, products of decomposition, behaviour with various reagents, and physiological and toxological effects. The present part does not exhaust the alkaloids.

A. W. B.

ON THE DAILY LABOURING FORCE OF THE HUMAN HEART

II.

IT remains for me to explain the manner in which the two elements of the calculation of the daily labouring force of the heart (see p. 255) have been ascertained. These elements are, the capacity of the left ventricle of the heart, and the hydrostatical pressure of the blood inside the ventricle at each pulse.

The average capacity of the left ventricle is ascertained by filling it with melted wax, at a pressure equivalent to that of 9 ft. vertical, of blood; and afterwards weighing the solidified wax cast of the ventricle and comparing its weight with that of a known volume of the same wax. In this manner, it has been found that the average capacity of the left ventricle does not differ much from 3 ounces.

In the unavoidable absence of any direct experiment on the hydrostatical pressure of the blood in human arteries, we are obliged to have recourse to indirect methods of estimating its amount. The first attempt made by me was the following:—On the 22nd of March, 1863, I had an opportunity of witnessing the removal of a large fibro-cellular tumour from the left groin of a middle-aged, large sized man, in the operating theatre of the Meath Hospital. In the course of the operation, the external epigastric artery (which appeared enlarged to feed the tumour) was divided, and before it could be ligatured, strong jets of blood were thrown from it in various directions about the floor of the theatre. I noticed, as the poor fellow struggled on the operating table, that the jets of blood fell short, or enjoyed a longer range, according to the angle of elevation of the orifice of the bleeding artery, and that there was a certain maximum range on the floor of the theatre, which was not exceeded. Having afterwards measured the vertical height of the bleeding artery, and the horizontal distance of the squirts of blood corresponding to the maximum range, I found them to be 3 ft. 6 in. and 8 ft. respectively. From these *data*, I readily calculated (by the parabolic theory of maximum range of projectiles on a descending inclined plane) the velocity of the blood issuing from the orifice of the artery, and found it to be 12·905 ft., corresponding to an hydrostatical pressure of 2·586 ft.

This result, although of great value, leaves us still in ignorance of the hydrostatical pressure of the blood inside the arteries when they are intact; for, owing to the wonderful perfection of the mechanism of the heart, its force of contraction is exactly regulated by the resistance it is compelled to overcome, and as soon as a large artery is opened, the heart instinctively feels that the resistance is lessened, and spontaneously reduces its force of contraction, to correspond with the diminished resistance of the circulation. The beneficial effects of this remarkable property of the heart, in the case of wounded arteries, are evident, for its reduced force of contraction greatly diminishes the loss of blood.

Dr. Hales, in the course of his Hæmastatics, remarks that the blood did not spout much higher than 2 feet from the wounded artery of the horse, although the pressure inside the arteries, when the circulation is complete, exceeded 9 feet of blood. The difference in the force of the heart in the two cases arises from the resistance offered by the capillary circulation.

We find ourselves, therefore, obliged to estimate the force of the hæmastatical pressure in the human arteries, not by direct experiment, but by the following indirect reasoning.

The experiments of Poiseuille on the discharge of liquids through capillary tubes, prove that the resistance offered by such tubes is directly proportional to the length of the tubes and inversely proportional to the squares of their cross sections.

The quantity of liquid discharged by a capillary tube in a given time is inversely proportional to this resistance, and may be expressed by the following formula:—

$$Q = A \times \frac{h d^4}{l}$$

In this expression Q denotes the quantity of liquid discharged in a given time, A is a constant, h denotes the charge or hydrostatical pressure, and d and l are the diameter and length of the capillary tube.

Now, there is reason to believe that in animals, similar in bulk, the arrangement and structure of the capillaries are such that the ratio of the squares of their cross sections to the total lengths of the capillaries is practically constant, as may be proved from the following comparison of the sheep and dog. The left ventricle of a sheep's heart, according to Hales, contains 1·85 cubic inches, and its pulse beats 65 times in a minute; the quantity of blood passing through its capillaries in a given time being obviously proportional to the product of these two quantities. The hæmastatical pressure in the arteries of the sheep (Hales) is 6·46 feet of blood.

If we bring to the left hand side of equation (1) the quantities depending on capillary resistance, we find

$$A \times \frac{d^4}{l} = \frac{Q}{h} = \frac{1{\cdot}85 \times 65}{6{\cdot}46} = 18{\cdot}6.$$

The number thus found is to be regarded as the *capillary coefficient* of the sheep. The average of the capacities of the left ventricles of six dogs measured by Dr. Hales, was 0·954 cubic inches; and the average hæmastatical pressure in the arteries of sixteen dogs, was 4·75 ft. of blood; while the pulse of the dog beats ninety-seven times in the minute, on an average. Hence we can obtain the *capillary coefficient* of the dog,

$$A \times \frac{d^4}{l} = \frac{Q}{h} = \frac{0{\cdot}954 \times 97}{4{\cdot}75} = 19{\cdot}6.$$

The sheep and dog differ from each other, as much as man and the horse do, in size of heart and rate of pulse; they also differ in hæmastatical pressure; yet, notwithstanding these differences, the *capillary coefficient* depending on them all, comes out to be nearly the same in both animals.

The *capillary coefficient* of the horse is double that of the sheep and dog, showing that the resistance to circulation in the horse is only half that of the smaller animals. The left ventricle of the horse contains 10 cubic inches, the rate of pulse is 36 beats in a minute, and the average hæmastatical pressure is 9·14 ft. of blood. Hence we find for the *capillary coefficient* in the horse

$$A \times \frac{d^4}{l} = \frac{Q}{h} = \frac{10 \times 36}{9{\cdot}14} = 39{\cdot}3.$$

I now assume that the *capillary coefficient* in man is the same as in the horse; or, in other words, that man bears to the horse, in regard to blood circulation, the same relation as the dog bears to the sheep.

On this assumption, the hæmastatical pressure in the human arteries may be thus found. The human heart has a capacity, in its left ventricle, when in action, of 3 ounces, or 5·2 cubic inches, and beats 75 times in a minute. Solving equation (1) for h, we find

$$h = \frac{Q}{A \times \frac{d^4}{l}}$$

Substituting for Q, the product of the capacity of the ventricle and rate of pulse; and for the *capillary coefficient*, its value in the horse, we obtain

$$h = \frac{5{\cdot}2 \times 75}{39{\cdot}3} = 9{\cdot}923 \text{ ft. of blood.}$$

This is the hæmastatical pressure used in the preceding paper on the force of the heart.

Scientific Queries

MAY I venture to ask you, or one of your readers, for information on the following points :—

1. What is Le Verrier's Law of Storms?

2. What the latest state of our knowledge regarding the peculiar changes undergone by the Mexican Axolotls during their metamorphoses? Have changes, similar to those observed in 1866 by Duméril been noticed in the Zoological Gardens or elsewhere? Have any observations regarding generation in the so-called Pereniobranchiates been made on any other animals besides the Axolotl and the Siredon?

3. Where can I find any account of the earliest observations on the peculiar nesting arrangements of the Hornbills, as described by Wallace? I see that Captain Layard has sent a note on this subject to the Zoological Society, but I have no means of ascertaining what he states.

4. In a lecture published by Blanchard in the *Revue des Cours Scientifiques* a few months ago, on the Progress of Natural History in the Departments of France (excluding Paris), I see that a medal has been lately awarded to M. Lespes for his entomological researches. Are these recent researches, or are they those described several years ago by Mr. (now Sir John) Lubbock in the *Natural History Review?*

5. Is it not the general opinion of your readers that Sir John Lubbock would confer a great favour on those who possess the first edition of his *Prehistoric Times*, by publishing in the form of a pamphlet the chief additions which are introduced into his second edition?

F. R. S.

Haze and Dust

DR. TYNDALL, in his lecture upon Haze and Dust, says "that if a physician wishes to hold back from the lungs of his patient, or from his own, the germs by which contagious disease is said to be propagated, he will employ a cotton-wool respirator;" and, further on, "time will decide whether in lung diseases also the woollen respirators cannot abate irritation, if not arrest decay."

May I ask if there is any necessity for the unsightly respirators one sees over the mouths of people during the winter months and cold evenings? Has not Nature already provided us with an efficient one—one which, on experiment, will doubtless prove to be quite as trustworthy as the artificial one, without any of its inconveniences? I refer to the hair-sieve with which the sinuosities of the nasal passages are supplied; the hairs besetting its path freeing the indrawn air from contaminating particles of dust, whilst it is effectually warmed in its inward passage.

That the air is thus filtered might, I think, be ocularly demonstrated by inhaling exclusively through the nostrils, and then expiring through the glass tube, when the floating matter will be found absent, having been arrested in the nose; I suggest this experiment, because, from the eminent professor applying a handful of wool to his *mouth* and *nose*, I infer that he did not give his natural respirator a fair chance of showing its capabilities.

Apart from the use of respirators, *en passant*, I may perhaps be allowed to echo the opinion of our best medical men in saying that the mouth is not *the* organ for respiration; if it were, should we not find the olfactory nerves developed there also? By respiring through the mouth you do not properly exercise your sense of smell, you allow the hairs lining the nasal cavities to dwindle away and become suppressed through non-use, and finally, you clog up the minute tubercles of the lungs with all kinds of rotten matter.

It is a well-known fact, that people who habitually breathe through the nose are less liable to infectious diseases and pulmonary complaints, one very common benefit derived by such who sleep with the mouth closed, is that they never awake with the painful and disagreeable sensation produced by a parched throat and cracked lips. This may be a small matter, but I think it is deserving of attention. When we break Nature's laws we must pay the penalty.

A. L.

The Solution of the Nile Problem

I HAVE read with much pleasure Mr. Keith Johnston's remarks in your impression of the 27th ult. on the subject of Dr. Livingstone's explorations, not only because they manifest an intimate acquaintance with the general physical features of the field of inquiry and a proper estimate of the merits of the question; but because they help to establish the correctness of my opinion, that the Chambeze and its lakes belong to the Nile system, and not to that of the Congo. I have only to explain that, in my letter of December 1st (NATURE, No. 9), I did not "give the opinion that the river which forms the main part of the great traveller's latest discoveries is *the head stream* of the Nile," but merely said that it "joins" it.

On the question of levels your correspondent is substantially correct, and if he will look to the *Illustrated Travels* of the 1st inst., he will see how far I agree with him. From Dr. Livingstone's statements it appears that the general drainage level of the basin of the Chambeze does not exceed 3,000 feet; and it is not improbable that in the passage of the waters northwards on the west side of Tanganyika, they fall two or even three hundred feet lower, so as to descend nearly if not entirely to the level of the Albert Nyanza. But even if this be the case, I fail to see how the difference in height, however small, "could not give a sufficient lowness to the latter lake (Albert Nyanza) to allow this river (Chambeze) to flow down to it through the five degrees of latitude which separate them." The levels of the Lakes Liemba, Tanganyika, and Albert Nyanza—of which the first is in about 10° S. lat. and the last has its northern end in about 3° N. lat.—are respectively *circa* 2,800, 2,844, and 2,720 feet; and as the continuity of these three bodies of water is assumed by Mr. Keith Johnston, it follows that there is here a virtual dead level extending over not five, but *thirteen* degrees of latitude, or 780 geographical miles! If then it is possible for the waters of Lake Liemba, the head of Livingstone's "eastern line of drainage," to flow into the Albert Nyanza, it is equally possible for those of the Chambeze and its lakes, forming that traveller's central line of drainage, to do so.

In his last letter from Ujiji, Dr. Livingstone says that "the western and central lines of drainage converge into an unvisited lake west or south-west of this"—that is to say, situated in the unexplored regions west of Tanganyika, in the north-north-west direction in which he saw the Lualaba (as he calls the lower course of the Chambeze) flowing, after it had emerged from the crack in the mountains of Rua, north of Lake Moero. This "unvisited lake" is evidently the Lake Chowambe of the traveller's former communications, which by his now calling Baker's Albert Nyanza by the name of "Nyigi Chowambe," he would seem to identify with it. But this is quite consistent with Baker's own statement, that, to the south of about 1° 30′ S. lat., the Albert Nyanza "turns suddenly to the west, in which direction its extent is unknown."

"Albert Nyanza," "Nyigi Chowambe," and this "unvisited lake west or south-west of Ujiji," are, therefore, one continuous body of water, which, being on the lowest level of all, must form not merely the "western line of drainage," but the *main* drainage of the upper Nile Basin; and as, on its eastern side, it is the recipient of the waters of the lakes Victoria Nyanza and Tanganyika, so, on its western side, it receives those of the great lake discovered by Signor Piaggia, with an elevation (as I believe) of four or five thousand feet.

This is entirely in accordance with the opinion I have always entertained that the water-parting between the basin of the Nile and those of the rivers flowing into the Atlantic—the Ogowai the Kuango (Congo), the Kwanza, and the Kunene—is on about the twentieth meridian of east longitude, as it is, in fact, marked on my maps of "The Basin of the Nile" of 1849, 1859, and 1864. The Mossamba range of mountains, situate to the east of the Portuguese colony of Benguela, on the west coast of Africa, forms the southern extremity of this water-parting, and it is in these mountains that I find the head of the great river, which with the Lufira forms Livingstone's "western line of drainage," or, as it should be more correctly designated, the main stream of the Nile. This river is the Kasái, Kassávi, or Loke, whose sources are in the forests of Quibokoe or Kibokoe, on these Mossamba Mountains, within 300 miles of the Atlantic Ocean; which river was crossed by Dr. Livingstone within 160 or 170 miles of its head, on February 27th, 1854, in his adventurous journey across the African continent, and is described by him in page 332 of his "Missionary Travels," and the lower course of which river was followed down by the Hungarian traveller, Ladislaus Magyar, in 1850, as far as about 6° 30′ S. lat., *where he heard that it flowed eastward into Lake "Nhanja"*—a statement strikingly in accordance with Mr. Cooley's assertion, adverted to in my former communication, that "the drainage of the Cazembe's country is all into the Nyanza on the east."

The Nile of Egypt, in thus having its source at the opposite side of the continent of Africa, within a short distance of that ocean into which it does *not* flow, only follows an almost general law of Nature. In the *Athenæum* of July 22nd, 1865, when commenting on Sir Samuel Baker's announcement of his discovery of the Albert Nyanza, I compared the Nile and its Lakes with the Po and its Lakes, pointing out how the two rivers have some of their sources in *snowy* mountains, not at the extremity but at the side of their respective basins. Dr. Livingstone's present discoveries seem to establish the fitness of this comparison, and to extend it. For as the Po, whose exit is in the Adriatic, has its head sources in the Cottian and Maritime Alps, within a few miles of the Gulf of Genoa; so, in like manner, the Nile, which flows into the Mediterranean, has its head on the Mossamba Mountains, within 300 miles of the Atlantic Ocean.

The spot which I have thus discovered to contain the hitherto hidden Source of the Nile, and so to reveal

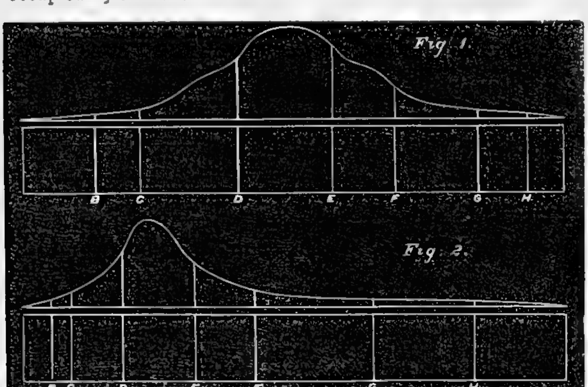
—fluori causas per sæcula tanta latentes,
Ignotumque caput,

is the most remarkable culminating point and water-parting of the African Continent, if not of the whole world; for, within the space of a degree east and west (between 18° and 19° E. long.) and half as much north and south (between 11° 30′ and 12° S. lat.) it includes not only the head of the mighty Nile, which runs northwards over one-eighth of the entire circumference of the globe, but likewise those of the Kuango, (Congo), the Kuanza and the Kunene flowing westwards; those of the Kuivi and the Kubango running to the south; and that of the Lungebungo having its course eastward and forming the head stream of the Zambesi. It is, in fact, what I have been endeavouring to determine since 1846, "the great *hydrophylacium* of the continent of Africa, the central point of division between the waters flowing to the Mediterranean, to the Atlantic, and to the Indian Ocean" (*Journal of the Royal Geographical Society*, vol. xvii. p. 82), as likewise to Lake Nyami, or some other depression in the interior of the continent.

Bekesbourne, Feb. 2 CHARLES BEKE

Analogy of Colour and Music—Supernumerary Rainbows

IN what I saw of a recent discussion in your paper as to the analogy between the colours of light and musical notes, I did not observe any reference made to an analogy on this subject, published, I believe, in 1845, by Prof. Mossotti, of Pisa. The analogy is pointed out at the end of a paper concerning the diffraction spectrum. This spectrum, the disposition of the colours in which depends solely on the wave-lengths, has its point of maximum brightness in the middle, which in this spectrum is occupied by a shade of colour rather nearer to the line E than



D. Fig. 1 represents the positions of the lines in the diffraction spectrum; and fig. 2 represents the spectrum formed by refraction through a certain flint glass prism which belonged to Fraunhoffer. The ordinate of the curve which is drawn above each spectrum represents the intensity of the light at each place of that spectrum. The curve drawn above fig. 2 is that due to Fraunhoffer's actual observations with the prism above referred to. The intensity of the light in the neighbourhood of the principal lines is given by him by the following numbers:—

B	C	D	E	F	G	H
·032	·094	·64	·48	·168	·031	·0056

These intensities were determined by comparison with the light of a lamp placed at various distances. It is hard to say, however, what physical and physiological facts are included in these numbers.

The curve given in fig. 1 is constructed by Mossotti analytically, on a principle which amounts to this:—He takes hold of the spectrum in fig. 2, and shifts it so that the fixed lines come into the positions of fig. 1, and decreases or increases the ordinate representing the brightness in the neighbourhood of each fixed line in exactly the proportion that the spectrum has been expanded or contracted in the neighbourhood of that line. The change of place of portions of colour not in the immediate neighbourhood of one of these lines is regulated by a formula founded on a certain physical investigation of Mossotti's as to the dependence of the refraction index upon the wave-length, which formula has its constants determined by the method of least squares, so as to represent with sufficient accuracy the truth at the fixed lines.

Following a method similar to that adopted by Newton, Mossotti supposes the spectrum in fig. 1 to be bent round the complete circumference of a circle, and he finds that if x be the wave-length in millionths of a millimetre at a point distant by an arc whose circular measure is x, from the brightest portion of the spectrum, then x is given for the fixed lines with sufficient accuracy by the formula

$$x = 553{\cdot}5 + 184{\cdot}5 \frac{\phi}{\pi},$$

extending this formula to the ends of the spectrum, it constrains the longest wave-length to be 738, and the shortest 369 millionths of a millimetre. This result Mossotti regards as sufficiently near the actual wave-lengths of the extremities of the spectrum.

The longest and shortest wave-lengths taken in conjunction with the wave-lengths of the brightest part of the diffraction spectrum and of the fixed lines B C D E F G H form ten wave-lengths, which Mossotti thus compares with the notes of the diatonic scale:—

1	$\frac{17}{25}$	$\frac{9}{8}$	$\frac{5}{4}$	$\frac{4}{3}$	$\frac{25}{18}$	$\frac{3}{2}$	$\frac{5}{3}$	$\frac{13}{8}$	2
$\frac{1}{738}$	$\frac{1}{688{\cdot}3}$	$\frac{1}{656}$	$\frac{1}{590}$	$\frac{1}{553{\cdot}5}$	$\frac{1}{531}$	$\frac{1}{492}$	$\frac{1}{443}$	$\frac{1}{393{\cdot}5}$	$\frac{1}{369}$
738	688	656	589	553·5	526	484	429	393	369
—	B	C	D	—	E	F	G	H	—

The first line represents the number of vibrations necessary to produce the notes of the diatonic scale. The numbers in the second line have the same ratio as the numbers in the first, and therefore the denominators of these fractions represent the wave-lengths of the respective notes. The third line represents the lengths in millionths of a millimetre of the waves corresponding to the lines respectively placed under them.

I need not here give any opinion as to the utility or inutility of such analogies, but I shall be glad if this letter should call the attention of any of your readers to the remarkable symmetry of the diffraction spectrum, which is in fact Nature's own graphical method of exhibiting the numerical wave-lengths which correspond to each part of the spectrum.

Trinity College, Cambridge, Feb. 9 JAMES STUART

IN your journal of January 20th Mr. Grove has honoured my little note on "Colour and Music" by a letter on the subject, in which attention is directed to a rainbow, or series of rainbows, *within* the primary. Mr. Grove asks if a description of this phenomenon has been published, and whether the effect may not be a repetition of the colours of the spectrum after the manner surmised by Sir John Herschel. I will endeavour as briefly as possible to reply to these inquiries.

So far as I can trace, the mention of inner or "supernumerary" bows first occurs in the Phil. Trans. for 1722, p. 241. It is there described by a Dr. Langwith, who had seen the phenomenon no less than four times in the course of that year. On one occasion it was so favourably seen, and lasted so long, that he is able to give the following careful description. Under the usual primary bow, Dr. Langwith says, "was an arch of green, the upper part of which inclined to bright yellow, the lower to a more dusky green; under this were alternately two arches of reddish purple and two of green, under all a faint appearance of another arch of purple, which vanished and returned several times so quick that we could not readily fix our eyes on it."

I do not know if this be similar to that Mr. Grove has seen, but it evidently corresponds with the appearance Mr. Newall describes in your journal for January 27th. The next mention of inner rainbows is in the Phil. Trans. for 1749, p. 193, when Mr. Daval, the then secretary of the Royal Society, corroborates, from his own experience, Dr. Langwith's description. Dr. Thos. Young next refers to the phenomenon in order to give his explanation of it in the Phil. Trans. for 1804, and he also twice alludes to it in his published lectures on Natural Philosophy. Further, at p. 374 of his "Optics," Brewster describes supernumerary bows that, at different times, he has seen within the primary rainbow; and, also, he mentions an analogous appearance observed without the secondary, a fact previously surmised by Dr. Young.*

An explanation of the phenomenon is first attempted by Dr. Pemberton (Phil. Trans. 1722), who classes it with the colours of thin plates, according to the theory of "fits." Dr. Young, in his paper on Physical Objects (Phil. Trans. 1804), disputes Dr. Pemberton's explanation, and shows that the appearance is readily explicable by the interference of two pencils of light, regularly reflected from the posterior surface of the drops of rain. The drops must, in this case, be between $\frac{1}{70}$th and $\frac{1}{80}$th of an inch in diameter. Evening appears to be the time these supernumerary bows are generally seen, and invariably they are observed beneath the *upper* part only of the primary bow. Hence, I presume, the phenomenon is similar to the diffraction colours seen in the cloud that is precipitated when the first portions of air are promptly removed from a receiver.

I have, in conclusion, to thank Mr. Grove for pointing out, in his second letter, that the word "correlation" implies too much when applied to the relationship of colour and music. "Analogy" is certainly far more appropriate to express what is merely a parallelism, and not a necessary or complementary relationship between light and sound.

Woodlands Grove, Isleworth, Jan. 29 W. F. BARRETT

P.S.—Since the foregoing letter was written,—which was sent to your office on the date it bears,—several contributions on the subject of my "note" have appeared in your journal. I will not now venture to intrude further upon your space, but, with your permission, shall reply to your other correspondents in a subsequent letter. W. F. B.

February 12

Sensation and Perception

HAVING in the *Journal of Mental Science* tried to show how Sensation and Intellect are distinguished from each other, allow me to state, in regard to Dr. Bastian's views on this head, that Dr. Lockhart Clarke, after a careful review of what has been written on Sensation, rejects Sir W. Hamilton's statement that "it is manifestly impossible to discriminate, with any rigour, sense from intelligence." "Although, in the lowest animals, there is this apparent identity of sense and intelligence, which seem as it were to be fused into one common state of consciousness, yet when we find them in the course of development, either in the fœtus or in the scale of animal life, emerge each in a distinct and different form out of that common or indifferent state, are we to ignore the distinction, and assert with Sir W. Hamilton and others, that sensation is simply a function of the intellect? It might with equal reason be maintained that there is no real difference between any other two organs of the body, because in the ovum they are developed out of one homogeneous tissue or common germinal mass."† According to Von Baer's law, it seems that while in the lower animals sense and intelligence are fused into one, in the higher they become differentiated, each having a separate seat. When Dr. Bastian, then, contends, with the metaphysicians, for the identity of sense and intelligence, he seems to be reversing the method of evolution, and going back to the medley out of which well-defined organs with *improved* functions were evolved. He would make us believe that as the sense-ganglia become more defined and eliminate the rudiments of intelligence, they assume a lower function than they had before, one not to be distinguished in kind from that of the excito-motor system previously differentiated. Is this likely? As to the impossibility of discriminating sense from intelligence there are the following facts indicating the contrary. Physiology shows that the external object of the many must be revealed in a seat that is not at the periphery; but such an object is not an idea or notion; therefore, there is a marked distinction between an external object in sense and an idea of one in intellect. A sense-object may be common to two distinct sets of ideas, as when it is now interpreted to be a ghost, now the stump of a tree. A sense-object is antecedent to an ideal object, for the latter only exists as a representation of the former. A feeling in sense may cause coughing or sneezing, *e.g.*, in spite of the veto of the intellect. A feeling in sense may be so intensely painful as, for the time, to paralyse intellectual energy. But what about the following argument? What is known at first hand is known *as it is*, for if you say not as it is; but as it is not, you imply that it is not known at first hand, but through something which does not even represent it, which is absurd. Therefore, as sense and intelligence must be known at first hand, and, as thus known, are distinguishable from each other in *many* respects, pre-eminently, the one as the sphere of objects at first hand, the other at second hand; the one as pertaining to *the organic ego*, the other to the *non-organic ego*—each must be known *as it is*, not *as it is not*.

Abergavenny. W. G. DAVIES

* Sir David Brewster, moreover, refers to the occurrence, spoken of by Mr. Newall, of a dark-coloured zone between the primary and secondary bow: a somewhat similar dark fringe is, on *à priori* grounds, apparently predicted by Dr. Young, at p. 369 of his "Lectures on Natural Philosophy," 1845 edition.

† Medical Critic and Psychological Journal, vol. ii. p. 574, *et seq.*

Transcendent Space

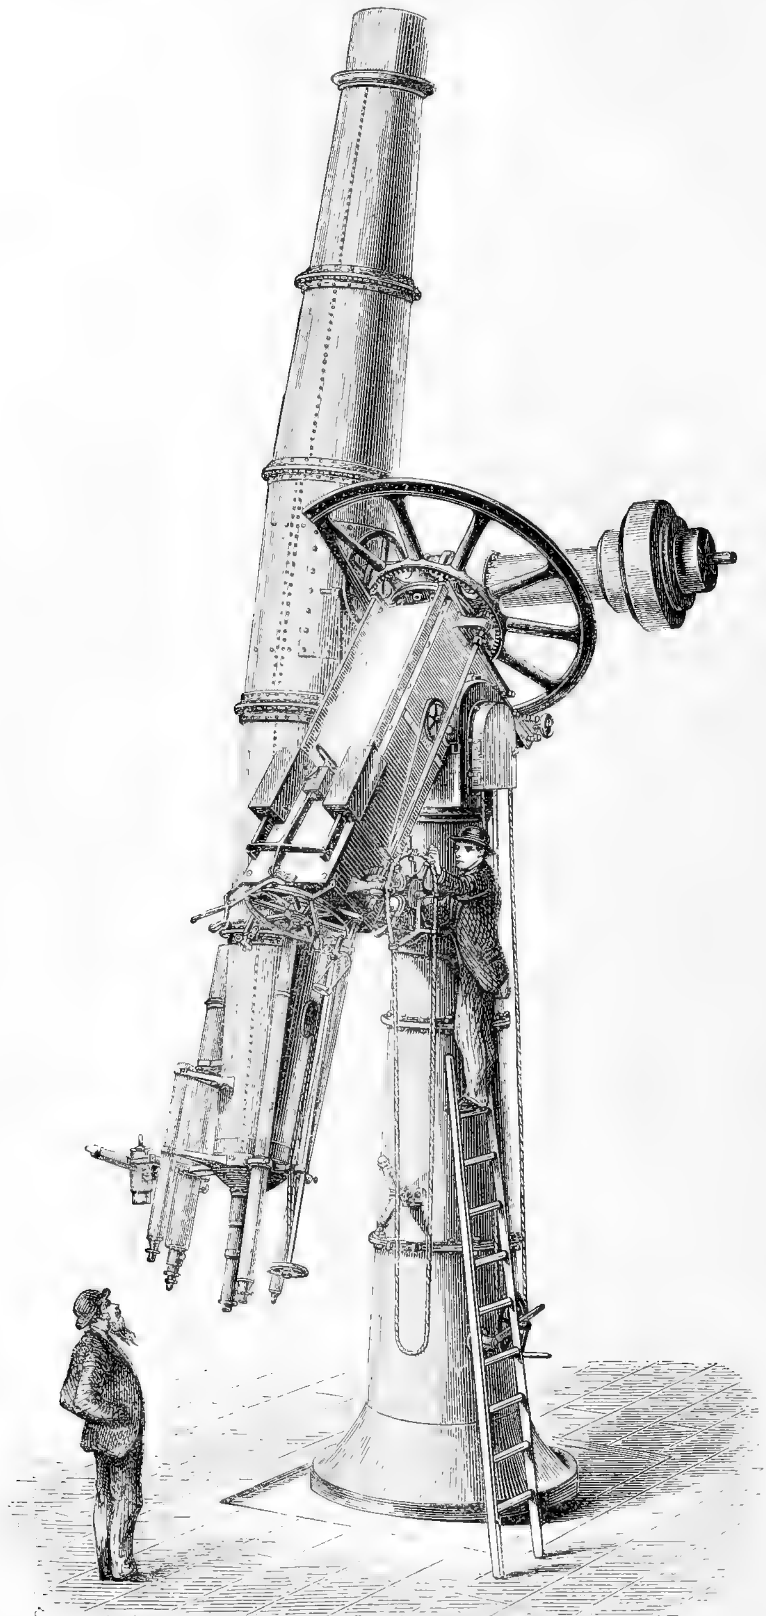
IN NATURE for January 13 I was permitted, as it were, to speak the prologue to the correspondence on "Kant's View of Space," now happily, if not satisfactorily, closed. I now ask permission to speak the epilogue, in strict reference to the subject of my first letter.

The most interesting period of incubation in Sir William Rowan Hamilton's discovery of *Quaternions* was October 15, 1843. On that day, as he relates in a letter to a friend, he was walking from his Observatory to Dublin with Lady Hamilton, when, on reaching Brougham Bridge, he "felt the galvanic circuit of thought *close;* and the sparks which fell from it were the *fundamental equations between i, j, k; exactly such*" as he used them ever since (*North British Review*, September, 1866, p. 57). Two days after he wrote a letter to his friend and coadjutor, Mr. J. T. Graves, a brother of the present Bishop of Limerick, giving a most interesting narrative of his transition from *Triplets* to *Quaternions*. It is here that I found, after much search and research, the confirmation of a notion which had floated for years in my mind, that Hamilton's speculations had borne a very remarkable relation to Transcendent Space of Four Dimensions. The letter in question is printed in the supplement to vol. xxv. (third series) of the L. E. and D. *Philosophical Magazine*, and of late years has escaped the notice of mathematical students, engrossed, as many are, in the geometrical and physical applications of Quaternions. It seems that after Hamilton had completed his Theory of Conjugate Functions, he endeavoured to obtain an Algebra of Pure Space, and for this purpose employed, after the Germans, the symbol i to express one root of negative unity, and introduced a new symbol, j, to express another root of negative unity. Further, he employed an operant, k; and with these elements he worked out a theory of Triplets in which $i^2=j^2=-1$, and $ij=-ji$, while k remained ambiguous. Assuming, at length, that $ij=k$, and $ji=-k$, and leaving it still undecided whether $k=0$ or not, there dawned on him, as he phrases it, "the notion that we must admit, in some sense, *a fourth dimension* of Space for the purpose of calculating in triplets."

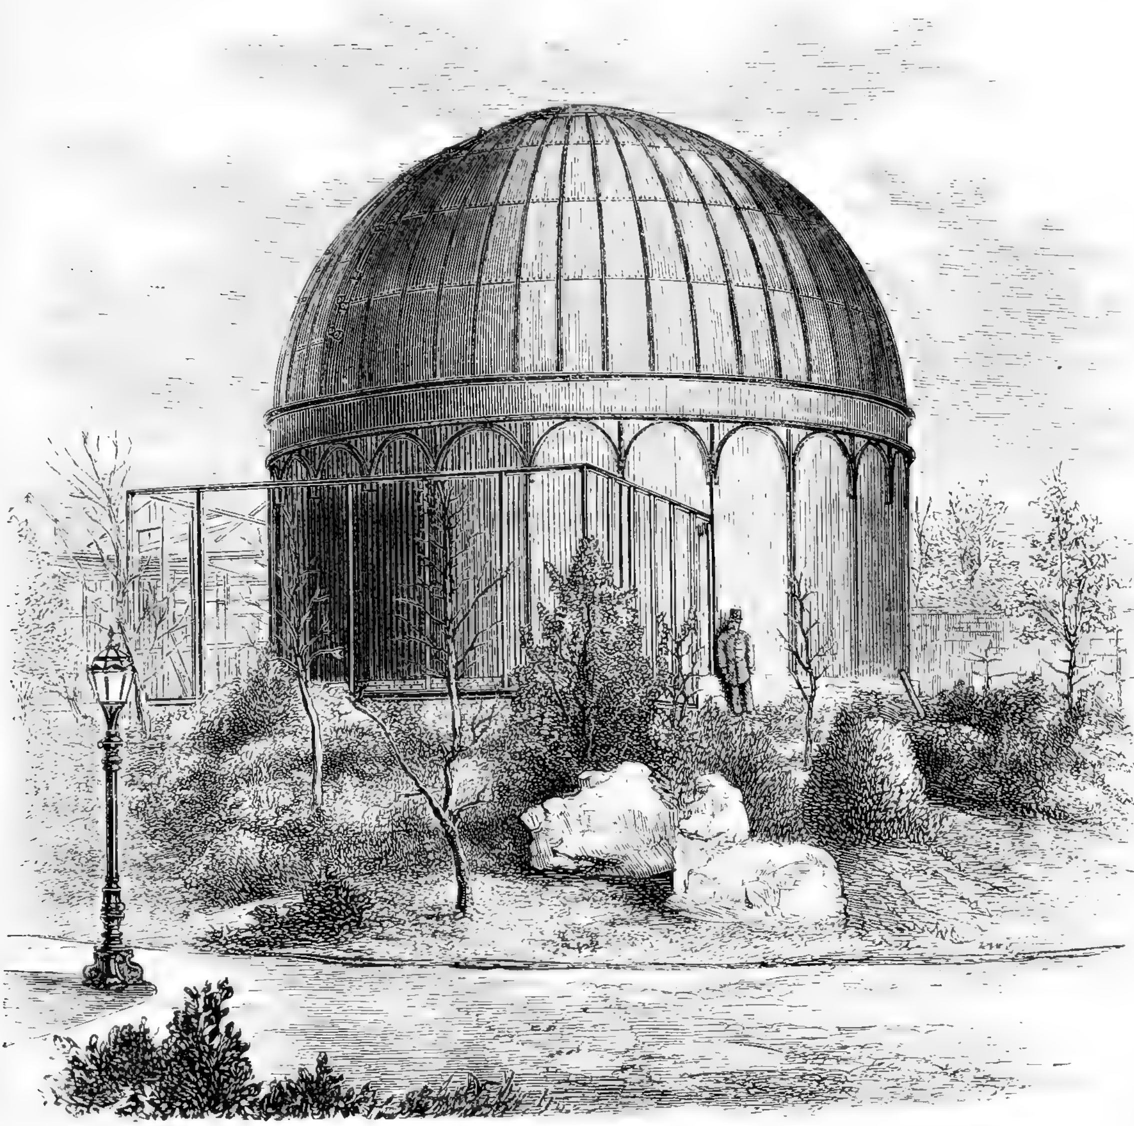
Now this curiously interesting phase in the generation of Quaternions is an admirable instance of what I mean by affirming Quadridimensional Space to be a mathematical figment springing out of an otherwise uninterpretable formula. Observe, in this case, what was the effect of the completion of the theory. So soon as Hamilton had passed from *Triplets* to *Quaternions*, and he had made his k a third root of negative unity, *this transcendent space vanished* out of thought. The ghost of a fourth dimension, which had haunted Hamilton's Triplets, was immediately laid; and thenceforth his system was, what he originally sought, an Algebra of Pure Tridimensional Space. The haunting notion, thus banished from Triplets, took refuge in Quinaries and other transcendent algebraical formulisations. To me it is a spurious product of "mental activity," not, even possibly or potentially, a form of mental receptivity, and *à fortiori* externally denied to experience.

In conclusion, I protest that in denying (for Kant) to Space and Time the title of Forms of Thought, I do *not* restrict the term Thought to the technical limits of Kant, but use it as synonymous with mental activity in general.

Ilford, Feb. 14 C. M. INGLEBY



THE GREAT NEWALL TELESCOPE OF 25 INCHES APERTURE, NOW BEING ERECTED AT GATESHEAD



THE OBSERVATORY FOR THE NEWALL TELESCOPE

THE NEWALL TELESCOPE

THE 25-inch Equatorial Telescope, commenced several years ago by T. Cooke and Sons, of York, for R. S. Newall, Esq., of Gateshead, is now so far completed that it has been removed from the works at York into its observatory in Mr. Newall's grounds, at Fern Deal.

The completion of a telescope with an object glass of 25 inches aperture, marks an epoch in astronomy, and its completion in England again places us in the front rank in the matter of the optical art, as we were in Dolland's time.

The history of the progress of the manufacture of telescopes since the time referred to, shows very clearly the long-lasting effects of bad legislation; for it is not too much to say that the duty on glass entirely stifled, if indeed it did not kill, the optical art in England. Hence we depended for many years upon France and Germany for our telescopes to such an extent indeed that the largest object-glasses at Greenwich, Oxford, and Cambridge are all of foreign make. The labours of the Germans culminated in the two magnificent instruments of 15½ inches aperture in the observatories of Pulkowa and Cambridge, U.S. And then for a time America, thanks to the genius of Alvan Clarke, took the lead with the 18½ inch glass now beginning to do good work in the observatory of Chicago. This instrument is at last eclipsed by the magnificent one now being erected at Gateshead.

In what we have said we have purposely omitted to touch upon reflecting telescopes, in the construction of which, since the time of Newton, England has always been pre-eminent, because we shall take occasion to refer to the reflector of four feet aperture, completed last year by Mr. Grubb, of Dublin, and now erected at Melbourne when it is fairly at work.

The general design and appearance of this monster among telescopes, which will be gathered from the accompanying woodcut, is the same as that of the well-known Cooke equatorials; but the extraordinary size of all the parts has necessitated the special arrangement of most of them.

The length of the tube, including dew-cap and eye-end, is 32 feet, and it is of a cigar shape; the diameter at the object-end being 27 inches, and at the centre of the tube 34 inches. The cast-iron pillar supporting the whole is 29 feet in height from the ground to the centre of the declination axis, when horizontal; and the base of it is 5 feet 9 inches in diameter. The trough for the polar axis alone weighs 24 cwt., the weight of the whole instrument being nearly 9 tons.

The tube is constructed of steel plates rivetted together, and is made in five lengths, screwed together with bolts and flanges. The plates of the central length are one-eighth of an inch thick, and those of each end one-sixteenth thick, so as to reduce the weight of the ends as much as possible, and avoid flexure.

Inside the outer tube are five other tubes of zinc, increasing in diameter from the eye to the object-end: the wide end of each zinc tube overlapping the narrow end of the following tube, and leaving an annular space of about an inch in width round the end of each for the purpose of ventilating the tube, and preventing, as much as possible, all interference by currents of warm air, with the cone of rays. The zinc tubes are also made to act as diaphragms.

The object-glass has an aperture of 25 inches (nearly), and in order as much as possible to avoid flexure from unequal pressure on the cell, it is made to rest upon three fixed points in its cell, and between each of these points are arranged three levers and counterpoises round a counter-cell, which act through the cell direct on to the glass, so that its weight in all positions is equally distributed among the 12 points of support, with a slight excess upon the three fixed ones. The focal length of the lens is 29 feet. A Barlow lens is arranged to slide on a brass framework within the tube. The hand is passed through an opening in the side of the tube, and by means of a handle attached to the cell, the lens may be pushed into or out of the cone of rays.

Attached to the eye-end of the tube are two finders, each 4 inches aperture; they are fixed above and below the eye-end of the main tube, so that one may be readily accessible in all positions of the instrument. It is also supplied with a telescope having an O. G. of $6\frac{1}{2}''$. This is fixed between the two finders, and is for the purpose of assisting in the observations of comets and other objects for which the large instrument is not so suitable. This assistant telescope is provided with a rough position circle and micrometer eye-pieces, and is illuminated by new apparatus lately described in NATURE.

Two reading microscopes for the declination circle are brought down to the eye-end of the main tube; the circle —38 inches in diameter—is divided on its face, and read by means of the microscopes and prisms.

The slow motions in declination and R. A. are given by means of tangent screws, carrying grooved pulleys, over which pass endless cords brought to the eye-end.

The declination clamping handle is also at the eye-end.

The clock for driving this monster telescope is in the upper part of the pillar, and is of comparatively small proportions, the instrument being so nicely counterpoised that a very slight power is required to be exerted by the clock, through the tangent screw, on the driving wheel (seven feet diameter), in order to give the necessary equatorial motion.

The declination axis is of peculiar construction, necessitated by the weight of the tubes and their fittings, and corresponding counterpoises on the other end, tending to cause flexure of the axis. This difficulty is entirely overcome by making the axis hollow, and passing a strong iron lever through it, having its fulcrum immediately over the bearing of the axis near the main tube, and acting upon a strong iron plate rigidly fixed as near the centre of the tube as possible, clear of the cone of rays. This lever, taking nearly the whole weight of the tubes, &c., off the axis, frees it from all liability to bend.

The weight of the polar axis on its upper bearing is relieved by friction rollers and weighted levers; the lower end of the axis is conical, and there is a corresponding conical surface on the lower end of the trough; between these two surfaces are three conical rollers carried by a loose or "live" ring, which adjust themselves to equalise the pressure.

The hour circle on the bottom of the polar axis is 26 inches in diameter, and is divided on the edge,* and read roughly from the floor by means of a small diagonal telescope attached to the pillar; a rough motion in R.A. by hand is also arranged for by a system of cog-wheels moved by a grooved wheel and endless cord at the lower end of the polar axis, so as to enable the observer to set the instrument roughly in R.A. by the aid of the diagonal telescope.

The declination and hour circles will probably be illuminated by means of Geissler tubes, and the dark and bright field illuminations for the micrometers will be effected by the same means.

Mr. Newall, after the preliminary testing of this magnificent instrument at his own residence, purposes to erect it in some climate favourable for astronomical observation. It is very unfortunate that this means in other words that the telescope cannot remain in England. It is or should be among the things generally known that every increase in the size of an object-glass or mirror increases the perturbating effects of the atmosphere, so that the larger the telescope, the purer must be the air. In the absence of this latter condition, a "big" telescope is a "big evil," and skilled observers, mindful of this, reduce the apertures of their instruments when the air is not good.

We may regard this telescope as a clear gain to English science, for Mr. Newall with princely liberality has expressed his intention of allowing observers with a special research on hand to have the use of the instrument during certain regulated hours.

The observatory, of which we also give a sketch, is nearly 50 feet in diameter, and notwithstanding the enormous weight of the dome, like the telescope, it is easily moved into any required position.

When complete it will have attached to it a transit-room and the observer's dwelling. And this reminds us that Mr. Marth, so well known for his good work done at Malta with the Lassell Reflector and elsewhere will have charge of this noble instrument of research.

NOTES

THE anniversary meeting of the Geological Society takes place to-morrow, when Professor Huxley will deliver his address, which, it is expected, will be of great scientific interest. The Wollaston Medal of the society has this year been awarded to the eminent French Malacologist, M. Deshayes, professor at the Musée d' Histoire Naturelle, and the proceeds of the Wollaston fund have been awarded to M. Marie Roualt, who, though in humble circumstances, has contributed largely to the advance of the palæontology of France. The choice of president for the coming year has fallen on Mr. J. Prestwich—a choice which will be hailed on all sides with the liveliest satisfaction.

IN reply to an address of last Session, Her Majesty has made known to the House of Commons that she will give directions for the carrying out of the arrangements necessary for observing the transit of Venus, which will take place in the year 1874.

THE Rev. Charles Pritchard, of St. John's College, Cambridge, has been elected to the Savilian Professorship of Astronomy, as successor of the late Professor Donkin. Astronomers may congratulate themselves on this appointment, as Mr. Pritchard's teaching powers are of the first order, the interest he takes in

* The hour circle is also divided on its face, and read by micrometer microscopes.

the science is well-known, and his labours for its advance, especially in connection with the Royal Astronomical Society, have now extended over many years.

THE President of the Royal Society has sent out cards for two evening receptions, which are to be held at Burlington House on March 5, and April 23.

WE understand that 75 towns have signified their intention of contributing to the fund required by the British Association Committee on the Treatment and Utilisation of Sewage, for the investigation of this subject, Manchester heading the list with a contribution of 100*l*.

AT the ensuing meeting of the Geological Society on the 23rd inst., a paper of especial interest will be read, on the subject of copper mining at deep levels in the South of Ireland, experience having disproved the dictum of Irish geologists as to the non-existence of metalliferous strata at any considerable depth.

THE number of candidates for election as members of the Royal Institution may, we hope, be taken as a fair indication of the daily increasing interest taken in scientific matters. The number elected last year was forty-seven. The number of candidates proposed during the first six weeks of the present year is forty-two.

M. NAUMANN has been elected a corresponding member of the mineralogical section of the Academy of Sciences in Paris, in the place of Sir Roderick Murchison, who has been made a foreign associate. He received 27 votes out of 44, of the remainder 10 being recorded in favour of our countryman, Professor Miller, and 5 for Professor Studer, of Berne.

AT the meeting of the Académie des Sciences, on the 31st of January, M. de la Roche Poncié was erected to the place rendered vacant in the Bureau des Longitudes by the death of M. Darondeau.

M. ALGLAVE announces in the *Revue des Cours Scientifiques*, that the total amount subscribed to the Sars Fund, is now upwards of 160*l*., including the subscriptions of twenty-eight members of the Royal Belgian Academy, the same number of members of the Anthropological Society of Paris, M. Drouyn de Lhuys, and several members of the Zoological Society. We have the satisfaction to announce further subscriptions to the fund in this country, which appear in our advertising columns.

WE hear that the eminent geographer Kiepert is about to proceed to the Holy Land, and spend some time there, for the purpose of personally determining geographical positions. He has the advantage over our University explorers, recently sent out, in being a skilful and experienced geodetist, and of acquaintance with the country obtained during a former sojourn of several years.

A COMMITTEE has been appointed to inquire into the education of naval officers, consisting of Rear-Admiral Shadwell, C.B., President; Captain W. H. Richards, R.N., Hydrographer, Captain A. A. Wood, R.N., Director of Naval Ordnance, the Rev. Dr. Woolley, Admiralty Director of Education, the Rev. A. Barry, D.D., Principal of King's College. S. P. Butler, Esq., Barrister-at-law, Richard Saintbill, Esq., R.N., Secretary.

PRIZES are offered by the Royal Belgian Academy for essays on the following subjects:—1. To give a *résumé* of and to simplify the theory of the integration of equations containing partial derivatives of the first two orders. 2. A study of electrical currents based as far as possible on new experiments. 3. To fix by new researches the place to be occupied in the natural system, by the species *Lycopodium*, *Selaginella*, *Psilotum*, *Tmesipteris*, and *Phylloglossum*. 4. To describe the mode of reproduction of eels. 5. New researches to establish the composition and mutual relations of albuminoid substances. The gold medal to be given for the first and fifth of these questions is to be worth 40*l*., that for the second, third, and fourth questions, 24*l*. The essays must be written in Latin, French, or Flemish, and addressed paid to M. Ad. Quetelet, the Perpetual Secretary, before the 1st of June, 1871. The Academy will require the greatest exactness in the quotations, and the pages as well as the editions of works cited, must be given.

ANTHROPOLOGY is being publicly taught in Paris by one of the most distinguished masters of that science, Dr. Paul Broca. The *conférences* are held every Monday and Friday at 3 o'clock at the Anthropological Laboratory, No. 15, Rue de l'Ecole de Médecine. The instruction given has reference chiefly to craniology and the comparative anatomy of man and the apes. We also learn from Herr F. von Hauer that a new Anthropological Society has been formed at Vienna. It already numbers twenty-four members, among whom are several distinguished men of science. The society will publish a journal. In a prospectus which has been issued it is stated that the study of the natural history of man has now reached a stage in which active support by association appears to be imperatively needful.

AT a recent meeting of the Zoological Society of London, Professor Owen communicated a very interesting letter, which he had lately received from Dr. Julius Haast, F.R.S., of Canterbury, New Zealand, on the subject of the extinction of the Moa, or *Dinornis*. Dr. Haast was of opinion that these gigantic birds had been extinct many hundreds of years, and had been so before the arrival of the Maories in New Zealand, having been exterminated by a race which previously inhabited these islands near the mouth of the river Rakaia. He had recently been so fortunate as to find the remains of a former large encampment of these "Moa hunters." The kitchen-middens and cooking-ovens, which were still completely preserved, were spread over more than forty acres in extent. Numerous stone weapons were discovered, consisting either of hard sandstone or of chipped flint. The Moa bones were very abundant, but belonged chiefly to the smaller species, *Dinornis casuarinus*, *D. didiformis*, and *D. crassus*. There were also some bones of *D. elephantopus*, and of a small *Palapteryx ingens*, but none of *D. giganteus* and *D. robustus*. The leg bones of these birds had all been broken at the ends, so as to allow the marrow to be extracted, and the skulls scooped out from below, so that the brain might be reached. The middens likewise contained bones of the domestic dog, sea-gull, and the tympanic bones of several species of whale, but no human remains had been found amongst the heaps, so that it might be presumed that the Moa-hunters were not cannibals.

PROFESSOR LIEBIG disputes Pasteur's view that the decomposition of sugar in fermentation, depends on the development and multiplication of yeast-cells and that fermentation generally is only a phenomenon accompanying the vital process of yeast. He expresses the opinion that Pasteur's researches have not explained fermentation; but have only made known another phenomenon—the development of yeast—which equally requires explanation.

A NEW Flora of India by Dr. Hooker and Dr. Thomson is in preparation, and the first volume is expected in the course of the present season. This will supersede the old "Flora Indica" by the same authors, the first volume of which was published in 1855. The fifth volume of Mr. Bentham's "Flora Australiensis" is also announced as nearly ready.

AT the monthly session of the Imperial Geographical Society of Russia, held December 3rd, under the presidency of Count F. de Lütke, a memoir was read from M. Popow, of the Russian embassy, Pekin, on the "export of tea from Hankow," amounting to 50,000,000 lbs.—one-third of the total export from China—of which 15,000,000 is sent by twenty-eight Russian merchants. Among the measures adopted by the council in November was one concerning Mr. Hayward's expedition in Central Asia.

At the request of Sir Roderick Murchison, president of the Royal Geographical Society, London, the council sent a request to the Governor-General of Turkestan, that he would welcome Mr. Hayward if he reached the Russian frontier. M. Ivaschintzew read a paper on the "eastern coast of the Caspian Sea, with reference to the commercial routes to Central Asia." The Volga, the only means of communication between the interior of Russia and the Caspian countries, presents great difficulties, there being only one channel available, the Western, which is navigable only by boats drawing four to five feet. The eastern coast of the Caspian is described as generally bare of any vegetation. From the Emba to the Atrek there are no springs; wells of brackish water are found, apparently the sea-water infiltrated. The north-east coast is inaccessible: vessels cannot even approach within sight of the shore. Among the important points on the south-east shore are Sarytasch and Manghischlak coalfields, and the port Tubkaragan, the gulfs of Karabougaz and Balkan. The bay of Krassnovodsk—the occupation of which was recently announced—does not freeze in the winter; navigation, however, is reported by the Turcomans to be impeded for fifteen days by floating ice. The writer gave an account of the various explorations of Central Asia, including the attempts of the English from the sixteenth century, the expedition of Prince Békovitch, the attempt of Voiniovitch to establish commercial relations at Astrabad in 1781. The new routes to Central Asia from the centre of Russia are superior to the old, as avoiding the Kirghiz-steppe. The necessity was shown of interesting the Turcomans and the inhabitants of Khiva in commerce, and of making accurate surveys of the country between the Caspian and the Amu-Daria.

THE *Academy* states that M. Leon de Rosny, Professor of Oriental languages at the Imperial College, has published a French translation of a Japanese treatise on the rearing of silkworms. This work is published "par orde de son Excellence le Ministre de l'Agriculture." It is the first French translation of a Japanese work.

THE *Lancet* in speaking of the arrangements of hospitals, instances, as much needing reform, the system of grouping together indiscriminately in medical wards, cases of various affections, in an atmosphere which may be destructive to some patients while it is suitable to others. Thus we may find lying side by side a case of bronchitis and one of fever; a patient with phthisis and another with gangrene of the lung; next perhaps one of rheumatic fever closely adjacent to a paralytic with offensive bed sores.

THE Royal Irish Academy has voted the sum of 25*l.* to Professor King, to enable him to carry out his researches "on the jointing, foliation and cleavage of rocks," also the same amount to Professor Ball, to enable him to carry out his experiments "on the velocity of smoke rings in air."

A NEW instance of the earnestness and liberality with which the King of Prussia encourages the prosecution of geographical discovery, has been communicated to us. The enterprising traveller, Gerhard Rohlfs, receiving kindness from the ruler of Kuka, he promised that presents should be sent from the King of Prussia, and Herr Nightingale is now on his way as the bearer of the presents. Poor Miss Tinne's death having proved the danger of the way beyond Mursuk, the Prussian Government has consented to send a guard of fifty soldiers (volunteers for the duty) to escort him in safety through the Touaregs to Kuka.

THE *Academy* reports that Herr O. Liebreich has found chloral may be employed with good results as a counteractive to poisoning by strychnine. On the other hand, the evil effects of an overdose of chloral may be remedied by the use of strychnine.

M. GORSEIX states in a letter, communicated to the Academy of Sciences, by M. St. Claire Deville, that Santorin was still in active eruption on the 6th of last month.

MAGNETIC AND SUN SPOT PHENOMENA FOR 1870

APPEARANCES would indicate that we are now approaching the epoch of maximum, both as regards the disturbances of terrestrial magnetism and also as regards solar disturbances or sun spots; for these interesting phenomena are believed to march together. There is still a third phenomenon intimately connected with magnetic disturbances, and that is, the Aurora Borealis, a meteor which seems to sympathise with the terrestrial magnetic system to such an extent that when this is fluctuating and disturbed, displays of the Aurora are almost sure to follow.

Finally, those of us who are of an intensely practical turn of mind will be delighted to know that this interesting chain of facts is bound by one of its links, if not by two, to the practicalities of everyday life. For, in the first place, displays of the Aurora are hardly ever unaccompanied by spontaneous currents making their appearance in telegraphic wires, and causing not a little confusion in the transmission of messages; and, in the next place, some mineralogists are of opinion that these very currents are connected in some way with metalliferous deposits.

Perhaps, after all, the relation between sun spots and California may be that of cause and effect!

The first great magnetic disturbance recorded at Kew Observatory, during the last month, began about 7 a.m. on January 3, by considerably and abruptly diminishing the declination and the horizontal force, without greatly affecting the vertical force. It lasted for about 16 or 17 hours, and during its continuance an Aurora was visible.

A smaller disturbance began on January 8, about 9 p.m., its tendency being to diminish the declination and the vertical force, without much affecting the horizontal force; it was likewise accompanied by an Aurora.

The solar disc was photographed at Kew Observatory nine times during the month of January, with an average of five groups of spots on the sun's surface, one of them being always large. Thus we have:—

January	1	6	groups	2 of them rather large
,,	6	5	,,	2 rather large
,,	10	5	,,	2 large
,,	11	6	,,	1 large
,,	12	5	,,	1 very large, another large
,,	13	5	,,	1 large
,,	14	4	,,	1 large
,,	24	5	,,	1 very large, another large
,,	29	4	,,	1 large

February promises to be a still more active month, but we must wait.

SCIENTIFIC SERIALS

Moniteur Scientifique, February 1.—In this number M. Emile Kopp gives an account of Weldon's well-known process for the regeneration of "manganese." In a note on the Infinitesimal Calculus, M. Néhay maintains that neither the infinitely great nor the infinitely small can be considered as real quantities; that the algebraical relations established in the calculus for such quantities depend solely on the conservation of certain ratios and not on any particular unit, and are hence true for magnitudes as great or as small as we please; and that infinitesimals can always be exchanged for finite proportionals. Bolley finds on analysis that the artificial alizarine of Meister, Lucius, and Co. has very exactly the formula $C_{14}H_8O_4$.

Revue des Cours Scientifiques, February 12.—This number contains a long list of subscribers to the Sars Fund; a report by M. Cazalis de Fondouce, of the proceedings of the Anthropological Congress at Copenhagen; also a lecture delivered at the Faculté de Médecine at Paris, by M. Onimus, on the balanced forces (*forces en tension*) and active forces (*forces vives*) in the animal organism.

INDIAN GEOGRAPHICAL NAMES

THE Committee of the Geographical Society of Bombay appointed to prepare an index of geographical names in India, in vernacular and English spellings, with memoranda—geographical, etymological, antiquarian, and statistical—have published the outline of a general plan to guide in the formation of the proposed index, and to enumerate the particulars it might properly include.

The object is primarily *geographical* and *etymological*, but the Committee hopes information may be placed at its disposal to make it also historical and statistical.

The committee, therefore, considers that a full index of the kind ought to embrace—

1. Names of towns, villages of any size or note, railway stations, &c., with the taluka and district or state in which each is situated, its longitude and latitude; the population; name of the river or stream on which each is situated; altitude above the sea-level; the dates and names of founders; the etymology of the name; the Sanskrit or ancient name; notes of connected events, peculiar products or manufactures; places of note, temples, commemorative pillars, &c., in their vicinity, with references to fuller descriptions already published.
2. Names of the talukas or divisions in each district, with the area, chief town and population.
3. Shrines and places of pilgrimage, with notes of the objects of adoration or pilgrimage, dates of fairs, &c., and precise locality.
4. Rivers, their rise, course, and confluence or debouchure; lakes, with their size or area and products; hot springs, with their temperature.
5. Mountain ranges, with average heights; peaks, with their greatest altitudes; hill forts, with notes of events connected with them and their present condition.
6. Valleys, plateaux, &c., having particular designations, with notes on their peculiarities.
7. Tribes and peculiar sects, with notes of their habitats, castes, race, peculiar deities, occupations, &c.

These notes are not intended to be lengthy and need seldom extend to half-a-dozen lines; but may generally be restricted to one or two: whilst all detailed information collected might be preserved by the Geographical Society for reference.

If this plan can be well filled up, the proposed list will include the names on the maps of Rennell, Arrowsmith, Allen, Walker and Keith Johnston and in the road-books, with many others in addition. It would thus be of considerable extent and require a large amount of patient labour, besides the collection of much information that has never yet been brought together from the many districts of so vast a country.

The Committee proposes to compile every name in the characters of the vernacular or vernaculars of the district in which it occurs and in the language to which the name belongs. Purely Muhammadan names must be given in Urdu and in the characters of the Hindu dialect of the place; Hindu names in the form or forms used by educated Hindus of the vicinity, whether Hindi, Bengali, Panjabi, Kashmiri, Sindhi, Kachhi, Gujarati, Marathi, Uriya, Telugu, Tamil, Malayalim, Singalese, or Burmese; but, for convenience in printing, it may be best to use the Devnagari alphabet for all the Sanskritic dialects at least. Each name should be followed by its transliteration into Roman characters according to the alphabet of Sir William Jones, as now written by the Royal Asiatic and other Societies and by most orientalists, the English spellings in common use and on the Trigonometrical Survey maps, both the English and vernacular forms being arranged so that, either being known, a name may at once be found in its alphabetical place in the index.

The committee hopes to add any peculiar forms of Indian names found in the best-known historical and descriptive works on India, such as the writings of Orme, Dow, Elphinstone, Grant Duff, Mill, Wilson, Thornton, Montgomery Martin, Rennell, Hamilton, &c.; also the Greek and Sanskrit ancient names so far as they have been identified by Lassen, De Saint-Martin, Cunningham, &c.

Considering the nature and extent of the work, the committee feels that it must be mainly dependent upon fresh information from each locality. Believing also that with adequate assistance such an index would be of permanent value to all connected with this country, it recommends the Geographical Society to bring the matter before the Government at Bombay, with the request that the committee and society be afforded that assistance in procuring the desiderated information, which Government alone can afford, by obtaining the services of its officers in the Revenue, Educational and other departments, in collecting the vernacular names and other particulars and that the Government of Bombay graciously use its influence in obtaining for the society similar assistance from the other Governments of India.

SOCIETIES AND ACADEMIES

The Secretary of the Philosophical Society of Glasgow wishes us to state that the report of the proceedings of that Society in our Number of the 3rd inst. was not an official one. In acceding to this request we would point out the desirableness of the Secretaries of all Societies sending us official reports, since it is only by that means that accuracy can be insured. When this clear duty of an official is performed by an ordinary member, who, without having access to documents and notes, is yet anxious that the work of his Society should be represented, and sends a report faute de mieux, *it is impossible always to guard against error. All reports forwarded to us should be as short as possible, distinctly written, and deal only with advances on our previous knowledge.*

LONDON

Royal Society, February 10.—The following papers were read: "On some remarkable Spectra of Compounds of Zirconia and the Oxides of Uranium." No. 1. By H. C. Sorby, F.R.S. We shall return to this communication.—"On linear differential equations," No. 2. W. H. L. Russell.

"On the mathematical theory of stream-lines, especially those with four foci and upwards." W. J. Macquorn Rankine. A *stream-line* is the line that is traced by a particle in a current of fluid. In a steady current, each individual stream-line preserves its figure and position unchanged, marking the track of a filament or continuous series of particles that follow each other. The motions in different parts of a steady current may be represented to the eye and to the mind by means of a group of stream-lines. Stream-lines are important in connection with naval architecture; for the curves which the particles of water describe relatively to a ship, in moving past her, are stream-lines. If the figure of a ship is such that the particles of water glide smoothly over her skin, that figure is a *stream-line surface;* being a surface which contains an indefinite number of stream-lines. The author in a previous paper proposed to call such stream-lines *Neoïds;* that is, ship-shape lines. He refers to previous investigations relating to stream-lines, especially to those of Mr. Stokes, in the Cambridge Transactions for 1842 and 1850, on the "Motion of a liquid past a solid," of Dr. Hoppe, on the "Stream-lines generated by a sphere," in the *Quarterly Journal of Mathematics* for 1856, and his own previous papers on "Plane water-lines in two dimensions," in the Philosophical Transactions for 1864, and on "Stream-lines," in the *Philosophical Magazine* for that year. He states that all the Neoïd or ship-shape stream-lines whose properties have hitherto been investigated in detail, are either *unifocal* or *bifocal;* that is to say, they may be conceived to be generated by the combination of an uniform progressive motion, with another motion consisting in a divergence of the particles from a certain point or focus, followed by a convergence either towards the same point or towards a second point. Those which are continuous closed curves, when unifocal, are circular, when bifocal, they are blunt-ended ovals, in which the length may exceed the breadth in any given proportions. To obtain an unifocal or bifocal neoïd resembling a longitudinal line of a ship with sharp ends, it is necessary to take a part only of a stream-line: there is then discontinuity of form and of motion at each of the two ends of that line.

The author states that the occasion of the investigation described in the present paper, was the communication to him by Mr. William Froude of some results of experiments of his on the resistance of model boats, of lengths ranging from three to twelve feet. A summary of those results is printed at the end of a Report to the British Association on the State of "Existing Knowledge of the Qualities of Ships." In each case two models were compared together of equal displacement and equal length; the water-line of one was a wave-line with fine sharp ends, that of the other had blunt rounded ends, each joined to the midship body by a slightly hollow neck; a form suggested, Mr. Froude states, by the appearance of water-birds when swimming. At low velocities, the resistance of the sharp-ended boat was the smaller; at a certain velocity, bearing a definite relation to the length of the model, the resistances became equal; at higher velocities, the round-ended model had a rapidly increasing advantage over the sharp-ended model.

Hence it appeared to the author to be desirable to investigate the mathematical properties of stream-lines resembling the water-lines of Mr. Froude's bird-like models. He has found that endless varieties of such forms, all closed curves free from discontinuity of form and of motion, may be obtained by using *four* foci instead of two. They may be called from this property *quadrifocal stream-lines*, or, from the idea that suggested such shapes to Mr. Froude, *Cycnoïds*; that is, swan-like lines.*

Those lines are not to be confounded with the lines of a yacht, having at a distance the appearance of a swan, which was designed and built some years ago by Mr. Peacock, for the figure of that vessel is simply oval. The paper contains four chapters. The first three are mainly cinematical and geometrical, relating to the forms of stream-line surfaces in two and in three dimensions, especially those with more than one pair of foci and surfaces of revolution—the method of constructing graphically and without calculation (by means of processes first applied to lines of magnetic force by Mr. Clerk Maxwell) the traces of such surfaces, which methods are exemplified by diagrams drawn to scale—the motions of the particles of liquid past those surfaces. The fourth chapter is dynamical: it treats of the momentum and of the energy of the disturbance in the liquid, caused by the progressive motion of a solid that is bounded by a ship-shape stream-line surface of any figure whatsoever—the ratio borne by the total energy of the disturbance in the liquid to that of the disturbing body when that body displaces a mass of liquid equal to its own mass, which ratio ranges in different cases from $\frac{1}{2}$ to 1—the acceleration and retardation of ships as affected by the disturbance in the water—the use of experiments on the retardation of ships in finding their resistance—the disturbances of pressure which accompany the disturbances of motion in the liquid. Up to this point, the dynamical principles arrived at in the fourth chapter are certain and exact, like the geometrical and cinematic principles in the three preceding chapters. The results obtained in the remainder of the fourth chapter are in some respects approximate and conjectural, being to a great extent designed to suggest plans for future experiments and rules for their reduction. These results relate to the disturbance of level which accompany the disturbances of motion, when the liquid has a free upper surface—to the waves which originate in those disturbances of level and to the action of those waves in dispersing energy and so causing resistance to the motion of the vessel;—to friction, or skin-resistance and to the "wake" or following current which that kind of resistance causes the disturbing solid body to drag behind it—lastly, to the action of propelling instruments in overcoming different kinds of resistance. The resistance caused by viscosity is not treated of, because its laws have been completely investigated by Mr. Stokes, and because, for bodies of the size of ships, moving at their ordinary velocities, that kind of resistance is inconsiderable compared with skin-resistance and wave-resistance. The resistance caused by discontinuity of figure is stated to be analogous in its effects to friction; but it is not investigated in detail, because ships ought not to be built of discontinuous (commonly called "unfair") figures. In a supplement the author calls attention to the agreement between the position of the points at which there is no disturbance of the pressure on the surface of a sphere, as deduced from Dr. Hoppe's investigation, published in 1856 (*Quarterly Journal of Mathematics*), or on the surface of a short vertical cylinder with a flat bottom, as determined by the experiments of the Rev. E. L. Berthon before 1850 (Proc. Roy. Soc. vol. v. 1850; also, "Transactions of the Society of Engineers," 6th December, 1869. The theoretical value of the angular distance of those points from the foremost pole of the sphere is $\sin^{-1}\frac{2}{3} = 41° 49'$; the value deduced from the experiment is $41° 30'$. The author then adds some remarks on a suggestion made by Mr. William Froude, that the wave-resistance of a ship is diminished when two series of waves originating at different points of her surface partially neutralise each other by interference; stating that, with regard to this and many other questions of the resistance of vessels, a great advancement of knowledge is to be expected from the publication in detail of the results of experiments on which Mr. Froude has long been engaged.

Zoological Society of London, February 10.—Mr. John Gould, in the chair. The secretary stated the principal additions to the society's menagerie during January, amongst which was a specimen of the Great Northern Diver (*Colymbus glacialis*), captured in Cornwall, and presented to the society by A. R. Hunt, Esq.—A letter was read from Mr. W. H. Hudson, of Buenos Ayres, containing some observations on the ornithology of La Plata.—A communication was read from Mr. R. Swinhoe, describing a new deer from China, which Mr. Swinhoe regarded as constituting a new genus of the family *Cervidæ*, distinguished by the large canines and the entire want of horns in both sexes. This deer was stated to be common on the islands on the lower part of the river Yangtze-Kiang near Ching-Kiang, and to be often brought into the market of that city, but appeared hitherto to have escaped the observation of naturalists. Mr. Swinhoe proposed to call it *Hydropotes inermis*.—A communication was read from Mr. George Gulliver, on the size of the red corpuscles of the blood of *Moschus*, *Tragulus*, *Orycteropus*, *Ailurus*, and some other mammalia, to which were added some historical notices relating to the same subject.—A communication was read from Surgeon Francis Day, containing the second portion of his paper on the fishes of Burmah.—The Rev. O. P. Cambridge communicated a monograph of the genus *Idiops* belonging to the family Mygalides, in which were included descriptions of three species considered to be new to science.—A communication was read from Mr. John Brazier, containing descriptions of three new species of shells from the Australian coast belonging to the genera *Voluta* and *Conus*.—Mr. Henry Adams communicated a description of a new species of mollusk of the genus *Colus* from the L'Agulhas Bank, Cape of Good Hope, which he proposed to call *Colus ventricosus*.

* Κυκνοειδής.

Ethnological Society, February 8.—Dr. A. Campbell in the chair. The following new members were announced: Sir Charles Wentworth Dilke, Bart., M.P., Rev. A. S. Farrar, Messrs. M. C. Fisher, F. R. Munton, and F. B. Wright. "On some flakes of flint and chert discovered in the angular *detritus* beneath a submerged forest at Porlock and Minehead in West Somerset." Mr. Boyd Dawkins. These objects of human workmanship prove that man must have lived on the old land-surface before the destruction of the forest, and the accumulation of the series of overlying deposits. It has been supposed that this *detritus* was of glacial age; but the author doubts this. He believes, however, that there is evidence to show that the latest date which can be assigned to these remains is an early stage in the Neolithic period. Dr. Richard King, Colonel Lane Fox, Rev. Dr. Nicholas, and Mr. McLennan spoke upon this communication.—The Chairman then read some notes introductory to a paper on the remains of prehistoric man in the neighbourhood of the Crinan Canal in Argyleshire. This canal is nine miles in length, and connects Loch Fyne with Loch Crinan. The Rev. Mr. Mapleton described with great precision the prehistoric remains in this locality, among which the most curious were some peculiar cup-shaped cavities and concentric rings rudely sculptured on certain stones. In addition to these petroglyphs, there are many menhîrs, and numerous cairns of various forms: crannoss occur in most of the lochs, but are usually merely solitary dwellings. Several duns, a vitrified fort, a brough, and a flint-manufactory are also among the remains in this district. The Rev. Dr. Nicholas and Colonel Lane Fox made some remarks upon this paper.—The assistant-secretary exhibited and described a stone hammer-head found by Mr. R. Mouat in the old workshop of a copper-mine in Portugal.

Entomological Society, February 7.—Mr. A. R. Wallace, president, in the chair.—Mr. Bates, Major Parry, and Mr. Pascoe were nominated as vice-presidents. It was announced that the council offered two prizes of the value of five guineas each, for essays of sufficient merit, drawn up from personal observation, on the anatomy or economy of any insect or insects. The essays to be sent in before the end of November next.—Mr. Bond and Prof. Westwood exhibited several butterflies, the colouration of each being partly that of the male and partly that of the female character. Mr. Bond, on behalf of Dr. Wallace, exhibited cocoons from various parts of the world, of *Bombyx Yamamai* and *Antheræa Pernii*. Mr. Stainton exhibited a large box full of *Micro-Lepidoptera*, each specimen being separately labelled to show the locality and date of capture. Mr. Bond exhibited some more specimens of *Acridium peregrinum*, from Plymouth; Mr. Fred. Smith made some observations upon the *Locusta migratoria* of Linné, and *L. Christii* of Curtis. Prof. Westwood exhibited a new form of *Cynipidæ*, from the Sula

Islands. Mr. Janson, on behalf of Mr. Crotch, exhibited *Philonthus cicatricosus*, *Dyschirius angustatus*, *Hydroporus unistriatus*, and *H. minutissimus*, four recent additions to the list of British beetles.—Major Parry exhibited *Hicagus obscurus*, a North-American species placed by Leconte among the *Scarabæidæ*, of which it has since been suggested that it might possibly belong to the *Lucanidæ*.—The secretary read a letter from Mr. Roland Trimen, on the habits of some South-African species of *Paussidæ*.—The following papers were read:—"A revised catalogue of the *Lucanoid coleoptera*, with remarks on the nomenclature and descriptions of new species" (the concluding part), by Major Parry; "On the species of *Charaxes* described in the 'Reise der Novara,' with descriptions of two new species," by Mr. A. G. Butler. Mr. M'Lachlan presented the MS. of "A catalogue of the *Neuroptera* of the British Isles," being the first instalment of the proposed list of all our indigenous insects.

EDINBURGH

Royal Physical Society, January 26.—Mr. R. F. Logan, president, in the chair. Mr. F. W. Lyon, M.D., and Mr. B. N. Peach, of the Geological Survey, were elected resident members. The following communications were read:—

"Notes on the meteoric shower of November 1869, as observed at the Cape of Good Hope; and on the supposed fall of an aerolite there." By D. R. Kannemeyer. A number of specimens of star-fish and echini, recently added to the British fauna, from Shetland, &c., were exhibited and commented on by Mr. Charles W. Peach. The specimen first mentioned by Mr. Peach was *Comatula rosacea*, for a long time the only known representative, in our seas, of the fossil encrinites; two other species are now known, viz., *Antedon Sarsii*, of which several specimens have been taken in 80 to 100 fathoms off Unst, and *Antedon Celticus*, which has been captured in the Minch and Sleat of Sound, and about 10 years ago in the Sound of Skye. The other specimens exhibited were as follows:—*Ophiura affinis*—got on both sides of Shetland, at Wick, N.B., and off the coast of Northumberland; was taken for *Ophiocoma bellis*. *Luidia Sarsii*—Shetland in deep water, at Wick, N.B., and in Cornwall. *Archaster Parleii*—Two specimens only were taken off Shetland in 1864 and 1867; the most beautiful of our native stars. *Goniaster aculeatum*—Variety of *G. phyrgianus*; very deep water off Unst, Shetland, 1864, two specimens only. *Cribella curta*—Variety *C. sanguinolenta*, occurs between tide-marks from Cornwall to Shetland. *Cidaris papillata*—the "Piper" of the Shetland fisherman, although not new, has hitherto been considered as very rare; has turned up in numbers on the west coast of Shetland in 100 to 110 fathoms. *Echinus Norvegicus* has been also found occasionally in great numbers in deep water, same locality, with *Toxopneustes pictus*, another beautiful addition. The one of the greatest interest is *Spatangus meridionalis*, from equally deep water, same locality, it being especially a Mediterranean form; it is a magnificent species. Several of the above species are also found in the Mediterranean and as these are living in the same spot with Boreal and Arctic forms, it would be interesting to know how they got there, as it is now well ascertained that the Gulf Stream does not reach those seas. All the above are additions to the British list. He was at present unable to give their names. Although he was aware that many new *Holothuriæ* had been found, he did not notice them.

Remarks on the Bill and Food of the Indian Skimmer (*Rynchops albicollis*). By Mr. William Bell. Communicated by Dr. Davidson. It has been stated that the African species of the genus feed on the ground, searching the soft mud with their bills. Mr. Bell had watched these birds near Saharunpore; he had seen them on the mud, but never searching it as if for food. They were well named skimmers, as with their long and powerful wings they flew along the surface of the water; they opened their bills very wide and struck the water at a low angle of 10 deg. or 15 deg., dipping into it in this way to catch small fish and other inhabitants of the water and he had found their stomachs filled with the bones of fish.

Notice of *Larus minutus*, the Little Gull, recently captured in Berwickshire, &c. By John Alex. Smith, M.D. (the specimen was exhibited).—This rare gull, the smallest of the genus *Larus*, was shot in the harbour of Coldingham, Berwickshire, on the 27th of December. It was the property of Mr. Andrew Wilson, Coldingham. It is a native of Eastern Europe, migrating from the Baltic and Gothland, where it breeds, to the South of Europe and Caspian Sea in the winter and is a rare straggler to Scotland, only some two or three specimens having been previously observed. The bird is a young male in immature plumage. Temminck states that it feeds on insects and worms and very little is known of its habits. Dr. Smith found the stomach and gullet of this bird filled with fishbones and was able to detect among these part of the fifteen-spined stickleback, *Gasterosteous spinachia*. The bird was easily distinguished by its small size, measuring only 11½ inches from the bill to the extremity of the tail. Dr. Smith exhibited a fine adult male *Mergusalbellus*, the seamew recently shot, he believed, in Forfarshire; also a specimen of the *Mergulus alle*, the little rotche shot in the end of December at Seacliff. He had hoped to be able to exhibit a very fine specimen of the rare *Alauda alpestris*, the shore lark, which he had examined. It was killed at St. Andrews in company with a flock of snow buntings, on the 31st of December and is the property of Mr. R. Wardlaw Ramsay, jun. He had just learned that another specimen had been killed at Dunbar in the beginning of this month and was in the possession of Mr. F. Balfour of Whittinghame. Very few instances are on record of this bird having been seen in Scotland. Mr. Scott Skirving was inclined to think that the general resemblance borne by this bird to the buntings might help to make it overlooked, and that it might not be so very rare as it was considered to be.

DUBLIN

Royal Irish Academy, January 24.—The Rev. Dr. Jellett, president, in the chair. Mr. Eugene A. Conwell read a paper on a tumulus and chamber in the Island of Gavr' Inis, Morbihan, Brittany; and described the conditions of the purchase of the Island in 1832, in regard to the treasure supposed to be concealed in this tumulus, and the subsequent clearing out of the interior chamber and gallery, measuring 50 feet 8 inches in length. The large blocks composing the walls and roof were not of the native rock of the island; and, excepting three, which were quartz, were granite, and must have been procured from the adjoining continent. Supposing this monument to have been erected by an essentially primitive people, and at a period subsequent to the time when the present island of Gavr' Inis was a portion of the adjoining continent, what a miracle of mechanical power must have been exerted to drag these immense blocks to the shore, to place them on solid rafts, and, after disembarking them, to haul them to the opposite end of the island, where the tumulus is erected, adjoining a cliff! The paper was illustrated by three large sheets giving minute details of the general plan and section of the tumulus, with ground plan, elevations, and measurements of the stones composing the interior chamber—planned and drawn in 1869 by Sir Henry Dryden, Bart., and Rev. W. C. Leukis—together with 21 sheets of drawings of the sculptures on the stones, executed by Sir Henry Dryden. No capstone, and only one pavement-stone, was found sculptured. Twenty-two of the upright stones were profusely covered with sculptures, of the intended significance of which, whether ideographic, symbolic, or intended merely for ornamentation the author could offer no explanation.—Mr. Conwell also exhibited two series of drawings from the cairns on Sliabh-na-Caillighe, one to show the kindred character of the ancient sculptures of Ireland and Brittany, and the other the sculptures on twenty-eight inscribed stones in a single cairn on Sliabh-na-Caillighe, exhibiting an elaborate diffuseness and a variety of characters unequalled in any single cairn hitherto opened and described in any part of the world.—Professor R. S. Ball read a paper "On the small oscillations of a rigid body about a fixed point under the action of any forces, and more particularly when gravity is the only force acting."—Dr. Sigerson read an account of some examinations of the minute organisms found floating in the air of cities, comparing them with those met with in the sea breezes and in country air.

Royal Geological Society of Ireland, February 9.—Mr. G. Dixon in the chair. Professor Macalister read the Annual Report of the Council. The Rev. Professor Haughton, M.D., read a paper "on the mineral constituents of the granites of Scotland." Dr. J. E. Reynolds exhibited a new mode of exhibiting ordinary hand specimens of minerals to a class, by means of the lime light.

Institution of Civil Engineers in Ireland, February 9.—Mr. J. Ball Greene in the chair. The chairman delivered the annual address.

GLASGOW

Geological Society of Glasgow, January 27.—Mr. John Young, vice-president, in the chair. On the "Sutherlandshire gold-fields." Mr. William Cameron. The author referred to a paper he had read before this society in 1866 upon the Auriferous Rocks and Drifts of Victoria, in which he stated that it was possible there might yet be found in Scotland fields where, with modern appliances, gold might be profitably worked. This conjecture has since been realised as a fact. He exhibited a rough-sketch map, showing the geographical position and geological structure of the gold-bearing districts of Scotland, also several interesting sections of the rocks and drifts in the vicinity of Kildonan, describing the prominent geological features of the country as lower Silurian, consisting of mica schist, gneiss, granite, chloritic schist, &c., with occasional quartz veins. No discovery of gold *in situ* had yet been made, and the question as to the true matrix of the Sutherland gold had yet to be decided. In regard to this question, it was pointed out that the materials associated with gold in the drifts are the same as those of the surrounding rocks. Moreover, the gold of each stream varies in character, apparently pointing to some local peculiarity rather than to a glacial origin. The chairman said he could not detect glacial striæ in the drift, which resembled usual river gravel. Dr. Boyce agreed with Mr. Cameron as to the probable local origin of the gold.

NORFOLK

Norfolk and Norwich Naturalists' Society, January 25.—The president, the Rev. J. Crompton, in the chair. Two Richards pipits, two shore larks, an immature goshawk, and a fulmar petrel were exhibited by Mr. Gunn, all procured on the Norfolk coast during the present winter. The Rev. J. A. Lawrence, of Bergh Apton, exhibited some remarkable fasciated stems of the holly (*Ilex aquifolium*), one specimen resuming its ordinary growth at the summit, the branches into which it separated being clothed with leaves in the usual manner.—Mr. Stevenson read a paper on the rare birds which have visited us during the past autumn and winter, in which he stated that no less than thirteen shore larks had been killed on the Norfolk coast between the 7th of November and the 12th of January. Of this species, at one time considered a very great rarity, thirty-two specimens have been procured in Norfolk since 1830. Of those recently obtained, it was remarkable that only four out of thirteen proved to be males, whereas out of eleven examples killed between 1830 and 1862, all were males but two; but in the winter of 1866–7, four pairs were males and females. Six specimens of Richards pipits had been procured in Norfolk; and the present season was remarkable for the number which had been obtained in other and more southern counties, amounting to eleven examples in the neighbourhood of Brighton alone. This species was apparently a bird of passage, but out of its ordinary line of migration, when thus accidentally met with upon our Eastern coast. The goshawk may now be ranked amongst the rarest of our raptorial visitants. He knew of only ten examples procured in Norfolk during the last forty years, of which all but two were young birds. Mr. Stevenson alluded to the unusual number of woodcocks killed during the past autumn, including a strange melanoid variety killed near Cromer. He mentioned the following birds as having been killed on the coast in October and November:—the pomarine skua, Buffon's skua, purple sandpiper, little gull (immature), and a considerable number of storm petrels, some of which had been found far inland. Mr. Southwell stated that the food of one of the Richards pipits, which he examined, consisted of a small species of lady-bird, and that two of the shore larks (which were very fat) had been feeding entirely on seeds of *Arenaria peploides*.—Mr. Crowfoot, of Beccles, read a paper on rare European birds, their nests and eggs, and exhibited eggs of the wall creeper (*Tichodroma muraria*), taken in Switzerland; Baillon's crake, from Potter Heigham, Norfolk, in 1866; the little crake, and little gull, the latter eggs taken on 31st of May, on Lake Ladoga.

PARIS

Academy of Sciences, February 7.—M. C. Sainte-Claire Deville communicated a note by M. C. Naudin, describing an extraordinary fall of snow at Collioure, in the Eastern Pyrenees. This fall commenced on the 21st January, about 5 A.M., and lasted until the morning of the 23rd, or for at least forty-four hours. M. Naudin estimates the average thickness of snow which fell during this period at 0·80 metre (about thirty-two inches); the thermometer during the fall departed very little from the freezing point (0° C). Great damage was done to the olive-trees, which were broken by the weight of the snow, but the author stated that palms, although pressed flat by the snow and afterwards encased in ice for ten or twelve days, received no injury.—M. de Saint-Venant presented a report on a memoir by M. Maurice Lévy, entitled "An essay on a rational theory of the equilibrium of recently moved soils, and its applications to the calculation of the stability of supporting walls," supplementing it by a memoir of his own on the approximate determination of the thrust exerted by soils without cohesion, against a wall of a certain inclination.—M. E. J. Maumené presented a memoir on the general theory of chemical action, embodying a fresh proof of the breaking down of the chemical type in the so-called actions of substitution.—M. Delaurier forwarded some investigations on thermo-electricity, M. de Plagniol a further note on the silk-worm disease (*Morts-flats*), and M. Gaudin a letter relating to his mode of manufacture of artificial gems.—M. Bontemps offered for the acceptance of the Academy some manuscript works of M. Charles, who first employed hydrogen gas in balloons.—M. Faye communicated a note by M. Laussedat on the application of the graphic method to the prediction of eclipses of the sun; and also two notes by M. Heis on observations of the zodiacal light and of the aurora borealis at Münster in Westphalia.—A note was received from M. H. de Kéricuff on the determination of the parallax of Venus.—The fourth and concluding portion of the paper by M. Pierron de Mondesir, "On a new method for the solution of mechanical problems," was presented by M. Sainte-Claire Deville, who also communicated a paper by MM. L. Troost and P. Hautefeuille "On the heat of combination of silicium with chlorine and oxygen," to which he appended some remarks.—Other chemical papers communicated were:—"On a new method for the synthesis of the organic acids," by M. Berthelot, and "On the simultaneous formation of isomers in definite proportions," by M. A. Rosenstiehl.—M. E. Becquerel communicated a note by M. E. Bouchotte on a simplification of Holtz's electrical machine, and on a process for the estimation of the relation existing between the dynamical work expended and the electricity produced.—MM. A. Béchamp and A. Estot presented a note "On the nature and origin of the blood-corpuscles," in which they maintain that these globules are "aggregations of microzymata," which may become developed into Bacteria, Bacteridia, &c.—M. Lacaze-Duthiers communicated a valuable paper "On the organisation of the *Aspergillum javanum*.—A note by M. G. Cotteau on the genus *Asterostoma*, a group of fossil sea-urchins, probably of cretaceous date, was communicated by M. de Verneuil. The author described two new species from Cuba, viz., *A. jimenoi* and *A. cubensis*; only a single species was previously known.—A note by M. Gorseix on the present state of the volcano of Santorin was also read, and M. F. Lenormant presented a note on the antiquity of the ass and horse among the Aryan peoples.

BERLIN

Royal Prussian Academy of Sciences, November 8, 1869.—M. Hagen read a paper on the movement of water in tubes directed vertically downwards.—Prof. Ehrenberg communicated an extract from a letter received from Dr. Julius Haast, of Canterbury, New Zealand, describing his discovery of an old dwelling of moa-hunters, with its cooking-places and other objects of interest. The stone implements found in this place were made of flint, and not polished; they resembled those found at Amiens. Dr. Haast considers that his researches confirm the opinion that the moa-hunters belonged to a different race from the Maories, who, he added, have no tradition concerning the former existence of the extinct gigantic birds.

November 25.—Prof. Poggendorff read a long and elaborate paper on Holtz's rotation electricity and the force manifested by it, which he regards as the most powerful yet produced by frictional electricity.—Prof. W. Peters communicated descriptions of some new species of Saurian reptiles and Batrachia, namely: *Polychrus* (*Chaunolæmus*, subg. n.) *multicarinatus*, from Costa Rica; *Tropidolepisma Richardi*, from North Australia; *Gymnodactylus Steudneri*, from Sennaar; *Cyclorhamphus fasciatus*, from Chili; and *Hyla gracilenta*, from North-east Australia.—Professor Hoffmann read a memoir on the sulphuretted urea-compounds, and another upon the action of iodine upon thiobenzamide.—A supplement to the November *Monatsbericht* contains M. du Bois-Reymond's memoir on the movement of magnets under the influence of moisture.

VIENNA

Imperial Geological Institution, January 4.—A note by M. von Lipold relating to M. Krezci's views on the "colonies" of the Silurian basin of Bohemia was communicated by Mr. J. Barrande, who also presented his reply to M. Lipold's remarks.

M. J. Rumpf presented a notice of the magnetic pyrites of Leoben in Carinthia, and of crystals of magnesite from Maria-Zell in Styria. M. C. von Ettingshausen read a paper on the fossil flora of Sagor in Carniola, which presents the characters of the Aquitainian flora. Prof. E. Suess noticed the occurrence of *Fusulinæ* in the upper carboniferous limestone of the Southern Alps, which he had already compared with the Russian *Fusulina*-limestone. The species found agrees with the *F. robusta* of Meek, from California. Abich has described a *F. sphærica* from the upper carboniferous limestone of Armenia, whch is probably identical with *F. robusta*. *F. cylindrica* occurs in Spain. M. Karl von Hauer communicated a paper on the occurrence of sulphur near Szwosyowice in Galicia; and M. K. M. Paul exhibited the geological map of the northern parts of the counties of Zemplin and Ungh in Hungary, and made some remarks upon the geology of the district.

PHILADELPHIA

Academy of Natural Sciences.—August 17.—Dr. Leidy made some remarks on a tooth of *Equus fraternus*, reading an extract from a letter by T. C. Broadhead relating thereto.—A paper on "Brevoortia" by Alphonzo Wood was read.

September 7.—Mr. Meehan made some remarks upon the development of the buds of plants. He said it was well known that all vegetable physiologists taught there were two classes of buds in plants—one called adventitious buds, which had a kind of nomadic existence, the other axillary buds, which were supposed to owe their origin to the leaf from the base of which they sprang. It was customary to speak of these as the parent leaves of the axillary buds. He would show that the leaf not only did not aid the axillary bud formation, but was rather a foe to bud development. He exhibited vigorous shoots of the Kentucky coffee and honey locust trees, and hichorins of walnuts, showing what had either been entirely overlooked by other botanists or passed over of no importance, that there were in these two or three buds instead of the usual axillary bud, one above another in direct line, and that in all these instances the farthest removed from the base of the leaf, and, of course, the one the least under its influence, was the largest and best developed. He gave the results of extended observations as proof of the same principle from single bud cases. He exhibited specimens of some maple shoots of the present season's growth.—Mr. C. H. Redfield stated that the *Aspidium aculeatum* (L.), though widely distributed over the globe, had, in the United States, been restricted, as was supposed, to the mountains and mountain gorges of New Hampshire, Vermont, and Northern New York, and to Northern Minnesota. He had, however, recently found it growing in abundance in the Stony Clove of the Catskill Mountains, about two degrees farther south than it had before been noticed, and under conditions very similar to those in which it grows in the notch of Mount Mansfield, Vermont.

October 5.—A written communication was received from Prof. Ennis, entitled "Meteors, their composition and the Cause of their Ignition," and another, "On variations in the genus *Ægieothus*," by Elliott Cours, A.M., Ph.D.

October 12.—Mr. Meehan presented a paper for publication, entitled "On the Law ofDevelopment in the Flowers of *Ambrosiæ artemisillfolia*." Mr. Meehan accompanied the presentation with verbal remarks illustrated by the plants.

October 19.—Mr. A. H. Smith made some remarks in regard to a plant discovered some years back by Michaux, and named by him *Carex miliaris*. Some time ago, near Moosehead Lake, Mr. Smith discovered plants which, when submitted to Gray, were called by him *Carex retundata*, and *Carex pulla*. These plants were immature; afterwards procuring perfect plants Mr. Smith thought that they were identical with the *Carex miliaris* of Michaux.

December 21.—Prof. Cope made some remarks on a cranium of the *Hyperaodron bidens* from the coast of Rhode Island, presented by Samuel Powell of Newport. He stated that it was a female which entered the harbour of the latter place with a calf. A male was some time after cast ashore dead near Dennis, Mass., and was preserved complete in the Mus. Comp. Zoology, Cambridge. (See Allen, Mammals, Massachusetts.) He said that the muzzle of the female was longer than represented for European specimens, but that of the male was as short, and that no difference could be detected in the skeleton of either. He, therefore, retained the name *H. bidens.* He stated that *Mesoplodon Sowerbiensis* also occurred on the coast of Nantucket. He next exhibited the left ramus of the mandible of a finner whale of the miocene of Edgecombe Co. North Carolina. He pointed out its characters were nearest those of the *Eschrichtius cephalus*, but that there was a groove inside the upper edge of the jaw. He called it *Eschrichtius polyporus*. He exhibited a number of remains of fossil reptiles from Sampson Co. North Carolina, of cretaceous age, which were intrusive in miocene beds. Among these were humerus, tibia, fibula, metatarsus, caudal vertebra, and, perhaps, cervical vertebra and dermal bone of a gigantic Dinosaur, found together by Prof. H. C. Kerr, Director of the Geological Survey of North Carolina. The remains indicated a species having the same general form and size as the *Hadrosaurus Foulkei*. The caudal vertebra was of very different form, and resembled more that of Hylæosaurus *minus* the diapophysis. This vertebra was elongate, depressed, and angulate. The animal presented various other points distinguishing it from *Hadrosaurus*, and was named *Hypsiberma crassicauda*.

Two caudal vertebræ of another animal from the same county, but different locality, indicated a true *Hadrosaurus*. One, near the thirtieth caudal, was twice the size of that of *H. Foulkei*, the vertical diameter of the centum being 4·5 inches. It presented so many peculiarities of form that Prof. Cope thought it to have belonged to a species distinct from *H. Foulkei*. A caudal apparently *terminal* was shorter than the same in that species. He named it *Hadrosaurus tripos*. Another reptile from the same locality was indicated by an elongate conic tooth. He named it *Polydectes biturgidus*.

January 4.—Dr. Linz exhibited the broken extremity of the snout of a large extinct mammal brought by Dr. Hayden from Colorado Territory, which resembled in some respects the genus *Sivatherium*, especially in presenting a horn core on each side of the front. The nasals were even shorter than in *Sivatherium*, and the horn cores appear to be in advance of the orbits. He suggested that it might belong to *Titanotherium*, but named it *Megacerops coloradensis*. He stated that he had received from the same region remains of a large reptile allied to *Porcilopleurum*. Prof. Cope exhibited the ischiatic bones of two *Dinosauria*. One of these, the *Megadactylus polyzebus* of Hitchcock, had probably been one of those that left its tracks in the strata of the Connecticut valley sandstone. With these a subround bilobed impression had frequently been found, just behind the heels on the median line. This he showed to be the impression of the extremities of the ischia. These bones were directed backwards, and for the posterior half of their length were in close contact, forming an elongate rod, on which the animal rested when in a sitting position. The structure in *Laelaps* was shown to be quite similar.—Prof. O. C. Marsh, of Yale College, exhibited a tooth of a new species of Rhinoceros from the miocene of Squankum, New Jersey, which he regarded as representing a species distinct from those already known. He called it *R. matutinus*, and stated that it was the first species discovered east of the Mississippi. He exhibited several vertebræ of a Hadrosaurus from the upper cretaceous greensand of Bamerbaro, New Jersey, which belonged to a species of smaller size than the *H. Foulkei*. He regarded it as distinct, and called it *H minor*. He exhibited a large tooth of a mosasauroid reptile, of a shorter and thicker form than usual, and which had been taken from a fragment of a jaw, which indicated a species with short, massive muzzle. It is from North Carolina. He proposed to call it *Mosasaurus crassidus*. The vertebra of another Mosasauroid was exhibited, which he referred to the genus *Liodon* (regarded by Prof. Cope as synonymous with *Macrosaurus*), and which presented peculiarities which separated it from *L. laevis* and *L. validis*. Its diapophyses were prolonged to an unusual distance on the caudal series of vertebræ. He proposed for it the name of *Liodon laticaudus*.—Thomas Mecham referred to his former observations that the so-called leaves of coniferæ were but phylloid branchlets, and that the real leaves existed chiefly in the form of adnate scales. In some coniferæ these adnate leaves had the power of elongating into free foliaceous awns. The larch was an instance. In *Pinus* this had never been noticed. He now exhibited specimens of *Pinus serotina*, in which the leaf scales under each fascicle of phylloidæ had developed into leafy awns two inches in length, demonstrating the correctness of his original observation. He further remarked that those adnate true leaves were as different on different species, as the leaves of other plants, and afforded excellent specific characters, much better in fact than many derived from the number of phylloidæ in a fascicle, or even from many points in the cones. Specimens to illustrate this were exhibited.

BUFFALO

Society of Natural Sciences, December 9, 1869.—Annual meeting.—The president, G. W. Clinton, in the chair. The following officers were elected for the ensuing year:—President, Geo. W. Clinton, LL.D.; vice-presidents, A. T. Chester, D.D., Everard Palmer, and Henry A. Richmond; treasurer, James Sweeney; librarian, Otto Bessar. Dr. Bird, of Sioux City, Iowa, and Johnson Pettit, of Grimsby, Ontario, were chosen corresponding members.

BOSTON

Society of Natural History, December 15, 1869.—The following paper was presented:—"Notes on the mammals of Iowa." By Mr. J. A. Allen.

The list of the mammals given in this paper is based mainly upon notes gathered during three months spent in the state of Iowa in the summer of 1867, for the purpose of collecting and studying its animals and plants. A few species have been inserted upon the authority of other authors, while a few others are given from their known occurrence in nearly all the adjoining states, though not, to the author's knowledge, yet reported from this. The whole number enumerated is forty-eight, and probably but two or three remain to be added to perfect the list of the indigenous mammals of the state. Attention is also called to such others as are most likely to occur. If three or four northern ones be found to reach the northern parts of the state, the whole number, including the introduced house-rats and mice, may be increased to about fifty-five or fifty-six, which is a number somewhat greater than is found in many of the Atlantic states, excluding the marine species, the seals and cetaceans. Iowa being situated in a prairie region, it necessarily differs considerably in the general character of its fauna, and especially in respect to its mammalia, from that of the wooded portion of the United States to the eastward, as all who have given attention to the geographical distribution of animals must be aware. Yet we do not in this state fairly enter upon the so-called Middle Province of the continent, which differs so markedly, both in fauna and flora, from the Eastern Province. A great change in the fauna and flora is met with, however, at the point of junction of the wooded and woodless regions of the eastern half of the continent, which in the latitude of Iowa occurs more than a hundred miles to the eastward of that state. At this point as great and as abrupt a change occurs as usually takes place between two contiguous faunal districts, one of which lies to the north or to the south of the other, or where the line of division is an isothermal one, separating different climatic and zoological zones. A few only, if any, of the species embraced in this list seem to find their eastern limit of distribution in this state; but, with two or three exceptions, they range through southern Wisconsin, Illinois, and even into north-western Indiana and southern Michigan, or to the eastern limit of the prairies. Also, with very few exceptions, none are restricted to it in either their northward or southward range. A few of the more northern species, whose southern range is restricted to the southern border of the Alleghanian fauna, may reach the northern counties of Iowa, as a few essentially southern species may approach, or even be found occasionally within its southern borders. Iowa is hence mainly embraced within the Carolinian fauna, at least so far as its mammals, birds, and reptiles are concerned, though generally heretofore supposed to belong, in great part, at least, to the Alleghanian. Among the strictly prairie mammals represented, are at least four rodents (*Spermophilus tridecemlineatus, S. Franklinii, Geomys bursarius, Hesperomys michiganensis*), two carnivores (*Canis latrans, Taxidea americana*), and at least one insectivore (*Scalops argentatus*). Only one eastern species, the red squirrel (*Sciurus hudsonius*), appears to find at the prairie line its western limit, if, as some have supposed, it be true that this animal does not range across the continent. Hence the difference between the mammalian fauna of the prairies of the Upper Mississippi valley and that of the forest region to the eastward consists in the addition of a number of species peculiar to the prairies. Since all the larger species of mammalia are everywhere rapidly disappearing before the revolutionising influences of civilisation, and since great and general changes occur in the faunal and floral features of every country when brought under cultivation, it becomes a matter of unusual interest to preserve as correct a record as possible of the primitive conditions of our own country in this respect, for comparison with its subsequent altered status, as well as a history of the change.

DIARY

THURSDAY, FEBRUARY 17.

ROYAL SOCIETY, at 8.30.—On a Distinct Form of Transient Hemiopsia: Dr. Hubert Airy.—Account of the Great Melbourne Telescope, from April, 1868, to its commencement of operations in Australia in 1869: A. Le Sueur.
LINNEAN SOCIETY, at 8.—On the Tree Ferns of British Sikkim: Mr. Scott.
CHEMICAL SOCIETY, at 8.
ZOOLOGICAL SOCIETY, at 4.
ANTIQUARIES, at 8.30.—On Some Monastic Inventories: Rev. M. E. C. Walcott.—On Some Roman Antiquities: S. Sharp.
ROYAL INSTITUTION, at 3.—On the Architecture of the Human Body: Prof. Humphry.

FRIDAY, FEBRUARY 18.

ROYAL INSTITUTION, at 8.—Theories of the Physical Forces: Mr. W. K Clifford.
PHILOLOGICAL SOCIETY, at 8.30.
GEOLOGICAL SOCIETY, at 1.—Anniversary Meeting.

SATURDAY, FEBRUARY 19.

ROYAL INSTITUTION, at 3—Science of Religion: Prof. Max Müller.

MONDAY, FEBRUARY 21.

VICTORIA INSTITUTE, at 8.—Spontaneous Generation, or the Problem of Life: Rev. Prof. Kirk.
LONDON INSTITUTION, at 4.
MEDICAL SOCIETY, at 8.
ENTOMOLOGICAL SOCIETY, at 7.
ROYAL ASIATIC SOCIETY, at 3.

TUESDAY, FEBRUARY 22.

ETHNOLOGICAL SOCIETY, at 8.—On Recent Archæological Discoveries in Yorkshire: C. Monkman, Esq.—On the Natives of Naga, Philippine Island: Dr. Jagor.
INSTITUTION OF CIVIL ENGINEERS, at 8.
ROYAL MEDICAL AND CHIRURGICAL SOCIETY, at 8.30.
ROYAL INSTITUTION, at 3.—On the Architecture of the Human Body: Prof. Humphry.

WEDNESDAY, FEBRUARY 23.

ARCHÆOLOGICAL ASSOCIATION, at 8.
GEOLOGICAL SOCIETY, at 8.—Additional observations on the Neocomian Strata of Yorkshire and Lincolnshire, with notes on their relations to the Beds of the same age throughout Northern Europe: By Mr. J. W. Judd.—On Deep-mining with relation to the Mineral-bearing Strata in the S.W. of Ireland: By Mr. Samuel Hyde. Communicated by Mr. R. Etheridge.—On the Structure of a Fern-stem from the Lower Eocene at Herne Bay, and on its allies, recent and fossil: By Mr. W. Carruthers.
SOCIETY OF ARTS, at 8.—On Economy of Fuel for Domestic purposes: Mr. D. Galton, C.B.

THURSDAY, FEBRUARY 24.

ZOOLOGICAL SOCIETY, at 8.30.—On the Classification of the Capitonidæ: Messrs. Marshall.—On the White Wag-tails of China: Mr. R. Swinhoe.—On the Deer living in the Society's Menagerie: Mr. Sclater.

BOOKS RECEIVED

FOREIGN.—Les Oiseaux décrits et figurés d'après la Classification de Georges Cuvier mise au courant des progrès de la science, 72 Planches, les espèces remarquables et les caractères, génériques tirés du bec et des pattes: texte explicatif; Figures Coloriées.—Pétrifications remarquables des Alpes Suisses, le Corallien de Wimmis; W. A. Ooster; avec une Introduction Geologique et 24 Planches des Fossiles: C. de Fischer-Ooster.—Monographique der Molluskengattung Venus: Linné; Dr. Edward Römer.—Fossile Flora der jüngsten Steinkohlenformation und des Rothliegenden im Saar-Rhein Gebiete: Ch. Ernst Weiss. (Williams and Norgate.)

CONTENTS

PAGE

CLARENDON PRESS PUBLICATIONS.

VESUVIUS. By Professor PHILLIPS.

CONTENTS:—Vesuvius at Rest—In Action—In the Nineteenth Century—Periods of Rest and Activity—Characteristic Phenomena—Forms and Structure—Minerals—Lava and Ashes, &c. With numerous Illustrations. Crown 8vo. 10*s.* 6*d.*

"Contains much historical and scientific matter reduced to a pleasant and readable form. Of the volume as a whole, we can only speak in terms of the highest praise, and we regard it as a work which deserves a place on the shelves of every student of physical science."—*Examiner.*

"A work of high value both to the student and to the tourist on the shores of the Bay of Naples."—*Pall Mall Gazette.*

"This is an attractive book for those who have no enthusiasm for 'Alpine Plants.' Its pure style, the interesting excursion details, and the beautiful descriptions of scenery, make it a winning book to general readers."—*Record.*

OXFORD: Printed at the CLARENDON PRESS, and Published by MACMILLAN & CO., LONDON, Publishers to the University.

CLARENDON PRESS SERIES.

Extra fcap. 8vo. price 7*s.* 6*d.*

A SYSTEM OF PHYSICAL EDUCATION.

Theoretical and Practical; with numerous Illustrations drawn by A. MACDONALD. By ARCHIBALD MACLAREN, The Gymnasium, Oxford.

"It is marked in every line by good sense, and is so clearly written that no one can mistake its rules. We earnestly hope that the book will find not only many readers, but earnest disciples."—*Lancet.*

Recently published, in Crown 8vo. price 7*s.* 6*d.*

EXERCISES in PRACTICAL CHEMISTRY:

Qualitative Analysis. By A. G. VERNON HARCOURT, F.R.S. Lee's Reader in Chemistry at Christ Church, Oxford, and H. G. MADAN, F.C.S. With numerous Illustrations.

"The plan of the book appears to us to be admirable, and the directions given for performing the various operations involved in the course are wonderfully precise and clear."—*Chemist and Druggist.*

Second Edition, with Solutions.

CHEMISTRY FOR STUDENTS. By

A. W. WILLIAMSON, Phil. Doc., Professor of Chemistry, University College, London. Extra fcap. 8vo. Cloth. Price 8*s.* 6*d.*

"This volume is really a too rare example of what a good elementary text-book in any science ought to be: the language, brief, simple, exact; the arrangement logical, developing in lucid order principles from facts, and keeping theory always dependent upon observation; a book that keeps the reason of the student active while he strives to master details difficult but never without interest, and that furnishes him with means for practising himself in the right management of each new tool of knowledge that is given to him for his use."—*Examiner.*

Extra fcap. 8vo. cloth, price 7*s.* 6*d.*

AN ELEMENTARY TREATISE ON

HEAT, with numerous Woodcuts and Diagrams. By BALFOUR STEWART, LL.D., F.R.S., Director of the Observatory at Kew.

"This compact little treatise is commendable both as an elementary exposition of the chief phenomena of heat and their practical applications, and also as a brief exposition of the philosophical theories which have recently given a new interest to the phenomena. The structure of the work is also excellent."—*Fortnightly Review.*

Demy 8vo. cloth, 856 pp., price 21*s.*

DESCRIPTIVE ASTRONOMY. A Hand-

book for the General Reader, and also for practical Observatory work. With 224 Illustrations and numerous Tables. By G. F. CHAMBERS, F.R.A.S., Barrister-at-law.

The aim of this work, briefly expressed, is general usefulness, whether in the hands of the student, the general reader, or the professional observer. Great pains have been taken to present the latest information on all branches of the science. The development of Astronomy is now so rapid that unless an author exercises constant vigilance his book must fall behindhand: and it is believed that this volume not only contains the most recent discoveries and deductions, but that in it will also be found information hitherto to be met with only in the publications of learned societies, difficult of access and inconvenient for reference even to the Astronomer, and absolutely out of the reach of the general reader.

MACMILLAN & CO., LONDON.

WILLIAMS AND NORGATE'S PUBLICATIONS AND IMPORTATIONS.

THE DOCTRINE OF EVOLUTION.

MR. HERBERT SPENCER'S WORKS.

In 1 vol. 8vo. cloth, price 16*s.* Second Edition, re-organised and further developed,

THURSDAY, FEBRUARY 24, 1870

THE MINISTER OF PUBLIC INSTRUCTION

ENGLISH politicians have peculiar ways of giving us what we want. For some time every one has felt, as it were, by a sort of instinct, that we shall at last have what all other civilised nations have long known to be indispensable,—a Minister of Public Instruction. Out of Parliament this has been on all sides spoken of as a matter of course. But in Parliament it is different. When the inevitable time comes for it to be spoken of there, it must be carefully avoided, or only coyly glanced at, by those who have thoroughly determined to give it, for etiquette imposes on them the necessity of appearing to yield to external importunity. A very pretty example of this parliamentary coquetry occurred last week on the first reading of the new Education Bill. Mr. Forster displayed no little ingenuity in avoiding the slightest allusion to a provision which everyone of his hearers knew to be absolutely essential to the success of the great measure he was introducing. He said, "The first thing that would suggest itself probably to the minds of all hon. members would be a system of organisation throughout the country," knowing perfectly well that "the first thing" that must suggest itself would be a central authority to create and direct that organisation. But the suggestion must not come from a Minister. It was not long, however, in coming from other quarters. Sir John Pakington, as a leading member of the Opposition, and other speakers, promptly supplied the deficiency, and the proposal was received with "ministerial cheers." All men know that the meaning of this amusing, and no doubt most necessary, little comedy is, that we may now hope soon to have a Minister of Public Instruction. That being the case it may not be amiss therefore that the probable scope of the duties connected with such an office should be briefly considered.

Such a Minister should, we think, take charge of the whole range of natural knowledge in all matters in which the State in any way intervenes to advance such knowledge. We understand the comprehensive term natural knowledge to include Education, Science, the Fine Arts, and Music. Towards the promotion of all these the Government at present, more or less contributes its direct influence. In order to ensure continuity of system and avoid its interruption when the head of the department vacates office with the change of Ministers, it will, we believe, be found necessary to place over each of these subdivisions a permanent, that is unparliamentary, Under Secretary of State; unless indeed the two last, Fine Arts and Music, may be found capable of being united under one head. But Education, Science, and Fine Arts, with Music, should certainly be kept distinct, not only with a view to division of labour, but to the special efficiency of each.

The Education branch would include the national system of compulsory primary education about to be established, public schools, universities, and agencies of all kinds aided by the State, which have for their object the training of youth. It would include also general literature in so far as that is recognised or subsidised in any way by the State.

The Science branch would include all establishments, in receipt of Government assistance, in which Science is taught as a special study; all those in which scientific observations or investigations are conducted under State auspices, and all museums in which natural objects are displayed for scientific purposes.

The Fine Arts branch would include all national collections of paintings, sculpture, and decorative works, national schools of design, the national buildings and monuments, whether of the present or the future.

The Music branch would include subsidies for cultivation of music, and rewards for pre-eminence in the art.

Such, it can hardly be doubted, will be the broad classification. No doubt a debateable ground will be found to exist between the different subdivisions, through which it will be difficult to trace a clear line of separation. For instance, between Science and Fine Arts there will be points of contact requiring perhaps careful re-adjustment; as in the cases of the British and South Kensington Museums, in each of which both Art and Science collections are under one roof. The opportunity presented by the institution of the new Minister is perhaps the last that will ever be afforded us of deciding whether collections differing so entirely in their characters and objects as those of Art and Science should be in juxtaposition. It is certain that the classes who visit collections of Natural History, *bonâ fide* for instruction, are not at all aided, and but little interested, by the immediate presence of antiquities and objects of *vertu*. The classes who only visit museums for amusement, are doubtless interested in both. But in creating a consistent system, which of these two classes should be chiefly considered? If the latter, is there not considerable danger of our falling into the error of making such collections mere places of amusement? Again, the minds best qualified to organise and maintain Art collections do not usually possess equal knowledge of, or feel equal interest in, Science, and *vice versâ*. It seems desirable then that the question of separating the two of kinds collections should now be settled once for all.

Coincident with the re-classifying of our national collections should be an endeavour to engraft on some of them, in which the want has long been felt, arrangements for facilitating the study of their contents.

Assuming that the scope of the new Minister's jurisdiction will be generally such as we have indicated, we may be at ease with respect to the Education branch. This has received so much attention of late, and the whole subject has been so thoroughly mastered by Mr. Forster, who will, let us hope, be our first Minister of Public Instruction, that he will enter with confidence on this part of his duties. But with Science it is far different. Our present very meagre and partial scientific arrangements are dislocated and scattered over every existing department of the State, as if with the express object of putting consistency, system, and efficiency out of the question. The first step towards organising this branch of knowledge must be by collecting facts and opinions relating to it. This step can only be taken through the agency of a Royal Commission instructed to give the widest possible scope to its inquiries into everything relating to both Instruction and Investigation in Science.

PROTOPLASM

As regards Protoplasm, in relation to Professor Huxley's Essay on the Physical Basis of Life. Pp. 68. By James Hutchinson Stirling, F.R.C.S., LL.D., Edinburgh. (Blackwood and Sons. 1869.)

WHEN one of the most powerful representatives of the Transcendental school of philosophy, himself possessing a knowledge of biological science, consents to do battle against the modern doctrines concerning Life and its assumed material substratum, *Protoplasm*, we may expect, at least, that the strongest arguments which can be adduced will be brought to bear against the obnoxious theories and their supposed materialistic tendencies. Still more especially must we prepare ourselves for battle *à outrance*, when the champion that steps forward is one who has already grappled so manfully with the "Secret of Hegel" and is otherwise so distinguished a leader amongst the adverse school of thinkers.

Although differing altogether from Prof. Huxley on the main subject of his essay, we find that in one respect the opinions expressed therein are perfectly in accordance with those of Mr. Stirling. With reference to the views enunciated concerning Comte and his writings, Mr. Stirling says: "I acknowledge in Mr. Huxley's every word the ring of a genuine experience." Mr. Stirling is even more severe on the hitherto much-lauded Positive philosopher than Prof. Huxley himself. He says:—

> There is not a sentence in his book that, in the hollow elaboration and windy pretentiousness of its build, is not an exact type of its own constructor. On the whole, indeed, when we consider the little to which he attained, the empty inflation of his claims, the monstrous and maniacal self-conceit into which he was *exalted*, it may appear, perhaps, that charity to M. Comte himself—to say nothing of the world—should induce us to wish that both his name and his works were buried in oblivion.

When the phrase "Physical Basis of Life" was employed, this was intended to convey the notion that there was one kind of matter, that is, one genus—including an almost infinite number of specifically different, though closely related, kinds—common to all living beings: this matter being named Protoplasm. In connection with this doctrine, though based upon other facts, there was a further inference. Life was believed to be a function of living *matter* rather than of living *form*—whether cellular or other. No secondary visible organisation, at all events, was supposed to be needed, though a primary but invisible *molecular* organisation was deemed all essential for the display of vital manifestations. Such a doctrine being once admitted, there is, as Mr. Stirling points out, no logical halting-place short of Prof. Huxley's further conclusion, "*that all vital action whatever, intellectual included, is but the result of the molecular forces of the protoplasm which displays it.*"

Let us see, then, what is to be said in favour of a *matter* of Life, and how far Mr. Stirling's objections to this doctrine are valid.

At the time when the doctrines of Schleiden and Schwann—that the 'cell' was the ultimate morphological unit capable of displaying 'vital' manifestations—were announced, and long after, the simplest independent living things, whether animal or vegetable, were supposed to be unicellular organisms. *Form* and visible organisation were, therefore, regarded by most as necessary for the manifestation of Life: it was supposed that a more or less spherical structure was needed, possessing a distinct cell-wall, with a nucleus, and other cell contents. But, of late years, increasing knowledge and faithful investigation has necessitated much change of doctrine, in regard to the nature of those simplest parts of complex organisms which are capable of displaying a vitality of their own, and in regard to the nature of the simplest independent living things.

Some of the principal modifications in the 'cell' doctrine of organisation are thus sketched by Mr. Stirling himself:—

> The first step taken in resolution of this theory was completed by Max Schultze, preceded by Leydig. This was the elimination of an investing membrane. Such membrane may, and does ultimately form; but, in the first instance, it appears the cell is naked. The second step in the resolution belongs, perhaps, to Brücke, though preceded by Bergman, and though Max Schultze, Kühne, Haeckel, and others ought to be mentioned in the same connection. This step was the elimination, or at least subordination, of the nucleus. The nucleus, we are to understand now, is necessary neither to the division nor to the existence of the cell.
>
> Thus, then, stripped of its membrane, relieved of its nucleus, what now remains of the cell? Why, nothing but what *was* the contained matter, the intracellular matrix, and *is*—Protoplasm.

Thus, then, we seem to reach our elementary life-stuff—our living *matter*. But Mr. Stirling would warn us against coming to any such conclusion—he will not so easily yield. He tells us we are quite wrong if we think we have got rid of the cell and have reduced ourselves to a simple matter of Life. And why? "Because," as he says, "all the great German histologists still hold by the cell, and can hardly open their mouths without mention of it." But, if this be so, after what Mr. Stirling has himself told us, to what else can we ascribe the practice, save to a seeming reality of that reputed fondness in the German mind for courtesy or conventional titles? Some such excuse there may be, but assuredly no other. We would ask Mr. Stirling to reconsider the bearing of the statements which he has himself adduced. In place of the old morphological vital unit—the cell—with its definite characters, we are reduced to a mere naked, non-nucleated bit of protoplasm, as the simplest material substratum adequate to display all those vital manifestations, previously considered to be the essential attributes of the formed elements above mentioned. The power of displaying vital manifestations has, in fact, been transferred from definitely formed morphological units, to utterly indefinite and formless masses of Protoplasm. Instead, therefore, of an obvious *form* of Life, we are reduced to a *matter* of Life, presenting no appreciable morphological characters. It becomes evident, moreover, that if the old term "cell" is still applied to these mere bits of living stuff or protoplasm—not because they are morphological units, but simply because biologists have been compelled to transfer the power of manifesting vital characteristics to such indefinite protoplasmic masses—then this term, thus employed, must be seen to have so entirely lost its old signification, that it can be regarded only as a mere courtesy title. Vital power has obviously been transferred from a definite morphological unit—the cell—to mere living matter, and if any people do persist in still calling a portion of such mere matter by the name of the morphological unit, simply because this was of old also *assumed* to be the vital unit, *we* must not allow such mere confusion in language to confuse us as to the real facts and inferences.

There is another point of view, also, to which Mr. Stirling does not seem to have given an adequate attention. The old doctrine did well enough at a time when the lowest known living things were "unicellular organisms," closely approximating in their characters to those morphological units of which the higher plants and animals are built up. But, since our knowledge has increased—since we have become more familiar with the various living things constituting the lowest groups of Professor Haeckel's third organic kingdom—PROTISTA—the maintenance of such doctrines has become impossible. Do we not now know that although the *Protoplasta* are amœboid animals possessing the old cell characters—that is, having a distinct nucleus, and a definite bounding membrane—there are, nevertheless, adult animals, leading an entirely independent existence, composing the lowest group *Monera*, some of which have no bounding membrane, though they have a nucleus, whilst others, simpler still, are mere bits of protoplasm—naked, non-nucleated, structureless? Yet, such minute, homogeneous, and altogether indefinite bits of protoplasm, are as capable of displaying the fundamental characteristics of life, as are the more definite unicellular organisms to which such attributes were formerly supposed to be restricted. Without visible structure, they nevertheless assimilate materials from their environment, and grow; they constantly vary their shape, and are capable of executing slow movements; though possessing no nucleus, they are able to divide and reproduce their kind.

It seems only fair to mention in this place, that so far back as 1853, before the doctrine as to the constitution of the "cell" had undergone such a modification, or rather, as we should have said, before it had been generally acknowledged that vital manifestations could be displayed by mere bits of protoplasm lacking the supposed necessary elements of *form*, Professor Huxley had put forth a powerful remonstrance against the then all-prevalent "cell theory" of organisation.* His opinions were announced even five years before Virchow, the last great champion of the doctrine, issued his celebrated "Cellular Pathologie." Following, in the main, the doctrine of Wolff and Von Baer, Prof. Huxley contended that the primitive organic substance is a homogeneous plasma, in which a certain differentiation takes place, but that there is no evidence whatever to show that the molecular forces of this living matter ("vital forces" of most modern writers) are, by this differentiation, localised in any one part rather than in any other part—be it cell, or be it intercellular tissue. "Neither is there any evidence," he says, "that any alteration or other influence is exercised by the one over the other; the changes which each subsequently undergoes—though they are in harmony—having no causal connection with one another, but each proceeding, as it would seem, in accordance with the general determining laws of the organism." Whilst believing that the *periplast*—corresponding with the cell-wall and intercellular tissue of other writers—is the seat of all the most important metamorphic processes out of which the various tissues are produced, he also believes that this differentiation is not brought about by any mysterious action on the part of the cell or nucleus, but that it is rather the result of intimate *molecular* changes taking place in the plastic matter itself, after a definitely successive though inexplicable fashion. Prof. Huxley's fundamental position was, in fact, that "the primary differentiation is not a *necessary* preliminary to further organisation—that the cells are not machines by which alone further development can take place; they are rather mere indications of accustomed modes of evolution." This main position he has further illustrated by saying: "We have tried to show that they [the cells] are not instruments, but indications—that they are no more the producers of the vital phenomena than the shells *scattered in orderly lines* along the sea-beach, are the instruments by which the gravitative force of the moon acts upon the ocean. Like these, the cell only marks where the vital tides have been, and how they have acted."

* Brit. and For. Med. Chir. Review, 1853, p. 306.

Certainly the essence of this doctrine is, that the vital forces are "molecular forces"—that they are not dependent upon morphological forms or "cells" and, therefore, that essentially vital manifestations may take place in mere formless living matter—Protoplasm, if you will. As we have just seen, this is precisely the doctrine to which so many other distinguished biologists have now given in their adhesion. They too—Max Schultze, Haeckel, Kühne, and others—have gradually recognised that a something of definite form is no longer necessary: that there are independent living things, even lower in the scale than the old "unicellular organisims": that to constitute one of these, or to constitute a vital unit of one of the higher living things, all that is needed is mere formless, indefinite Protoplasm—or, as Mr. Stirling contemptuously expresses it, a mere "shred" of the matter of Life.

Much of what immediately follows, in Mr. Stirling's essay, we consider to be somewhat irrelevant. We think it has been written under the influence of a misconception as to Professor Huxley's real meaning. Mr. Stirling argues against Protoplasm, on the assumption of its being a substance definite in kind—as definite, we may say, as chloride of sodium—whilst apparently, Professor Huxley's meaning was rather that Protoplasm was the name of a genus of matter, or else of a species including almost innumerable varieties: that it was a proteinacious substance, in fact, of which there might be as many hundreds of isomeric modifications, as there are similar varieties of protein itself.

We regret that we are unable to follow Mr. Stirling into this second part of his essay. It seems to us to be the most interesting part of it, and we recommend our readers to study it for themselves. Much, however, of its reasoning, is, for us, deprived of its seeming cogency, because we cannot agree with Mr. Stirling in his previous conclusion as to the non-existence of a matter of Life. This, as he fully admits, is the really fundamental question about which the difference of opinion exists. And, if we cannot agree with him upon this first point, it is useless for us to follow him into his subsequent reasonings. We cannot, however, but admire his candour when he says:

It is to be acknowledged . . . that Mr. Huxley would be very much assisted in his identification of differences, were but the theories ot the molecularists* on the one hand, and of Mr. Darwin on the other, once for all established. The three modes of theorising indicated, indeed, are not without a tendency to approach one another; and it is precisely their union that would secure a definitive triumph for the doctrine of materialism. Mr. Huxley, as we have seen—though what he desiderates is an autoplastic living *matter* that, produced by ordinary chemical processes, is yet capable of continuing and developing itself into new and higher forms—still begins with the egg. Now, the theory of the molecularists would, for its part, remove all the difficulties that, for materialism, are involved in this beginning; *it would place protoplasm undeniably at length on a merely chemical level; and would fairly enable Mr. Darwin, supplemented by such a life-stuff, to account by natural means for everything like an idea or thought that appears in creation.*

Nothing could be more outspoken and candid than this utterance of Mr. Stirling. He evidently believes that such doctrines of the "molecularists" concerning the new evolution of living things will have long to "await the proof"; but we, on the contrary, firmly believe the time to be not far distant when this will be as much an accredited dictum of science as are the other doctrines of the Correlation of the Physical Forces, and of the Correlation of the Vital and Physical Forces which have been its necessary predecessors. We would ask the Transcendentalists, at least, to speculate upon the possibility of this. Let them learn in the meantime how they may best readjust their doctrines, so that when the time comes in which such change will be absolutely necessary—if their views are to be in accordance with the established truths of science—there may be no sudden bewilderment, no feeling as if the very ground were being swept from underneath their feet. To such a thinker as Mr. Stirling, we should imagine the necessary modification of doctrine would not prove difficult. For, after all, the acceptation, to the fullest extent, of the doctrines concerning Life to which we have been alluding, involves, even from the Transcendentalists, only a somewhat different point of view. So long as Matter, and Force or Spirit, are but two aspects of a something one and indivisible, there is still room for opposite philosophical systems. The old questions may be discussed as earnestly as ever by those who have the leisure and the taste for such ontological inquiries. And, if perchance lured into such discussions, it would often be found that he who was most vehemently charged with Materialism would, from an ontological point of view, prefer to rank himself amongst those who professed the principles of a pure Idealism.

H. CHARLTON BASTIAN

AGRICULTURAL CHEMISTRY

How Crops Grow: A Treatise on the Chemical Composition, Structure, and Life of the Plant, for Agricultural Students. By Samuel W. Johnson, M.A., of Yale College, U.S. Revised, with numerous additions, and adapted for English use, by A. H. Church and W. T. Thiselton Dyer. 1 vol. 8vo., pp. 399. (London, 1869.)

THIS revised edition of an excellent American work ought to find its way into the hands of a very numerous class of youths whose future avocations will require a special acquaintance with the phenomena concerned in the growth of plants—either naturally or under the influence of cultivation—some familiarity with the general structure of plants, with the functions of their several organs and the nature of the various materials which it is the work of vegetation to produce for the food of animals and for numerous other purposes.

It is surprising that in a country where the practice of agriculture is one of the chief sources of wealth and is, directly or indirectly, the means of employing a vast

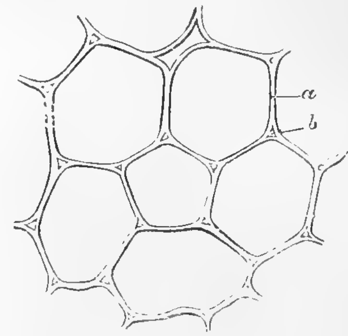

Fig. 1.—Section of cells in a cabbage stem, shewing at *a* the union of the cell-walls and the intercellular spaces at *b*.

amount of capital and labour, very little should have been done towards the scientific elucidation of agricultural practice so as to ensure improvement of the art. Yet such is still the case in this country with some rare exceptions like the experimental farm at Rothamsted, where Messrs. Lawes and Gilbert have done so much to aid the farmer in applying manures and cattle-feeding materials to the best advantage. The Royal Agricultural Society, the Highland Agricultural Society, and the Agricultural College at Cirencester, have also contributed towards the attainment of the same object; but, as a rule, agriculture is practised almost exclusively under the guidance of mere traditional principles and habitual routine, without those engaged in this business having any appreciation of the phenomena and natural laws which govern the growth of plants, even so far as they are known to science. This fact is, in part, no doubt a consequence of the general

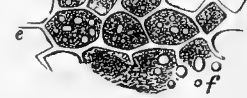

Fig. 2.—Section of a flax-seed, highly magnified, exhibiting *a* cells containing mucilage, *e* cells containing caseine and drops of oil *f*.

disregard of scientific teaching in this country; but it is also referable in some degree to the absence of any organised scientific investigation of plant-life in relation to agriculture, such as that carried on of late years in Germany by the aid of the various governments and with the hearty support of farmers. It is indeed strange that in a country like ours, where agriculture is no longer a mere

* Mr. Stirling so designates those who believe in the possibility of an evolution of living things; or, in other words, those who believe in the possibility of a so-called "spontaneous generation."

gathering of the natural produce of the earth, but has become, more thoroughly than elsewhere, the art of manufacturing food, there should not be an activity in the teaching and prosecution of agricultural science proportionate to that existing where agriculture is in a more primitive state.

However, a beginning is being made in this direction, and it is to aid students in acquiring a knowledge, both technical and scientific, of the less obvious aspects of plant-life, that the volume mentioned above has been written. The classification of the subjects treated of is

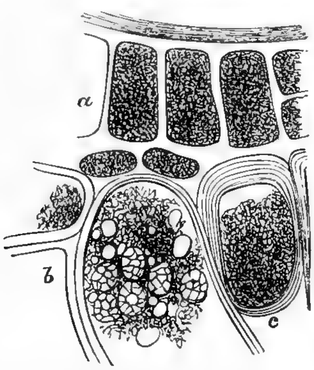

Fig. 3.—Section of outer cells of an oat grain; *a* and *c* containing chiefly caseine, and *b* starch granules.

adapted both to this object and to the wants of the lecture-room, while the illustrations of particular phenomena are in all cases chosen with reference to agricultural practice.

The first division is devoted to the chemical composition of the plant. Here the elementary substances of which plant organs and their materials consist are briefly described, chemical force is defined and the technical language of chemistry explained; then follows an account of the characters and composition of substances which are common products of vegetation in all its forms, of others which are more or less peculiar to certain plants; and lastly, the important subject of the ash of plants is discussed in regard to its general and special character, the extent to which its constituent parts are accidental or essential, and the functions it or its several parts may perform in the growth and development of the plant.

The special organized forms in which the common materials of plants present themselves are well illustrated

Fig. 4.—Forms of various albuminoid grains; *a* from vetch seed; *b* from the castor bean; *c* from flax seed; *d* from *Myrica Cerifera*; and *e* from the aril of the nutmeg.

by numerous woodcuts, of which figs. 1, 2, 3, and 4 will serve as examples.

Copious references to special investigations and monographs are given throughout this division of the book; but unless we have credit for doing even less than has been done in this country, it would seem that the references are too exclusively to German authorities. Only in one instance are the elaborate observations of Lawes and Gilbert mentioned (p. 316), and French experimenters are also but rarely referred to.

One excellent feature of this division consists in the tabulated statements of the amounts of particular constituents contained in various plants, in a form that will be not only instructive to the student, but very useful for reference.

The second division deals with the structure of the plant, the offices of its organs, the nature of the plant cell, the organs of nutrition and of reproduction, with their several functions.

The third division treats generally of the life of the

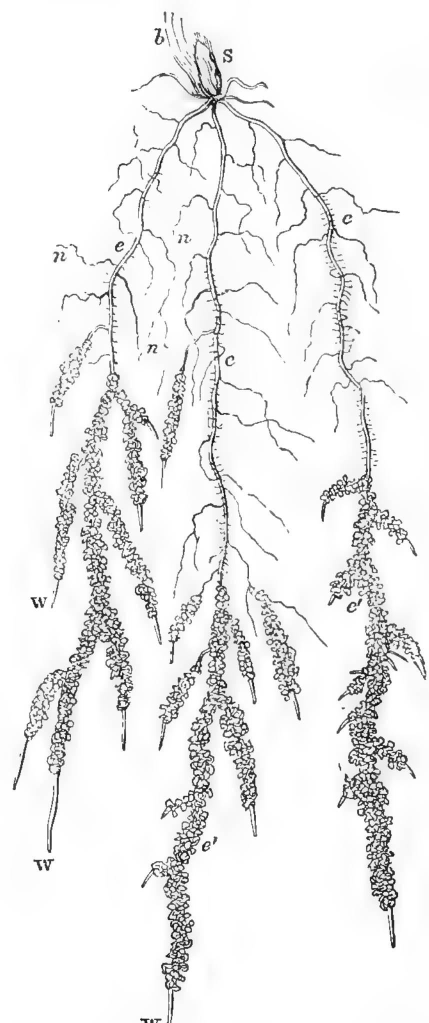

Fig. 5.—Young wheat plant with earth adhering to roots at *e'*, while the root tips W, and the other parts of the primary roots *e*, and of the secondary roots *n* are bare. *S* is the seed and *b* the blade.

plant, describes how the seed germinates, what is the food of plants, how it is taken up, the nature and the motion of the sap and the various forces by which this is influenced, the mode of reproduction, and, lastly, the death of the plant.

Then follows an appendix, with copious tables of the composition of agricultural plants and products, cattle feeding materials, &c., which cannot fail to be useful.

The first and third divisions of this work seem unexceptionable; but the more purely botanical portion might be improved by revision, thus, for instance, at p. 178, cystoliths and crystallised concretions in plant-cells are treated of in a manner which suggests want of familiarity with the microscopic examination of plants, and is calculated to make a beginner suppose all the crystalline concretions of plants are cystoliths of some sort.

At p. 216, it is stated that "In some cases, cells consist only of protoplasm and nucleus, being destitute of cell-walls during a portion or the whole of their existence," and a single line might have been added to explain the exceptional conditions under which these cells—that are not cells—present themselves. Again, at p. 218, after the passage "many cells are altogether empty, and consist of nothing but the cell-wall," there might have been added "after cessation of the functions."

The Screw pine referred to at p. 227 is not a palm; and while the term "imbricated buds" is awkward, the reference, on the same page, to roots that have no buds seems to suggest that buds are generally present on roots inconsistently with what precedes.

Before concluding the notice of this work we must refer to one part of the introductory chapter, where the author very justly condemns as a delusive error the notion that there is any opposition or conflict between science and art, or between theory and practice. "They are, as they ever have been, and ever must be, in the fullest harmony. If they appear to jar or stand in contradiction, it is because we have something false or incomplete in what we call our science or our art; or else we do not perceive correctly; but are misled by the narrowness and aberrations of our vision. It is often said of a machine, that it is good in theory, but fails in practice. This is as untrue as untrue can be. If a machine fail in practice, it is because it is imperfect in theory. It should be said of such a failure—the machine was good, judged by the best theory known to its inventor, but its incapacity to work demonstrates that the theory had a flaw."

It is the boast of some who affect to glory in the sufficiency of practice and to decry theory, that the former is based upon experience, which is the only safe guide. But this is a one-sided view of the matter. Theory is also based upon experience, if it be truly scientific. The vague surmise of an ignorant and undisciplined mind is not theory. Theory, in the proper and good sense, is always a deduction from facts—the best deduction of which the stock of facts in our possession admits. It is the interpretation of facts. It is the expression of the ideas which facts awaken when submitted to a fertile imagination and well-balanced judgment.

If the appreciation of these views were at all equal to their truth, and if the importance of their bearing on the advancement of agriculture were at all adequately recognised, there would probably be little reason to lament the want of attention either on the part of the farmer or the statesman, to the scientific aspects of that pursuit, and less scope for that blatant obstructive, the "practical man," who shuts his eyes and ears against everything his grandfather did not know of, believes only in the folly of wisdom, and is supremely happy in his own ignorance.

OUR BOOK SHELF

A Geographical Handbook of all known Ferns, with Tables to show their Distribution. By K. M. Lyell. (Murray, 1870.)

THIS useful and unpretending, but elegant little volume, consists of two parts. In the first, the genera and species of ferns are enumerated under a number of geographical divisions and subdivisions, which appear to have been judiciously selected. The stations, habitats, and geographical range of each species, are given with much care, and the authorities fully quoted. It thus forms a series of fern catalogues for eighteen divisions of the globe. The second part consists of a systematic list of all the species, with their range of distribution indicated in eighteen columns. Sir William Hooker's arrangements and limitations of species have been followed throughout, and this gives a unity to the work which has its value. But as ferns have generally so wide a range that genera restricted to any one part of the globe are exceptional, we think it would be as well in a work of this nature, to adopt the additional genera of John Smith and others.

We would also suggest for another edition, that a summary of the genera and species might be usefully given at the head of each geographical subdivision. Thus for "Europe Proper" we should have:

1. Woodsia . .	2 species	13. Asplenium . .	17 species
2. Dicksonia . .	1 ,,	14. Scolopendrium .	2 ,,
3. Hymenophyllum	1 ,,	15. Aspidium . .	2 ,,
4. Trichomanes .	1 ,,	16. Nephrodium. .	6 ,,
5. Davallia . .	1 ,,	17. Polypodium. .	4 ,,
6. Cystopteris .	4 ,,	18. Nolhochlæna .	2 ,,
7. Adiantum. .	2 ,,	19. Gymnogramme.	2 ,,
8. Cheilanthes .	3 ,,	20. Osmunda . .	1 ,,
9. Cryptogramme	1 ,,	21. Ophioglossum .	2 ,,
10. Pteris . . .	4 ,,	22. Botrychium . .	5 ,,
11. Lomaria . .	1 ,,		—
12. Woodwardia.	1 ,,		55 species

Such summaries would offer useful materials for comparison, and show at a glance what genera were abundant, rare, or wanting, in a given district. We also think the specific names should have been printed with some difference of type, so as more readily to catch the eye; but these are small matters in so useful a work, which must have been a labour of love to its author, and which no lover of ferns should be without. A. R. W.

Agricultural Analysis.—*Agricultural Qualitative and Quantitative Chemical Analysis.* After E. Wolff, Fresenius, Krocker, and others. Edited by G. C. Caldwell. Pp. vi. and 307. 8vo. (New York: Judd. London: Trübner, 1869.)

MR. CALDWELL (Professor of Agricultural Chemistry in the Cornell University) prepared this compilation for the use of his own pupils and agricultural students generally. Many of the chapters consist of translations from Wolff's "Anleitung," and much more is taken from Fresenius's well-known works on analysis. The metric system of weights and measures, and the centigrade thermometric scale are adopted throughout; and a useful, but not sufficiently extensive set of tables is given at the end of the work.

The merit of a treatise of this kind consists in a proper selection and arrangement of materials; and Prof. Caldwell seems to have performed his task satisfactorily, though, as he admits, somewhat hastily. It is hardly necessary to add, that the book would be quite as much out of place in the hands of an unassisted student as any of those of which it is an adaptation. Under the guidance of a teacher, however, it would undoubtedly be of much service in an agricultural laboratory.

Jahrbuch der Erfindungen. H. Hirzel und H. Gretschel. (Leipzig: Quandt und Händel, 1869.)

THIS is one of a type of books which is not published in this country, either because our publishers are not sufficiently energetic, or because our public has not as yet sufficient interest in science. We may hope that in the yearly volumes of a periodical like NATURE, the general reader will find everything brought down to the latest date, with a sufficiently clear account of all important discoveries. There is needed, however, a sort of "bird's-eye view" book of the year's work, in which a great deal that emerges every week and is of little permanent importance, may be left out, and really considerable discoveries alone given. It is necessary, besides, that the narrative of these discoveries should not be written from the point of view of the man of science, who knows at once where to place them in relation to his previous knowledge. A brief account must be added of that part of what has been accepted or known which the new acquisition illustrates, supplements, or contradicts.

Thus in the description of Wüllner's interesting investigations, confirming those of Frankland and Lockyer as to the alterations which take place in gas spectra when the pressure of the gas is altered, it is necessary to give some account of the previously accepted doctrine of Plücker's "spectra of the first order," and "spectra of the second order." Again, it is useless to describe discoveries relating to circular polarisation without recalling to the general reader the meaning of the term.

We need not attempt in this place to give any account of the new discoveries which are explained in the *Jahrbuch*. It is a closely-printed volume of 416 pages, with 43 illustrations, and its execution appears to us as excellent as its plan. There is a full account of the acquisitions in solar and stellar physics, which have made the year 1868 memorable in science. In molecular physics we have Graham's discussion of the absorption of hydrogen by palladium. In acoustics we have a careful compendium of Regnault's recent laborious and excellent work on the velocity of sound propagation and of the less gigantic experiments by Kundt, which have since been followed out by Schneebeli and Seebeck with promise of bringing us to results more interesting and important from a theoretical point of view than those of Regnault. In heat there is a full account of the investigations, especially with regard to dark heat by Magnus and Dessains. We have all the modifications and improvements in "influence machines," like that of Holtz, which have been realised in the year. For domestic readers there are 25 pages on the sewing machine—single stitch, double stitch, and lock stitch, and 7 more on the knitting machine. Finally, there is a mass of detail, much of it extremely interesting, on the latest chemical discoveries, appropriately introduced by an account of Bunsen's method of washing and filtering precipitates under the pressure of a column of water. W. J.

Mohr's Titrirmethode.—*Lehrbuch der Chemisch-Analytischen Titrirmethode.* Von Dr. Friedrich Mohr. Third and improved edition. Part I. (Brunswick: 1870.)

WE are glad to see that Dr. Mohr's well-known work on volumetric analysis has reached a third edition, and that the author, who well deserves to be called the foster-parent of this branch of chemistry, has taken advantage of the opportunity to recast it entirely. We cannot do better than state his own account of its contents:—

"The work proffers, in the first place, an introduction to the manipulation and use of instrumental appliances, of which the best forms are completely described. Then follows Alkalimetry, under which are comprised all analyses that terminate with the saturation of acids and alkalies. The determination of potash, soda, ammonia, earths, and free acids generally is here described.

"The third section embraces analyses by reduction and oxidation, and especially their subdivision, according as permanganate, dichromate, or iodine solution is added in the final stage. It will be found to contain the determination of chlorine, iodine, bromine, chromic acid, all peroxides, and generally all substances which evolve or combine with oxygen, chlorine, cyanogen, &c. The next section includes analyses by precipitation, the estimation of silver, chlorine, cyanogen, copper, lead, &c.—where a precipitation begins or ends the process.

"The conclusion of the work" (which has not yet reached us) "is the practical part, which teaches the application of individual methods to the entire course of an analysis. Complete methods are stated for the analysis of alkalies, salt-cake, mineral waters, soils, guanos, and the ores of copper, zinc, and iron."

Those of our readers who are acquainted with the previous edition will perceive, from the above account of the contents of the present one, that Dr. Mohr has very much extended his original plan. Accordingly the new *Lehrbuch* contains six additional sheets, and thirteen fresh woodcuts. We need hardly say that the author has executed his work with the detailed care and enthusiasm which are known to characterise him; and the numerous illustrations, for which Messrs. Vieweg are responsible, are as remarkable for sharpness and portraiture as those in most English manuals are deficient in these respects. We shall feel much interested in reading the conclusion of the book, which will supply a want long felt in certain departments of manufacture. For the sake of English experimenters who are not familiar with German, a translation of the entire work, adapted to the prevailing notation, would be very desirable.

THE TRIAL OF THE PYX

THE trial of the Pyx is the formal testing of the coin of the realm, to ensure its being of the requisite weight and fineness. The name is derived from the Pyx, or chest, in which the coins selected for the purpose are contained. The first trial of the Pyx took place in the ninth and tenth years of Edward I. And as the last observance of this ancient ceremony was held during the past week, a few brief notes may not be without interest.

The authority under which the trials were made varied considerably. First, the members of the King's Council, then the Barons of the Exchequer constituted the court, King James I. presiding at one trial. The court now consists of several members of the Privy Council, under the presidency of the Lord High Chancellor and a jury selected from the Hon. Company of Goldsmiths.

Last week the high officers of the Mint assembled at the Treasury, and in their presence the Lord Chancellor charged the jury to examine the coin of the late Master of the Mint, Thomas Graham, F.R.S., and to ascertain whether it was within the latitude of "remedy" allowed by law.

This remedy amounts to 12 grains on each troy pound of gold coin, or to 0·257 grain on each sovereign; and 24 grains on each pound troy of silver coin. Portions cut from standard test-plates were handed to the jury who adjourned to Goldsmiths' Hall. They then opened the Pyx-chest and tested the coin by weight; having done this, a certain number of gold coins were melted into an ingot, which was then assayed; the same process being adopted with the silver coin. In the present instance the Pyx represented a coinage of 14 millions gold and 1 million of silver coin; the verdict of the jury being, that the coin both as to weight and fineness was within the remedy allowed by law. The details, however, were most favourable to the late illustrious Master who has so lately passed away.

An adverse verdict would probably have been followed by no more serious penalty than the forfeiture of the Master's sureties, but it is interesting to note that in the reign of Henry I. the money was so debased as to call for the exemplary punishment of the "Moneyers," while in Anglo-Saxon times the chief officer or Reeve would have been punished by the loss of his hand should he fail to clear himself of the charge of producing false coinage.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Red-Necked Grebe

A FINE specimen of the Red-necked Grebe, picked up alive, but wounded, near Bedford, on the 11th of February, has been sent to me dead, and is being stuffed. It is a female, in winter plumage.

Taunton, Feb. 16 W. TUCKWELL

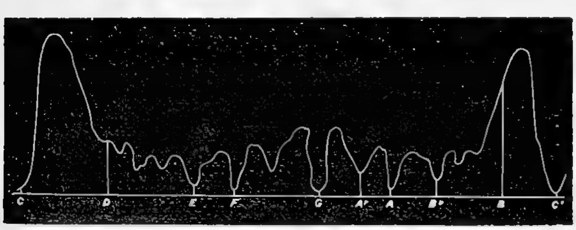
Professor Listing's Amplifier

IN reference to your report of the Boston Natural History Society in NATURE of 27th January, nothing more is requisite to amplify the power of a microscope than to cut off the rims of two or three eye-pieces and insert them in pairs into the ends of a draw tube. Any degree of *amplification* can be obtained whilst the achromatism is preserved. The Huyghenian eye-piece has generally been preferred because the dust accumulating on the inverted eye lens of a positive eye-piece is inconveniently magnified, and obscures the field of view. To those who are desirous of trying Professor Listing's plan, described in your last number, this simple method of mounting may be acceptable.

Lansdowne Crescent, W. ROYSTON PIGOTT

Analogy of Colour and Music

IT appears to me that in the discussion raised by Mr. Barrett's letter in your columns, too little attention has been paid to differences between harmony in music and harmony in colour, which are sufficiently great to show that the coincidences pointed out cannot be regarded as more than *numerical*. Your correspondents have hitherto regarded the subject rather from an optical than a musical point of view. I propose, with your permission, to make a few remarks from the latter stand-point. It is well known that to get a good concord, exact tuning is requisite—*i.e.*, that a slight deviation from the right pitch is sufficient to make a concord into a discord. Moreover, the better the concord, the more intolerable is any appreciable variation of its pitch. Thus unisons, fifths, and octaves are the most sensitive to defective tuning, while the intervals adjacent to them, such as minor seconds, sharp fourths, and sevenths are the harshest discords in the scale. The degree to which this holds will be seen at once by the following diagram, roughly copied from Helmholtz's "Ton-empfindungen." The ordinates of the curve represent the amount of "roughness"—*i.e.*, discordancy corresponding to the intervals marked on the line of abscissæ. The *quality* of tone selected is that of the violin.



A glance at the figure will show that the sounds which produce the most discordant effects with the key-note lie in the immediate neighbourhood of the unison, the octave and the fifth; and further, that a very slight departure from accurate pitch in any concord will provoke a harsh dissonance.

If we now turn to the spectrum, the state of things is widely different. The various colours shade off insensibly one into the other, and in any one colour there is very little, if any, change of tint, except close to its extremities. Thus, then, as far as mere colour goes, any part of any one colour-division produces an equally harmonious effect on the eye, and has an equal claim to be compared to a concord of the gamut.

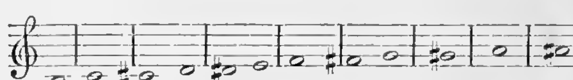
Mr. Barrett, by taking the *central point* of each band of the spectrum as the basis of his comparison, has left this important circumstance out of sight. If we take it into consideration, the result will, I think, be to deprive Mr. Barrett's comparison of any serious importance.

In order to fix our ideas, let us assume that the *mean* red of the spectrum corresponds to *middle C* of the pianoforte with 264 vibrations per second. Taking the limiting and mean wave-lengths as quoted from Prof. Listing by Mr. Barrett, and calculating the number of corresponding sound-vibrations per second, we get the following table:—

	Wave-lengths in 10 millionths of a millimetre.	Number of sound vibrations per second.	Corresponding positions on gamut, with number of vibrations.	
	7234	250	247·5	B
Red	6853	264	264	C
	6472	280 –	282 –	C♯
Orange	6164	293·5		
	5856	309 –	297	D
Yellow	5601·5	323 –	317 –	D♯
	5347	338 +	330	E
Green	5133	352·5	352	F
	4919	368 –	376	F♯
Blue	4737	382 –		
	4555	397 +	396	G
Indigo	4398	411 +		
	4241	427 –	422	G♯
Violet	4104	441 –	440	A
	3967	456 +	469 +	A♯

(+ or – means that the number of vibrations given is a fraction less than ½ above or below the actual amount. In the last column are given the vibration-numbers of the sounds of the chromatic scale.)

By comparing the last two columns it will be seen that Red covers very nearly the portion of the scale between B natural and C sharp: Orange that from C♯ to half-way between D and D♯, and so on. The whole relation is exhibited in the following figure:—



It will be seen that each colour, on the whole, corresponds to *very discordant* intervals in the scale of pitch, and that only at one point in each (and that by no means always the middle point of each band) can it answer to a concord.

What has been said is probably enough to show how little real "correlation" Mr. Barrett's letter has succeeded in establishing. I will now notice the observations on Newton's rings contained in that signed "W. S. Okely." The diameters of these rings vary in lights of different refrangibility, as the *square root* of the wave-lengths,* and therefore they give a spectrum unfit for the purpose to which Mr. Okely applies them. Indeed this is otherwise obvious from the lengths of these diameters given in his letter from a work by Prof. Zannotti. They are as 1, $\sqrt[3]{\frac{8}{9}}$, $\sqrt[3]{\frac{5}{6}}$, $\sqrt[3]{\frac{3}{4}}$, $\sqrt[3]{\frac{2}{3}}$, $\sqrt[3]{\frac{3}{5}}$, $\sqrt[3]{\frac{9}{16}}$, $\sqrt[3]{\frac{1}{2}}$, and therefore, of course, the intervals between them are not as Mr. Okely makes them, $\frac{9}{8}$, $\frac{16}{15}$, $\frac{10}{9}$, $\frac{9}{8}$, $\frac{10}{9}$, $\frac{16}{15}$, $\frac{9}{8}$, but the *cube roots* of these fractions. The interval from red to red $\sqrt[3]{\frac{1}{2}}$, comes out rather less than 1·26, which lies between a major third and a fourth. Mr. Okely's view, which requires the interval from red to red to correspond to an octave, must therefore fall to the ground at once.

Mr. Deas' conception of "millions" of violinists performing "every conceivable sound within" the octave, with a view to the production of the "purest and most ethereal of sounds," seems to me the wildest delusion. Let us suppose the comparatively modest number of thirty-three at work on the interval from middle C to D, so that the first produces 264 vibrations per second, the second 265, the third 266, and so on up to the last, with 297 vibrations. We should obtain a charming variety of *beats*, one a second, two a second, three a second, &c., up to thirty-three a second, those near the higher limit adapted to produce the very worst barking dissonance attainable. Mr. Deas' million-fiddler-power sound, so far from being "pure" or "ethereal," would not be a musical sound at all, but a mere bewildering chaos of noises, likely to drive the inventor himself,

* See Airy's Tracts or Lloyd's Wave Theory of Light.

after one trial of this *spectral* music, to take refuge in the awful solitudes described by Dante:—

" —— dove *il Sol tace.*"

Trinity College, Cambridge SEDLEY TAYLOR

Solar Spots Visible to the Naked Eye

OWING to the smoke and clouds which generally obscure the sky at Glasgow, opportunities to observe the phenomena of the heavens are very rare.

When gazing at the sun this morning (February 16th), I observed on its disc a dark line on the upper half of the disc. In order to convince myself that it was not a delusion, I directed a small pocket telescope (magnifying power about six times linear) and observed several spots. The principal one, as near as I could guess, was 5′ long by 1′ broad.

I would be glad to hear the extent of it from any one of your correspondents, who has measured it, as it must have been of enormous dimensions.

Argyle Street, Glasgow ROBERT M'CLURE

[The dimensions of this spot have been taken by M. Tremischini, who communicated his observations to the French Academy of Sciences at the meeting on the 14th inst., as will be seen from our report of the proceedings further on.—ED.]

Flight of Birds

IN reply to J. H.'s query respecting the flight of the albatross mentioned in a paper of mine on the flight of birds, read at the November meeting of the Norfolk and Norwich Naturalists' Society, I beg to assure him that no bird is able to fly without flapping its wings.

The birds observed by your correspondent's brother were performing one of the most beautiful feats of "wingmanship"—a feat which can only be indulged in, to any extent, by birds possessed of a superabundance of wing-power. The albatross is the great master of this style of flight. Having by repeated flappings of the wings raised itself into the air, and acquired a certain degree of velocity, it brings its body and outstretched wings to such an angle that the pressure of the breeze against its surface is sufficient, or nearly so, to neutralise the force of gravity; it can then "sail" on as long as the momentum lasts. It has been known to sail in this way, with the wings and body perfectly motionless, for more than an hour (though this is an unusually long time), and when the momentum becomes exhausted, a few strokes of the wing are sufficient to restore it. From its frequent indulgence in this sailing flight, the albatross may be said seldom to flap its wings, but certainly cannot be said *never* to do so.

Inserting this explanation may be what J. H. requires.

Norwich, February 7 T. SOUTHWELL

Relations of the State to Scientific Research

AS an old worker in science, and as one who, had Nature not been unkind, might have been eminent, I desire to say a few words on the relations of the State to Scientific Research, a matter likely, I understand, to be the subject of a "Commission."

I take it for granted that it is a natural and proper function of the State to assist and develop labours, the results of which are of national importance, though their market value cannot be satisfactorily ascertained at the time they are being carried on, and therefore they can seldom be immediately remunerative. Of the seed sown to-day, the nation will reap in years to come, long after the sower is dead and gone. It is only right that the nation should help in the sowing. To continue, as of old, merely to reap where others have sown, may seem good in the sight of temporising politicians; but it will not seem so when there comes to be a scanty harvest by reason of the sowers having been feeble and few. It was bad political philosophy when the rulers of the great city overlooked the poor wise man.

But what I wish more particularly to deal with now, is the manner in which the State can best perform this acknowledged duty. In what way can Government most beneficially interfere with the spontaneous energy of original scientific labourers? And this I confess is a matter of no little difficulty. Let us suppose that a certain large sum of money should be set aside, in order to enable a large body of elect men to prosecute original inquiries undisturbed by the bark of the wolf at the door; in other words, let us suppose that Government pays directly for simple scientific investigation. In that case, such elect men will either have to work by the piece, being paid for and by their results when they have brought them forward, or they will have to receive a salary, —to be paid beforehand for work which they will be expected to do. The former plan is, in the first place, impracticable, for the simple reason that the value of the work cannot be satisfactorily gauged,—in the second place it would be most pernicious, and inevitably bring about a deluge of delusions. It would be a gigantic system of prize essays, and we all know that nothing but lies and nonsense proceed out of the mouths of prize essays.

The second plan flies in the face of a fundamental law of human nature. Suppose a hundred men to receive each, say, seven hundred a year, paid quarterly, in order that they may devote themselves to original research. How much of the divine afflatus would list to come into the minds of ninety and nine of them? The morning after they had received their quarter's salary, they would take up their apparatus and sit down by the side of the pool waiting till the waters should be stirred. But the stirring would never come. They would always be paulo-post-futurists; they would ever be writing title-pages of books that would never be seen. They would become admirable critics, keenly sensitive of the follies and errors of the pushing, squabbling, busy, outside mob of unpaid workers; but they, the ninety and nine, would not produce. As they grew old they would ask permission to retain their salaries while they went to live in a land in "which it always seemed afternoon." And when they, the first batch, died, those who succeeded them would boldly declare, as I am told the Fellows of the old Universities do, that they were paid not for the work of which their ability gave promise, but as a reward for having shown themselves worthy of filling the posts. The one man who would do any work at all would be the man who would find the greatest difficulty of getting into the guild, and he, most probably, would only get in by accident after all.

There may be a little exaggeration in the above. As an old man I am prone to be garrulous; but of this I feel above all things assured, that in all the higher functions of the scientific man, in all work that is not mechanical, help from Government or from elsewhere must be given—not directly and in exchange for actual scientific work, but indirectly for some other tasks that do not demand original thought—and given in such a way that active private research may comfortably be carried on at the same time.

In the good old times when the ties which bound together State and Church were not such ticklish ties as now, they used to reward abstract unremunerative learning indirectly by bestowing on it the rich offices of religion. Greek and philosophy took the bishoprics which rightly belonged to piety.

It is possible for science to copy the indirectness and yet to avoid the injustice of this old method; to retain the good while rejecting the evil of such a method of payment *not* by results. How such a plan may be carried out, I will venture with your permission, Sir, to trace in a succeeding letter.

IN SICCO

NOTES

IN the last number of the *Revue des Cours Scientifiques*, M. Alglave again announces further subscriptions to the Sars Fund amounting to 40*l.*, half this sum being a prize awarded by the Zoological Society of Paris in recognition of Sars's works.

M. STAS has been elected director of the Classe des Sciences in the Royal Academy of Belgium.

A DEPUTATION consisting of Earl Fortescue, the Right Hon. C. B. Adderley, Dr. Farr, and others, had an interview with Mr. Shaw-Lefevre at the Board of Trade on Saturday to recommend the legalisation of metric weights and measures in the Post Office, and the legal substitution of metric weights for the troy weight which the Standard Commissioners propose to abolish.

ALL who are interested in the science of ethnology in this country, and their number is daily on the increase, will be glad to learn that the Council of the Royal College of Surgeons are in treaty with Dr. Nicolucci of Nola di Sora, for the purchase of his fine collection of Italian and Greek skulls. This collection, comprising 165 specimens of ancient and modern crania, upon which the celebrated Italian ethnologist's well-known researches into the history of the races of Southern Europe have been mainly founded, will prove a valuable acquisition to the already extensive series in the Hunterian Museum.

MR. SCOTT, the Director of the Meteorological Office, has requested us to state that the French minister of the marine department has made arrangements for hoisting the "drum" signal at all semaphore stations on the French coast, between Dunkerque and Nantes, on receipt of telegraphic intelligence from the Meteorological Office. This signal will, therefore, have the same significance at those ports as on the Elbe and at our own stations. Herr von Freeden in the report of the Norddeutsche Seewarte states, that out of thirty telegrams which might be considered real storm-warnings, there were thirteen instances when the storm followed the same evening or next day; four when it was the previous day (in three of these instances a Sunday intervened and no telegram could be sent), six instances when the weather proved squally, and seven when it remained fine. On two occasions no telegram was received; in one of them on account of an interruption of the wires. As the result of observation, Herr von Freeden considers that the N.W. gales take a southerly direction from Ireland towards the Bay of Biscay, and therefore, do not affect the mouth of the Elbe. He also thinks further investigation would show a connection between them and S.W. winds, further westward, which have been blowing hard before reaching the Channel and have veered to N.W., though not enough to exclude the British Isles from their effect, while in North Germany the compensating current comes from S.E. These facts are of value in showing the utility of the system of "Weather telegraphy" instituted by the Meteorological Committee of the Royal Society.

WE have just received from Herr F. von Hauer the three first sheets of his geological map of the Austro-Hungarian Empire, compiled from the Survey of the Geological Institute; also a map by Mr. Foetterle, showing the occurrence, production, and distribution of coal in Austria. The subsequent sheets of the geological map are in the press and will appear in a few weeks.

AT the dinner of the Foremen Engineers on Saturday, Sir J. Whitworth referring to the depressed state of trade and the signs of improvement that are visible, observed that the progress made during the last forty years in the construction of self-acting machinery has been very remarkable. Twelve shillings a foot was formerly paid for the labour of chipping and filing iron surfaces and it was now done by the planing-machine for a penny. Mr. Bessemer's method of making steel has reduced the cost of some kinds of steel to one-half or one-third what it was. The consumption of coal for manufactures has been reduced more than one-half. The saving on English railways last year by using coal instead of coke was 1,200,000*l*. Mechanical and civil engineers, chemists, and other scientific men, are continually finding out new modes of producing wealth, and the owners of self-acting machinery generally go on improving and increasing their productions, from which those who have fixed incomes derive great advantage. The full employment of such machinery required a free exchange of the produce of all countries. Engineers have so reduced the cost and time of transit that when we have that free exchange, England will probably be the cheapest country in the world to live in. Sir Joseph went on to say, that looking to the immediate future, we may congratulate ourselves on the great opportunity arising for the development of engineering enterprise. The cultivation of land by steam power is greatly on the increase. In regard to the use of horse tramways now being urgently pressed forward, Sir Joseph protested that they were not suited to the present time. He considered that if toll gates were abolished, and roads kept in good order, engineers would soon produce a small, light locomotive that would do its work quietly and efficiently. The consumption of fuel per horse-power is now so small that road locomotives could be employed at far less cost than horses.

WE learn from *L'Institut* that M. Tchibatcheff has published the eighth and last volume of his work on the physical geography, climatology, botany, geology, and palæontology of Asia Minor. The fossils described in this volume belong chiefly to the Devonian tertiary and quaternary series. The Jurassic rocks are represented by only four ammonites found near Angora; the cretaceous rocks by twenty-seven different species, the Devonian by seventy-nine, and the carboniferous by fourteen. The remainder of the 604 species in Asia Minor belong to the tertiary or quaternary rocks. An appendix contains descriptions of fossils found in Devonian strata near Constantinople by Colonel Abdullah Bey. The knowledge of the fossils of Asia Minor, furnished by this work, does not introduce any change in the views previously entertained. The succession of organisms at different epochs has been the same in Asia Minor as in other countries already studied in this respect.

THE *Athenæum* states that the Rev. A. E. Eaton, of Trinity College, Cambridge, is preparing a monograph on the Ephemeridæ, or May-flies, in two parts. Part I. (which will treat of their generic and special nomenclature) is to contain a chronological catalogue of authorities and a synonymic alphabetical index to their works, descriptions of the known genera and species, figures of some organs characteristic of the genera and drawings of many of the species. Part II. will be occupied with an account of the anatomy and development of one or more characteristic British species.

THE Melbourne correspondent of the *Times* remarks, that as a partial set-off against the rabbit and sparrow scourges resulting from ill-considered introductions of European animals to Australia, we now and then light on what seems a new fact in natural history. Among other importations is the ostrich, and being a strong, long-legged bird of uncertain temper, it was deemed unsafe company for children and nurses in the Park. The Acclimatisation Society, therefore, fixed an inquisitive and zoological squatter with the flock of ostriches up country, where he was to look after the birds. Mr. S. Wilson, writing from his station at Longeranong, informs the Society that twelve young birds have been hatched in one nest, and "are getting on nicely." Referring to a common notion, derived from such books as "Goldsmith's Natural History," that the ostrich lays her eggs in the sand, leaving them to be hatched by the heat of the sun, Mr. Wilson says that during the period of incubation —about six weeks—the male and female sit on the nest by turns, both being seldom absent at the same time. As it is not to be assumed that the ostrich departs from its natural domestic arrangements in a new country, we must believe that the female has been hitherto commonly maligned, and the peculiar virtues of her husband altogether overlooked. Another nest of eleven eggs came to no good, as they were laid too early in the winter. The nest is "in a sandy hollow, without grass or rubbish, and the eggs are entirely without any cover."

AT the meeting of the Linnean Society, held Feb. 17, a paper was read by Mr. C. B. Clark on the *Commylenaceæ* of Bengal, of which order he proposes a new system of classification, based on characters of the capsules and the seeds; a paper on the Tree-Ferns of British Sikkim by Mr. Scott, which comprise eight indigenous species belonging to the genera *Cyathea*, *Hemitelia*, and *Alsophila*, an intoxicating drink being obtained by the natives from three different species; and an interesting letter addressed to Dr. Hooker by Dr. Hunce, from Whampoa near Canton, on the Flora of some little investigated districts in that neighbourhood.

WE have to record the decease of Mr. J. E. Sowerby, so well-known in connection with the illustration of botanical works, especially the new edition of the English Flora, edited by Mr. J. Boswell-Syme, now nearly completed.

THE Professorship of Medical Jurisprudence in the Royal College of Surgeons, Ireland, is vacant by the death of Dr. Geoghegan. The election by the Council was to take place on the 17th inst.

DURING the recent discussion on Easter Island at the Royal Geographical Society, it was stated that the layers of guano could be traced and the deposit of each twenty-four hours distinguished. It was calculated that it must have taken 4,000 years to form the 20 feet deposits on the Chincha Islands.

THE town of Dantzic having given a concession of the sewage to Messrs. Aird of Berlin and granted them land for its utilisation, preparations are now being made for carrying out the work under the direction of Mr. Baldwin Latham.

WE have received a report of the Birmingham Natural History and Microscopical Society, which appears to be actively at work, and we notice that Mr. Fiddian read a paper, of which he has sent us a copy, on a "Screw Motion" to remedy the defects in the adjustment of compound microscopes.

THE *Bulletin de la Société d'Acclimatation* contains an article on the use of the skins of the Kangaroo for glove-making, which seems to promise a successful result in this respect, and as furnishing a new source of animal food, as these animals thrive well in Europe.

THE Warsop aero-steam engine has lately been much talked of, and was the other day prominently described in the *Times*. The invention consists essentially in mixing heated air with the steam before its admission into the engine, and results have been obtained which show considerable advantages in the case of certain engines and boilers. *Engineering* referring to the subject remarks, that it is to be regretted that those interested in the invention should not have afforded means of judging whether its application to engines of an economical class would furnish results as satisfactory as those obtained with the defective boiler of the *Fox*.

A CORRESPONDENT in the *Society of Arts Journal* suggests the necessity of a new house for that body, with sufficient room for an extensive library and museum, and adds, that if a hundred of our trade magnates were to set down their names for 1,000*l.* each, the object would be accomplished, and they would be the Greshams of a New Exchange, where art and science would incessantly supplement and extend an ever-growing commerce, and lessen the sphere of human want.

THE *British Medical Journal*, referring to the general impression that the mortality attending the larger operations performed in hospitals has diminished during the last two or three years, suggests that if this be due to really improved plans of treatment, the introduction and free use of carbolic acid may have been one of the measures most influential, and recommends the use of this material in hospitals for preventing accidental contagion.

WE have received, from the Editor, the "Year Book of Photography, and Photographic News Almanac for 1870," containing a number of interesting and useful papers and memoranda.

THE *Journal of the Society of Arts* states that application has been made by the French Government for plans and statements relating to the organisation of the South Kensington Museum and Schools. Schemes based on the same principle and method have, it is understood, been proposed in New York and Boston.

CAPTAIN HANS BUSK has issued a circular in which he expresses his conviction that much may yet be done to diminish loss of life by shipwreck, and suggesting the construction of an experimental steam life-ship of 80 to 100 tons and 50 horse-power, capable of keeping the sea in any weather. An institute has been established for this purpose, and Captain Busk offers a donation of 200*l.* on condition that 1,400*l.* be contributed by the public towards the cost of the vessel during the present month. Upwards of 700*l.* has already been received. Subscriptions are to be sent to the Hon. Secretary, Major Wallace Campbell, or Captain Busk, 3, Garden Court, Temple, or to Messrs. Coutts' Bank.

WE have received from the publishers the January number of the *North British Review*, in which we notice an admirable series of notices of contemporary literature, in which there are among the scientific works referred to Ångström's "Researches on the Solar Spectrum," Ladenburg's "History of Chemistry," Micé's "Report on the Progress of Chemistry," Odling's "Outlines," Foster's "Physical Geography of the Mississippi Valley," Sir J. Lubbock's "Pre-Historic Times," and Newman's "British Moths."

A METHOD of protecting iron from atmospheric influences has been proposed by Messrs. Macmillan and Macgregor, of Dumbarton and Glasgow. They bring melted sulphur into contact with the cold metallic surface to be coated. The sulphur chills and sets into a hard, thin, protecting covering.

MR. RUGGLES states in his report to the International Statistical Congress held at the Hague that, in 1868, the extent of land under wheat, rye, barley, oats, buckwheat, and maize in the United States was upwards of sixty-six million acres, the cereal crop amounting to more than four times as much as was needed for the population of the country.

THE Secretary of State for India announces, at the request of the Governor-General of India, that the Government of India offers a prize of 5,000*l.* for machinery or a method suitable for the separation of the fibre and bark of the Rheea or China-grass from the stem and for separating the fibre from the bark. Dried stems and specimens of the fibre will be suppled on application to the Secretary to the Government of India in the Home Department.

WE learn from a paper by Mr. Bartley in the *Society of Arts Journal*, that Science classes, attended by artizans, were in active operation last year in Chelsea, Hampton, Knightsbridge, Nine Elms, and Wandsworth, the total number of students being 223. The Chelsea School has just been enlarged by the students themselves, working from six to eleven at night. It will accommodate 200, the outlay being 50*l.* for material. This school has now 206 students in all. They are taught by Mr. Bickerton—formerly a cabinet-maker in Gloucestershire—who has distinguished himself as a pupil at the Royal School of Mines. With the exception of a few prizes, no local aid of any kind has been given to the school.

WE have received from Vienna the catalogue of a book-sale which is to take place during March, in which we notice the titles of many valuable works on Natural Science, History, Political Economy, Mathematics, &c., in various languages. Commissions for purchases are received by Messrs. Trübner in London.

A COURSE of eight lectures on English History, from the accession of Edward III. to the date of the Council of Constance, is now being delivered in the Pimlico Rooms, by Archibald Milman, Esq., under the auspices of the Committee for the higher education of women.

A DEPUTATION from the Society of Arts waited upon Earl Grey and Mr. Forster at the Privy Council Office on Friday, to present a memorial representing in reference to the system of State aid to science classes, the hardship of the new orders which are looked upon by teachers as a breach of faith by the department. Lord De Grey promised to consider the matter carefully.

IN consequence of the appointment of Mr. Dyer to the chair of Botany in the College of Science, Dublin, the Professorship of Natural History at the Royal Agricultural College at Cirencester is vacant.

VIEW OF PART OF THE MERCED CAÑON WITH THE VERNAL FALL, YOSEMITE VALLEY, CALIFORNIA
(From Report on Geological Survey of California by C. J. D. Whitney, State-Geologist)

CAÑONS

TO the south of Salt Lake and the Mormon Territory lies a dreary series of plateaux traversed by the Colorado river and its tributaries, which bear their burthen of waters into the Gulf of California. Though this region possesses many considerable streams, it is over large areas a kind of desolate wilderness, for instead of irrigating the ground these streams flow in profound gorges, which serve as natural drains to carry off the water which may fall upon the tablelands. Many fabulous tales have been told of these regions, their natural marvels receiving many amplifications as they came to be rehearsed by Indians, trappers, and adventurous wanderers into the far west. In 1857 the Government of the United States despatched an expedition to explore that little known portion of the Continent, and the report published by the expedition in 1861 gave the first trustworthy and detailed account of the Colorado region. The truth turned out to be almost stranger than the fiction. A vast territory was found to be intersected by ravines leading into the main line of gorges of the Colorado. These ravines, or cañons as they are termed, meander over the table-land as rivers do over alluvial meadows; but they are thousands of feet deep—hundreds of miles long, and so numerous that the country traversed by them is said to be impassable, save to the fowls of the air.

The longest and deepest gorge is the Grand Cañon of the Colorado. Its length was set down by Dr. Newberry as about 300 miles; and its walls were described as rising steeply, sometimes vertically, from the margin of the river which filled the bottom of the ravine, to a height of from 3,000 to 6,000 feet—a line of precipice or natural section which has not yet found its equal on any other part of the globe.* Attention has lately been again called to this remarkable gorge by the interesting narrative in Mr. Bell's "New Tracks in North America," and by the fuller details, as yet only partially published, obtained by an exploring party under Colonel Powell, of the United States army. By successive travellers and Government expeditions the gorges of the Colorado had been reached here and there. The surveying party of 1857-58 mapped them out and gave many admirable drawings of them, but declared the river not to be navigable above the Black Cañon. Profiting by previous failures, and by all the information which he could receive from Indians and others, Colonel Powell conceived the bold idea of attempting the descent of the Colorado in boats. After months of toil and danger, he succeeded in forcing the passage of these forbidding gorges, and emerging safely at their further end. From his survey it appears that the Grand Cañon is 238 miles long, and from 2,500 to 4,000 feet deep. But though this is the longest, there are other ravines of hardly inferior dimensions. On the Green River, Col. Powell's party navigated a series 190 miles long. From where the Green River joins the Colorado, they passed through a succession of cañons for a distance of 256 miles before they came to the Grand Cañon.

HEAD OF MERCED AND TUOLUMNE RIVERS (See Geology of the Sierra Nevada in Whitney's Geological Survey of California, pp. 415—419)

Each cañon has tributary cañons: these again have often also their tributaries. In some places the lateral gorges crowd so closely together where they join the main one, that they are divided by perpendicular walls of rock, which seem so narrow at top as hardly to furnish footing for a man, though in reality large enough to support cathedrals. And these walls shoot 2,000 or 3,000 feet above the river, "while rocks and crags and peaks rise still higher, away back from the river, until they reach an altitude of nearly 5,000 feet." They consist to a large extent of brown, grey, and orange-coloured sandstones, gently inclined or horizontal, beneath which marble and granite in some places have been deeply trenched. In some places

* See Dr. Newberry's section of this gorge in NATURE, No. 6, p. 163.

the walls are so absolutely vertical, that it is impossible to find a pathway between their base and the water. But where, owing to rapids, some portage was necessary, the explorers usually succeeded in carrying their stores, and sometimes even their boats, along the base of the cliffs.

The water of the Colorado River is red and muddy. It receives some tributary streams of clear water, but others are very turbid, particularly one which the expedition appropriately marked as the Dirty Devil. Moreover, after every heavy shower of rain, "cascades of red mud pour over the walls from the red sandstone above, with a fall of hundreds of feet." We await with interest the detailed report which Colonel Powell will furnish of these features of the river.

Dr. Newberry, who described this territory in the report of the former Exploring Expedition above referred to, declared his opinion that, notwithstanding the stupendous scale on which these cañons or ravines had been formed, they were all nevertheless true river-gorges, excavated by the erosive action of running water. Some geologists, as Dr. Foster of Chicago, in his recent work on the Mississippi Valley, have opposed this opinion, and have suggested that "the form and outline of these chasms were first determined by plutonic agency." But Dr. Newberry's explanation has been very generally accepted. He showed that there is nowhere any trace of fracture or disturbance, and that when the Cañon is dry its rocky bottom shows no mark of dislocation. Indeed, when we consider the intricate ramifications of these cañons, so precisely similar to the ordinary outlines of a drainage system over a low flat ground, it seems impossible to conceive of any agency capable of producing such ravines save the streams which flow in them.

But if cañons are merely the results of ordinary river erosion, why do they not occur everywhere? To such a question we may reply that river-ravines do occur everywhere, but it is only where the special circumstances which favour the formation of such ravines are most fully developed that they grow into the depth and length of cañons. What then are these special circumstances?

If we watch what takes place along the course of the rivers of this country, we can mark two kinds of erosion distinctly at work. First there is the river, grinding down the sides and bottom of its channel by sweeping along sand and shingle; and, secondly, there is the action of rain, springs, and frosts perpetually loosening the sides of the water-course, and sending the débris into the river which sweeps it away. If the river were not interfered with by these other subaërial agents, it would in time dig out for itself a gorge with more or less precipitous sides. But in proportion as these agents come into play, the ravine-like character passes into that of a valley with sloping sides. Where river erosion predominates we have ravines, where it is modified by rains and springs, but especially by frosts, we have valleys. Many of our rivers run both through gorges and along valleys, the changes in the nature of their banks being determined by corresponding changes in the nature and grouping of the rocks of which these banks consist, and the greater or less facility with which the rocks have been worn away by the one form of denudation or the other. The conditions needful for the formation of cañons, therefore, appear at present to be chiefly these:—1st. The erosive power of the streams must be greatly in excess of that of the other forms of atmospheric denudation. The rainfall must be small, or, at least, so equally distributed over the year as to reduce pluvial action to a minimum. Frosts must be equally rare and unimportant. The main streams drawing their supplies of water from a distance, either from melted snow or abundant rainfall in the upper parts of their basins, must be maintained in sufficient volume to keep their channels full, either for the whole, or a good part of the year. 2nd. There must be a considerable uniformity in the character of the rock which the stream has first to cut through. It is not necessary that the rock should be soft, but it should preserve for a long distance, and present to the erosive action of the river, the same kind of geological texture and structure. Hence, horizontal or gently undulating strata, as of sandstone, or limestone, offer the greatest facilities for the erosion of cañons, as we know they do in our own country for the formation of ordinary river-ravines. When once the river has excavated its channel so deep that it cannot quit it, the nature of the rock may vary indefinitely without materially altering the aspect of the cañon. Hence on the Colorado, while the upper and chief part of the cañon has been cut through flat sandstone, limestone, and other strata, the lower portion has been excavated in marble and even in granite. 3rd. The country must be sufficiently elevated above the sea, either originally or by subsequent upheaval, to permit of a considerable declivity in its river-channels. The slope must be sufficient, not merely to let the water run off, but to give rise to currents strong enough to sweep along sand and gravel, and to excavate pot-holes. It is by the ceaseless grinding of such detrital material along the bottom of the river that the ravine is slowly deepened. Geologists, although they have constantly recognised this action, have not, perhaps, been always fully aware of its rapidity and extent, partly, no doubt, from the want of reliable data as to the nature and amount of the detritus pushed by rivers along the bottom of their beds. Messrs. Humphreys and Abbot computed that the Mississippi annually pushes into the Gulf of Mexico 750,000,000 cubic feet of gravel and sand, "which would cover a square mile about twenty-seven feet deep." The writer of the present paper was surprised a few years ago to find that the Rhine, after escaping from all its ravines and entering the low country about Bonn, retained force enough to drive along shingle upon its bed. By laying the ear to the bottom of a boat floating down mid-channel, it was easy to hear the grating of the stones as they rolled over each other. Hence we see that a river, which may be perfectly navigable by steamers, may yet have rapidity enough to scour its bed with coarse shingle. The scour will, of course, be greater in proportion to the narrowing of the breadth of the stream and the increase of the slope.

It is mainly this eroding action which, so far as we know at present, has carved out the cañons of the Colorado. These wonderful ravines, meandering as ordinary rivers do, have sunk inch by inch into the country, retaining their original curves and windings, though continually increasing in depth. Unassisted, or aided but feebly, by the other subaërial agents, which, in such a country as ours, tend to break down the walls of ravines; and undisturbed by the inequalities of surface so characteristic of regions that have been under the influence of glacier-ice,* the rivers, probably once much fuller than now, have been allowed to dig out their gorges through the table-lands of the Colorado, and to convert a tract of country, originally, perhaps, green and well-watered, into a dreary desert, intersected by a network of profound impassable ravines.

ARCH. GEIKIE

SCIENTIFIC SERIAL

Revue des Cours Scientifiques, February 19.—This number contains a list of subscribers to the Sars Fund; also a lecture delivered at the Sorbonne by M. A. Cazin, on "Motive Power," in which are described the laws obtaining in regard to those natural forces which are already made available as sources of motive-power and the application of some other forces which may probably be turned to account in the same way as science progresses; for instance, the application by M. Mouchot and Ericsson of solar heat for working a steam engine is especially mentioned as worthy of consideration; and the application of the force of tides suggested by M. Tommasi.

* The absence of any trace of glacial action on the Pacific slope is noted by Whitney (Proc. Acad. Nat. Sciences, California, iii. 272), and by Foster ("Mississippi Valley," p. 338).

ON THE PROGRESS OF PALÆONTOLOGY

ANNIVERSARY ADDRESS DELIVERED BEFORE THE GEOLOGICAL SOCIETY

It is now eight years since, in the absence of the late Mr. Leonard Horner, who then presided over us, it fell to my lot, as one of the secretaries of this society, to draw up the customary Annual Address. I availed myself of the opportunity to endeavour to "take stock" of that portion of the science of biology which is commonly called "palæontology," as it then existed; and discussing one after another the doctrines held by palæontologists, I put before you the results of my attempts to sift the well-established from the hypothetical or the doubtful. Permit me briefly to recall to your minds what those results were.

1. The living population of all parts of the earth's surface which have yet been examined, has undergone a succession of changes which, upon the whole, have been of a slow and gradual character.

2. When the fossil remains which are the evidences of these successive changes, as they have occurred in any two more or less distant parts of the surface of the earth, are compared, they exhibit a certain broad and general parallelism. In other words, certain forms of life in one locality occur in the same general order of succession as, or are *homotaxial* with, similar forms in the other locality.

3. Homotaxis is not to be held identical with synchronism without independent evidence. It is possible that similar, or even identical, faunæ and floræ in two different localities may be of extremely different ages, if the term "age" is used in its proper chronological sense. I stated that "geographical provinces or zones may have been as distinctly marked in the Palæozoic epoch as at present; and those seemingly sudden appearances of new genera and species, which we ascribe to new creation, may be simple results of migration."

4. The opinion that the oldest known fossils are the earliest forms of life, has no solid foundation.

5. If we confine ourselves to positively ascertained facts, the total amount of change in the forms of animal and vegetable life since the existence of such forms is recorded, is small. When compared with the lapse of time since the first appearance of these forms, the amount of change is wonderfully small. Moreover, in each great group of the animal and vegetable kingdoms, there are certain forms which I termed PERSISTENT TYPES, which have remained, with but very little apparent change, from their first appearance to the present time.

7. In answer to the question "What then does an impartial survey of the positively ascertained truths of palæontology testify, in relation to the common doctrines of progressive modification, which suppose that modification to have taken place by a necessary progress from more to less embryonic forms, from more to less generalised types, within the limits of the period represented by the fossiliferous rocks?" I reply, "It negatives these doctrines, for it either shows us no evidence of such modification, or demonstrates such modification as has occurred to have been very slight; and, as to the nature of that modification, it yields no evidence whatsoever that the earlier members of any long continued group were more generalised in structure than the later ones."

I think I cannot employ my last opportunity of addressing you, officially, more properly—I may say more dutifully—than in revising these old judgments with such help as further knowledge and reflection, and an extreme desire to get at the truth, may afford me.

1. With respect to the first proposition, I may remark that whatever may be the case among physical geologists, catastrophic palæontologists are practically extinct. It is now no part of recognised geological doctrine that the species of one formation all died out and were replaced by a bran-new set in the next formation. On the contrary, it is generally, if not universally, agreed that the succession of life has been the result of a slow and gradual replacement of species by species; and that all appearances of abruptness of change are due to breaks in the series of deposits, or other changes in physical conditions. The continuity of living forms has been unbroken from the earliest times to the present day.

2, 3. The use of the word "homotaxis" instead of "synchronism" has not, so far as I know, found much favour in the eyes of geologists. I hope, therefore, that it is a love for scientific caution, and not mere personal affection for a bantling of my own, which leads me still to think that the change of phrase is of importance; and, that the sooner it is made, the sooner shall we get rid of a number of pitfalls which beset the reasoner upon the facts and theories of geology.

One of the latest pieces of foreign intelligence which has reached us is the information that the Austrian geologists have, at last, succumbed to the weighty evidence which M. Barrande has accumulated, and have admitted the doctrine of colonies. But the admission of the doctrine of colonies implies the further admission that even identity of organic remains is no proof of the synchronism of the deposits which contain them.

4. The discussions touching the *Eozoon* which commenced in 1864, have abundantly justified the fourth proposition. In 1862, the oldest record of life was in the Cambrian Rocks; but if the *Eozoon* be, as Principal Dawson and Dr. Carpenter have shown so much reason for believing, the remains of a living being, the discovery of its true nature carried life back to a period which, as Sir William Logan has observed, is as remote from that during which the Cambrian Rocks were deposited, as the Cambrian epoch itself is from the tertiaries. In other words, the ascertained duration of life upon the globe was nearly doubled, at a stroke.

5. The significance of persistent types, and of the small amount of change which has taken place even in those forms which can be shown to have been modified, becomes greater and greater in my eyes, the longer I occupy myself with the biology of the past.

Consider how long a time has elapsed since the Miocene epoch. Yet, at that time, there is reason to believe that every important group in every order of the *Mammalia* was represented. Even the comparatively scanty Eocene fauna yields examples of the orders *Cheiroptera, Insectivora, Rodentia*, and *Perissodactyla;* of *Artiodactyla* under both the Ruminant and the Porcine modifications; of *Carnivora, Cetacea*, and *Marsupialia*.

Or, if we go back to the older half of the Mesozoic epoch, how truly surprising it is to find every order of the *Reptilia*, except the *Ophidia*, represented; while some groups, such as the *Ornithoscelida* and the *Pterosauria*, more specialised than any which now exist, abounded.

There is one division of the *Amphibia* which offers especially important evidence upon this point, inasmuch as it bridges over the gap between the Mesozoic and the Palæozoic formations, often supposed to be of such prodigious magnitude, extending, as it does, from the bottom of the Carboniferous series to the top of the Trias, if not into the Lias. I refer to the Labyrinthodonts. As the address of 1862 was passing through the press, I was able to mention, in a note, the discovery of a large Labyrinthodont, with well-ossified vertebræ, from the Edinburgh coal-field. Since that time eight or ten distinct genera of Labyrinthodonts have been discovered in the carboniferous rocks of England, Scotland, and Ireland, not to mention the American forms described by Principal Dawson and Professor Cope. So that, at the present time, the Labyrinthodont Fauna of the Carboniferous rocks is more extensive and diversified than that of the Trias, while its chief types, so far as osteology enables us to judge, are quite as highly organised. Thus it is certain tha ta comparatively highly organised vertebrate type, such as that of the Labyrinthodonts, is capable of persisting, with no considerable change, through the period represented by the vast deposits which constitute the Carboniferous, the Permian, and the Triassic formations.

The very remarkable results which have been brought to light by the sounding and dredging operations, which have been carried on with such remarkable success by the expeditions sent out by our own, the American, and the Swedish Governments, under the supervision of able naturalists, have a bearing in the same direction. These investigations have demonstrated the existence, at great depths in the ocean, of living animals in some cases identical with, in others very similar to, those which are found fossilised in the white chalk. The *Globigerinæ*, Coccoliths, Coccospheres, Discoliths, in the one are absolutely identical with those in the other; there are identical, or closely analogous, species of Sponges, Echinoderms, and Brachiopods. Off the coast of Portugal, there now lives a species of *Beryx*, which, doubtless, leaves its bones and scales here and there in the Atlantic ooze, as its predecessor left its spoils in the mud of the sea of the Cretaceous epoch.

Many years ago* I ventured to speak of the Atlantic mud as "modern chalk," and I know of no fact inconsistent with the view which Professor Wyville Thomson has advocated, that the modern chalk is not only the lineal descendant of the ancient

* *Saturday Review*, 1858, "Chalk, Ancient and Modern."

chalk, but that it remains, so to speak, in the possession of the ancestral estate; and that from the cretaceous period (if not much earlier) to the present day, the deep sea has covered a large part of what is now the area of the Atlantic. But if *Globigerina*, and *Terebratula caput-serpentis* and *Beryx*, not to mention other forms of animals and of plants, thus bridge over the interval between the present and the Mesozoic periods, is it possible that the majority of other living things underwent a "sea change into something new and strange" all at once?

7. Thus far I have endeavoured to expand, and to enforce by fresh arguments, but not to modify in any important respect, the ideas submitted to you on a former occasion. But when I come to the propositions touching progressive modification, it appears to me, with the help of the new light which has broken from various quarters, that there is much ground for softening the somewhat Brutus-like severity with which I have dealt with a doctrine, for the truth of which I should have been glad enough to be able to find a good foundation, in 1862. So far indeed as the *Invertebrata* and the lower *Vertebrata* are concerned, the facts and the conclusions which are to be drawn from them appear to me to remain what they were. For anything that, as yet, appears to the contrary, the earliest known Marsupials may have been as highly organised as their living congeners; the Permian lizards show no signs of inferiority to those of the present day; the Labyrinthodonts cannot be be placed below the living Salamander and Triton; the Devonian Ganoids are closely related to *Polypterus* and to *Lepidosiren*.

But when we turn to the higher *Vertebrata*, the results of recent investigations, however we may sift and criticise them, seem to me to leave a clear balance in favour of the doctrine of the evolution of living forms one from another. In discussing this question, however, it is very necessary to discriminate carefully between the different kinds of evidence from fossil remains, which are brought forward in favour of evolution.

Every such fossil which takes an intermediate place between forms of life already known, may be said, so far as it is intermediate, to be evidence in favour of evolution, inasmuch as it shows a possible road by which evolution may have taken place. But the mere discovery of such a form does not, in itself, prove that evolution took place by and through it, nor does it constitute more than presumptive evidence in favour of evolution in general. Suppose A, B, C to be three forms, of which B is intermediate in structure between A and C. Then the doctrine of evolution offers four possible alternatives. A may have become C by way of B; or C may have become A by way of B; or A and C may be independent modifications of B; or A, B, and C may be independent modifications of some unknown D. Take the case of the Pigs, the *Anoplotheridæ* and the Ruminants. The *Anoplotheridæ* are intermediate between the first and the last; but this does not tell us whether Ruminants have come from the pigs, or pigs from Ruminants, or both from *Anoplotheridæ*, or whether pigs, Ruminants, and *Anoplotheridæ* alike may not have diverged from some common stock.

But, if it can be shown that A, B, and C exhibit successive stages in the degree of modification, or specialisation, of the same type; and if, further, it can be proved that they occur in successively newer deposits, A being in the oldest, and C in the newest, then the intermediate character of B has quite another importance, and I should accept it without hesitation as a link in the genealogy of C. I should consider the burden of proof to be thrown upon any one who denied C to have been derived from A by way of B; or in some closely analogous fashion. For it is always probable that one may not hit upon the exact line of filiation, and, in dealing with fossils, may mistake uncles and nephews for fathers and sons.

I think it necessary to distinguish between the former and the latter classes of intermediate forms, as *intercalary types* and *linear types*. When I apply the former term I merely mean to say, that as a matter of fact, the form B, so named, is intermediate between the others, in the sense in which the *Anoplotherium* is intermediate between the Pigs and the Ruminants—without either affirming, or denying, any direct genetic relation between the three forms involved. When I apply the latter term, on the other hand, I mean to express the opinion that the forms A, B, and C constitute a line of descent, and that B is thus part of the lineage of C.

From the time when Cuvier's wonderful researches upon the extinct Mammals of the Paris gypsum first made intercalary types known, and caused them to be recognised as such, the number of such forms has steadily increased among the higher Mammalia. Not only do we now know numerous intercalary forms of *Ungulata*, but M. Gaudry's great monograph upon the fossils of Pikermi (which strikes me as one of the most perfect pieces of palæontological work I have seen for a long time) shows us, among the *Primates*, *Mesopithecus* as an intercalary form between the *Semnopitheci* and the *Macaci*; and among the *Carnivora*, *Hyænictis*, and *Ictitherium* as intercalary, or, perhaps, linear, types between the *Viverridæ* and the *Hyænidæ*.

Hardly any order of the higher Mammalia stands so apparently separate and isolated from the rest as that of the *Cetacea*, though a careful consideration of the structure of the fissipede *Carnivora*, or seals, shows in them many an approximation towards the still more completely marine mammals. The extinct *Zeuglodon*, however, presents us with an intercalary form between the type of the seals and that of the whales.

The skull of this great Eocene sea monster, in fact, shows, by the narrow and prolonged interorbital region; the extensive union of the parietal bones in a sagittal suture; the well-developed nasal bones; the distinct and large incisors implanted in premaxillary bones, which take a full share in bounding the fore part of the gape; the two-fanged molar teeth with triangular and serrated crowns, not exceeding five on each side in each jaw; and the existence of a deciduous dentition—its close relation with the seals. While, on the other hand, the produced, rostral form of the snout, the long symphysis and the low coronary process of the mandible, are approximations to the cetacean form of those parts.

The scapula resembles that of the cetacean *Hyperoodon*, but the supra-spinous fossa is larger and more seal-like; as is the humerus, which differs from that of the *Cetacea* in presenting true articular surfaces for the free jointing of the bones of the fore-arm. In the apparently complete absence of hinder limbs, and in the characters of the vertebral column, the *Zeuglodon* lies on the cetacean side of the boundary line; so that, upon the whole, the Zeuglodonts, transitional as they are, are conveniently retained in the cetacean order. And the publication, in 1864, of M. Van Beneden's memoir on the miocene and pliocene *Squalodon*, furnished much better means than anatomists previously possessed, of fitting in another link of the chain which connects the existing *Cetacea* with *Zeuglodon*. The teeth are much more numerous, although the molars exhibit the zeuglodont double fang; the nasal bones are very short, and the upper surface of the rostrum presents the groove, filled up during life by the prolongation of the ethmoidal cartilage, which is so characteristic of the majority of the *Cetacea*.

It appears to me that, just as among the existing *Carnivora*, the walruses and the eared seals are intercalary forms between the fissipede *Carnivora* and the ordinary seals; so the Zeuglodons are intercalary between the *Carnivora*, as a whole, and the *Cetacea*. Whether the Zeuglodonts are also linear types in their relation to these two groups cannot be ascertained, until we have more definite knowledge than we possess at present, respecting the relations in time of the *Carnivora* and the *Cetacea*.

Thus far, we have been concerned with the intercalary types which occupy the intervals between families, or orders, of the same class. But the investigations which have been carried on by Prof. Gegenbaur, Prof. Cope, and myself, into the structure and relations of the extinct reptilian forms of *Dinosauria* and *Compsognatha*, have brought to light the existence of intercalary forms between what have hitherto been always regarded as very distinct classes of the vertebrate sub-kingdom, namely, *Reptilia* and *Aves*. Whatever inferences may, or may not, be drawn from the fact, it is now an established truth that, in many of these *Ornithoscelida*, the hind limbs and the pelvis are much more similar to those of birds than they are to those of reptiles, and that these Bird-reptiles, or Reptile-birds, were more or less completely bipedal.

When I addressed you in 1862, I should have been bold indeed had I suggested that palæontology would before long show us the possibility of a direct transition from the type of the lizard to that of the ostrich. At the present moment we have, in the *Ornithoscelida*, the intercalary type, which proves that transition to be something more than a possibility. But it is very doubtful whether any of the genera of *Ornithoscelida* with which we are at present acquainted are the actual linear types by which the transition from the lizard to the bird was effected. These are, very probably, still hidden from us in the older formations.

Let us now endeavour to find some cases of true linear types, or forms which are intermediate between others because they stand in a direct genetic relation to them. It is no easy matter to find clear and unmistakeable evidence of filiation among fossil animals. For, in order that such evidence should be quite satisfactory, it is necessary that we should be acquainted with all the most important features of the organization of the animals which are supposed to be thus related; and not merely with the fragments upon which the genera and species of the palæontologist are so often based. M. Gaudry has arranged the species of *Hyænidæ*, *Proboscidea*, *Rhinocerotidæ*, and *Equidæ* in their order of filiation from their earliest appearance in the Miocene epoch to the present time, and Professor Rütimeyer has drawn up similar schemes for the Oxen—with what I am disposed to think is a fair and probable approximation to the order of Nature. But as no one is better aware than these two learned, acute, and philosophical biologists, all such arrangements must be regarded as provisional, except in those cases in which, by a fortunate accident, large series of remains are obtainable from a thick and wide-spread series of deposits. It is easy to accumulate probabilities—hard to make out some particular case in such a way that it will stand rigorous criticism.

After much search, however, I think that such a case is to be made out in favour of the pedigree of the Horses.

The genus *Equus* is represented as far back as the latter part of the Miocene epoch; but, in deposits belonging to the middle of that epoch, its place is taken by two other genera, *Hipparion* and *Hipparitherium* (or *Anchitherium*); and, in the lowest Miocene and upper Eocene only the last genus occurs. A species of *Hipparitherium* was referred by Cuvier to the *Palæotheria* under the name of *P. Aurelianense*. The grinding teeth are in fact very similar in shape and in pattern, and in the absence of cement, to those of some species of *Palæotherium*, especially Cuvier's, *Palæotherium minus*, which has been formed into a separate genus, *Plagiolophus*, by Pomel.

But in the fact that there are six full-sized grinders, the first premolar being very small; that the anterior grinders are as large as, or rather larger than, the posterior ones; that the second premolar has an anterior prolongation; and that the posterior molar of the lower jaw has, as Cuvier pointed out, a posterior lobe of much smaller size and different form, the dentition of *Hipparitherium* departs from the type of the *Palæotherium*, and approaches that of the horse.

Again, the skeleton of *Hipparitherium* is extremely equine. M. Christol, who founded the genus, goes so far as to say that the descriptions of the bones of the horse, or the ass, current in veterinary works, would fit those of *Hipparitherium*. And, in a general way, this may be true enough, but there are some most important differences, which, indeed, are justly indicated by the same careful observer. Thus the ulna is complete throughout, and its shaft is not a mere rudiment, fused into one bone with the radius. There are three toes, one large in the middle, and one small on each side. The femur is quite like that of a horse, and has the characteristic fossa above the external condyle. In the British Museum, there is a most instructive specimen of the leg bones, showing that the fibula was represented by the external malleolus and by a flat tongue of bone, which extends up from it on the outer side of the tibia, and is closely ankylosed with the latter bone. The hind toes are three, like those of the fore leg; and the middle metatarsal bone is much less compressed from side to side than in the horse.

In the *Hipparion* the teeth nearly resemble those of the Horses, though the crowns of the grinders are not so long; like those of the Horses they are abundantly coated with cement. The shaft of the ulna is reduced to a mere style ankylosed throughout nearly its whole length with the radius, and appearing to be little more than a ridge on the surface of the latter bone until it is carefully examined. The front toes are still three, but the outer ones are more slender than in *Hipparitherium*, and their hoofs smaller in proportion to that of the middle toe. In the leg, the distal end of the fibula is so completely united with the tibia that it appears to be a mere process of the latter bone, as in the Horses.

In the Horses, finally, the crowns of the grinding teeth become longer, and their patterns are slightly modified; the middle of the shaft of the ulna vanishes, and its proximal and distal ends ankylose with the radius. The phalanges of the two outer toes in each foot disappear, their metacarpal and metatarsal bones being left as the "splints."

The *Hipparion* has large depressions on the face in front of the orbits, like those for the "larmiers" of many ruminants; but traces of these are to be seen in some of the fossil horses from the Sewalik Hills.

When we consider these facts, and the further circumstance that the Hipparions, the remains of which have been collected in immense numbers, were subject, as M. Gaudry and others have pointed out, to a great range of variation, it appears to me impossible to resist the conclusion that the types of the *Hipparitherium*, of the *Hipparion*, and of the ancient Horses constitute the lineage of the modern Horses, the *Hipparion* being the intermediate stage between the other two, and answering to B in my former illustration.

The nature of the process by which the *Hipparitherium* has been converted into the horse is one of specialisation or of more and more complete deviation from what might be called the average form of an ungulate mammal. In the Horses, the reduction of some parts of the limbs, together with the special modification of those which are left, is carried to a greater extent than in any other hoofed mammals. The reduction is less, and the specialisation is less in the *Hipparion*, and still less in the *Hipparitherium*; but yet as compared with other mammals, the reduction and specialisation of parts in the *Hipparitherium* remains great.

Is it not probable, then, that, just as in the Miocene epoch we find an ancestral equine form less modified than the horse, so, if we go back to the Eocene epoch we shall find some quadruped related to the *Hipparitherium*, as *Hipparion* is related to *Equus*, and consequently departing less from the average form?

I think that this desideratum is very nearly, if not quite, supplied by *Plagiolophus*, remains of which occur abundantly in some parts of the upper and middle Eocene formations. The patterns of the grinding teeth of *Plagiolophus* are similar to those of *Hipparitherium*, and they are similarly deficient in cement; but the grinders diminish in size forwards, and the last lower molar has a large hind lobe, convex outwards and concave inwards, as in *Palæotherium*. The ulna is complete and much larger than in any of the *Equidæ*, while it is more slender than in most of the *Palæotheria*. It is fixedly united, but not ankylosed with the radius. There are three toes in the fore-limb, the outer ones being slender, but less attenuated than in the *Equidæ*. The femur is more like that of the *Palæotheria* than that of the horse, and has only a small depression above its outer condyle in the place of the great fossa which is so obvious in the *Equidæ*. The fibula is distinct, but very slender, and its distal end is ankylosed with the tibia. There are three toes on the hind-foot having similar proportions to those on the fore-foot. The principal metacarpal and metatarsal bones are flatter than they are in any of the *Equidæ*.

In its general form, *Plagiolophus* resembles a very small and slender horse, and totally unlike the reluctant, pig-like creature depicted in Cuvier's restoration of his *Palæotherium minus* in the Ossemeus Fossiles.

It would be hazardous to say that *Plagiolophus* is the exact radical form of the Equine quadrupeds; but I do not think there can be any reasonable doubt the latter animals have resulted from the modification of some quadruped similar to *Plagiolophus*.

We have thus arrived at the Middle Eocene formation, and yet have traced back the Horses only to a three-toed stock. But these three-toed forms, no less than the Equine quadrupeds themselves, present rudiments of the two other toes which appertain to what I have termed the "average" quadruped. If the expectation raised by the splints of the horse that, in some ancestor of the horse, these splints would be found to be complete digits, has been verified, we are furnished with very strong reasons for looking for a no less complete verification of the expectation that the three-toed *Plagiolophus*-like "avus" of the horse must have had a five-toed "atavus" at some earlier period.

No such five-toed "atavus," however, has yet made its appearance among the few middle and older Eocene Mammalia which are known.

Another series of closely-affiliated forms, though the evidence they afford is perhaps less complete than that of the Equine series, is presented to us by the *Dichobune* of the Eocene epoch, the *Cainotherium* of the Miocene, and the *Tragulidæ*, or so-called "Muskdeer" of the present day.

The *Tragulidæ* have no incisors in the upper jaw, and only six grinding teeth on each side of each jaw, while the canine is moved up to the outer incisor, and there is a diastema in the lower jaw. There are four complete toes on the hind-foot, but the middle metatarsals usually become, sooner or later, ankylosed into a cannon bone. The navicular and the cuboid unite, and the distal end of the fibula is ankylosed with the tibia.

In *Cainotherium* and *Dichibune* the upper incisors are fully developed. There are seven grinders; the teeth form a continuous series without diastema. The metatarsals, the navicular and cuboid, and the distal end of the fibula, remain free. The *Cainotherium*, also the second metacarpal, is developed, but is much shorter than the third, while the fifth is absent or rudimentary. In this respect it resembles *Anoplotherium secundarium*. This circumstance, and the peculiar pattern of the upper molars in *Cainotherium*, lead me to hesitate in considering it as the actual ancestor of the modern *Tragulidæ*. If *Dichobune* has a four-toed front foot (though I am inclined to suspect it resembles *Cainotherium*) it will be a better representative of the oldest form of the Traguline series. But *Dichobune* occurs in the middle Eocene, and is, in fact, the oldest known artiodactyle mammal. Where, then, must we look for its five-toed ancestor?

If we follow down other lines of recent and tertiary *Ungulata*, the same question presents itself. The pigs are traceable back through the Miocene epoch to the upper Eocene, where they appear in the two well-marked forms of *Hyopotamus* and *Chæropotamus*. But *Hyopotamus* appears to have had only two toes.

Again, all the great groups of the Ruminants, the *Bovidæ*, *Antelopidæ*, *Camelopardalidæ*, and *Cervidæ*, are represented in the Miocene epoch, and so are the camels. The upper Eocene *Anoplotherium*, which is intercalary between the pigs and the *Tragulidæ*, has only two or, at most, three toes. Among the scanty mammals of the lower Eocene formation we have the perissodactyle *Ungulata* represented by *Coryphodon*, *Hyracotherium*, and *Pliolophus*. Suppose for a moment, for the sake of following out the argument, that *Pliolophus* represents the primary stock of the perissodactyles, and *Dichobune* that of the Artiodactyles (though I am far from saying that such is the case) then, we find in the earliest fauna of the Eocene epoch, to which our investigations carry us, the two divisions of the *Ungulata* completely differentiated, and no trace of any common stock of both or five-toed predecessors to either. With the case of the horse before us, justifying a belief in the production of new animal forms by modification of old ones, I see no escape from the necessity of seeking for these ancestors of the *Ungulata* beyond the limits of the tertiary formations.

I could as soon admit special creation, at once, as suppose that the perissodactyles and artiodactyles had no five-toed ancestors. And when we consider how large a portion of the tertiary period elapsed before *Hipparitherium* was converted into *Equus*, it is difficult to escape the conclusion that a large proportion of time anterior to the tertiary must have been expended in converting the common stock of the *Ungulata* into perissodactyles and artiodactyles.

The same moral is inculcated by the study of every other order of tertiary monodelphius *Mammalia*. Each of these orders is represented in the Miocene epoch:—the Eocene formation, as I have already said, contains *Cheiroptera*, *Insectivora*, *Rodentia*, *Ungulata*, *Carnivora*, and *Cetacea*. But the *Cheiroptera* are extreme modifications of the *Insectivora*; just as the *Cetacea* are extreme modifications of the Carnivorous type; and therefore it is to my mind incredible that monodelphous *Insectivora* and *Carnivora* should not have been abundantly developed along with *Ungulata* in the Mesozoic epoch. But, if this be the case, how much farther back must we go to find the common stock of the monodelphous *Mammalia*? As to the *Didelphia*, if we may trust the evidence which seems to be afforded by their very scanty remains, that a Hypsiprymnoid form existed at the epoch of the Trias, side by side with a carnivorous form. At the epoch of the Trias, therefore, the *Marsupialia* must have already existed long enough to have become differentiated into carnivorous and herbivorous forms. But the *Monotremata* are lower forms than the *Didelphia*, which last are intercalary between the *Ornithodelphia* and the *Monodelphia*. To what point of the palæozoic epoch then must we, upon any rational estimate, relegate the origin of the *Monotremata*?

The investigation of the occurrence of the classes and of the orders of the *Sauropsida* in time, points in exactly the same direction. If, as there is great reason to believe, true Birds existed in the Triassic epoch, the ornithoscelidous forms by which Reptiles passed into Birds must have preceded them. In fact, there is even, at present, considerable ground for suspecting the existence of *Dinosauria* in the Permian formations. But in that case Lizards must be of still earlier date. And if the very small differences which are observable between the *Crocodilia* of the older mesozoic formations and those of the present day, furnish any sort of approximation towards an estimate of the average rate of change among the *Sauropsida*; it is almost appalling to reflect how far back in palæozoic times we must go, before we can hope to arrive at that common stock from which the *Crocodilia*, *Lacertilia*, *Ornithoscelida*, and *Plesiosauria*, which had attained so great a development in the Triassic epoch must have been derived.

The *Amphibia* and *Pisces* tell the same story. There is not a single class of vertebrated animals, which, when it first appears, is represented by analogues of the lowest known members of the same class. Therefore, if there is any truth in the doctrine of evolution, every class must be vastly older than the first record of its appearance upon the surface of the globe. But if considerations of this kind compel us to place the origin of vertebrated animals at a period sufficiently distant from the upper Silurian, in which the first Elasmobranchs and Ganoids occur, to allow of the evolution of such fishes as these from a Vertebrate as simple as the *Amphioxus*; I can only repeat that it is appalling to speculate upon the extent to which that origin must have preceded the epoch of the first recorded appearance of vertebrate life.

Such is the further commentary which I have to offer upon the statement of the chief results of palæontology, which I formerly ventured to lay before you.

But the growth of knowledge in the interval makes me conscious of an omission of considerable moment in that statement, inasmuch as it contains no reference to the bearings of palæontology upon the theory of the distribution of life; or takes note of the remarkable manner in which the facts of distribution, in present and past times, accord with the doctrine of evolution —especially in regard to land animals.

That connection between palæontology and geology on the one hand, and the present distribution of terrestrial animals, which so strikingly impressed Mr. Darwin thirty years ago, as to lead him to speak of a "law of succession of types"; and of the wonderful relationship on the same continent between the dead and the living, has recently received much elucidation from the researches of Gaudry, of Rütimeyer, of Leidig, and of Alphonse Milne-Edwards, taken in connection with the earlier labours of our lamented colleague Falconer. And it has been instructively discussed in the thoughtful and ingenious work of Mr. Andrew Murray "On the geographical distribution of mammals."

I propose to lay before you, as briefly as I can, the ideas to which a long consideration of the subject has given rise in my own mind.

If the doctrine of evolution is sound, one of its immediate consequences clearly is, that the present distribution of life upon the globe is the product of two factors: the one being the distribution which obtained in the immediately preceding epoch; and the other, the character and the extent of the changes which have taken place in physical geography between the one epoch and the other. Or, to put the matter in another way—the Fauna and Flora of any given area, in any given epoch, can consist only of such forms of life as are directly descended from those which constituted the Fauna and Flora of the same area, in the immediately preceding epoch; unless the physical geography (under which I include climatal conditions) of the area has been so altered as to give rise to immigration of living forms from some other area.

The evolutionist therefore is bound to grapple with the following problem whenever it is clearly put before him:— Here are the Faunæ of the same area during successive epochs. Show good cause for believing, either that these Faunæ have been derived from one another by gradual modification, or that the Faunæ have reached the area in question by migration from some area in which they have undergone their development.

I propose to attempt to deal with this problem so far as it is exemplified by the distribution of the terrestrial Vertebrata, and I shall endeavour to show you that it is capable of solution in a sense entirely favourable to the doctrine of evolution.

I have, elsewhere,* stated, at length, the reasons which lead me to recognise four primary distributional provinces for the terrestrial Vertebrata in the present world; namely, firstly, the *Novozelanian*, or New Zealand province: secondly, the *Australian* province, including Australia, Tasmania, and the Negrito Islands: thirdly, *Austro-Columbia*, or South America plus North America as far as Mexico; and fourthly, the rest of the world, or *Arctogæa*, in which province America, north of Mexico, constitutes one sub-province; Africa, south of the Sahara, a second; Hindostan a third; and the remainder of the old world a fourth.

* "On the classification and distribution of the Alectoromorphæ." Proceedings of the Zoological Society, 1868.

Now the truth which Mr. Darwin perceived and promulgated as "the law of the succession of types" is, that in all these provinces the animals found in Pliocene or Pleistocene deposits are closely affined to those which now inhabit the same provinces, and that conversely, the forms characteristic of other provinces are absent. North and South America, perhaps, present one or two exceptions to the last rule, but they are readily susceptible of explanation. Thus, in Australia, the later tertiary Mammals are Marsupials (possibly with exception of the Dog and a Rodent or two, as at present). In Austro-Columbia the later tertiary Fauna exhibits numerous and varied forms of Platyrhine apes, Rodents, Cats, Dogs, Stags, *Edentata*, and Opossums; but, as at present, no Catarhine apes, no Lemurs, no *Insectivora*, Oxen, Antelopes, Rhinoceroses or *Didelphia* other than opossums. And, in the widespread Arctogæal province, the Pliocene and Pleistocene Mammals belong to the same groups as those which now exist in the province. The law of succession of types, therefore, holds good for the present epoch as compared with its predecessor. Does it equally well apply to the Pliocene Fauna when we compare it with that of the Miocene epoch? By great good fortune an extensive Mammalian Fauna of this epoch has now become known, in four very distant portions of the Arctogæal province which do not differ greatly in latitude. Thus Falconer and Cautley have made known the Fauna of the sub-Himalayas and the Perim Islands; Gaudry that of Attica; many observers that of Central Europe and France; Leidig, that of Nebraska on the eastern flank of the Rocky Mountains. The results are very striking. The total Miocene Fauna comprises many genera and species of Catarhine apes, of Bats, of *Insectivora*, of Arctogæal types of *Rodentia*, of *Proboscidea*, of Equine Rhinocenti, and Tapirine quadrupeds; of cameline, bovine, antelopine, cervine, and traguline Ruminants; of Pigs and Hippopotamuses; of *Viverridæ* and *Hyænidæ* among other *Carnivora;* with *Edentata* allied to the Arctogæal *Orycteropus* and *Manis*, and not to the Austro-Columbian Edentates. The only type present in the Miocene, but absent in the existing, Fauna of Eastern Arctogæa is that of the *Didelphidæ*, which, however, remains in North America.

But it is very remarkable, that while the Miocene Fauna of the Arctogæal Province, as a whole, is of the same character as the existing Fauna of the same province as a whole, the component elements of the Fauna were differently associated. In the Miocene epoch, North America possessed Elephants, Horses, Rhinoceroses, and a great number and variety of Ruminants and Pigs which are absent in the present indigenous Fauna. Europe had its Apes, Elephants, Rhinoceroses, Tapirs, Musk-deer, Giraffes, Hyenas, great Cats, Edentates, and opossum-like Marsupials, which have equally vanished from its present Fauna. And in Northern India, the African types of Hippopotamuses, Giraffes, and Elephants were mixed up with what are now the Asiatic types of the latter and with Camels, Semnopithecine and Pithecine apes of no less distinctly Asiatic forms.

In fact, the Miocene Mammalian Fauna of Europe and the Himalayan regions contains associated together the types which are now separately located in the South African and Indian sub-provinces of Arctogæa. Now there is every reason to believe, on other grounds, that both Hindostan, south of the Ganges, and Africa, south of the Sahara, were separated by a wide sea from Europe and North Asia, during the middle and upper Eocene epochs. Hence it becomes highly probable that the well-known similarities and no less remarkable differences between the present Faunæ of India and South Africa have arisen in some such fashion as the following. Sometime during the Miocene epoch, possibly when the Himalayan chain was elevated, the bottom of the nummulitic sea was upheaved and converted into dry land, in the direction of a line extending from Abyssinia to the mouth of the Ganges. By this means, the Dekhan on the one hand, and South Africa on the other, became connected with the Miocene dry land and with one another. The Miocene Mammals spread gradually over this intermediate dry land, and if the condition of its eastern and western ends offered as wide contrasts as the valleys of the Ganges and Arabia do now, many forms which made their way into Africa must have been different from those which reached the Dekhan, while others might pass into both these sub-provinces.

That there was a continuity of dry land between Europe and North America during the Miocene epoch, appears to me to be a necessary consequence; the fact that many genera or terrestrial Mammals such as *Castor, Hystrix, Elephas, Mastodon, Equus, Hipparion, Hipparitherium, Rhinoceros, Cervus, Amphicyon, Hyænarctos*, and *Machairodus*, are common to the Miocene formations of the two areas, and have as yet been found (except perhaps *Hipparitherium*) in no deposit of earlier age. Whether this connection took place by the east, or by the west, or by both sides of the old world, there is at present no certain evidence, and the question is immaterial to the present argument; but, as there are good grounds for the belief that the Australian province and the Indian and South African sub-provinces were separated by sea from the rest of Arctogæa before the Miocene epoch, so it has been rendered no less probable by the investigations of Mr. Carrick Moore and Prof. Duncan that Austro-Columbia was separated by sea from North America, during a large part of the Miocene epoch.

It is unfortunate that we have no knowledge of the Miocene Mammalian Fauna of the Australian and Austro-Columbian provinces. But seeing that not a trace of a Platyrhine ape, of a Procyonine carnivore, of a characteristically South American Rodent, of a Sloth, an Armadillo, or an Ant-eater, has yet been found in Miocene deposits of Arctogæa, I cannot doubt that they already existed in the Miocene Austro-Columbian province.

Nor is it less probable that the characteristic types of Australian Mammalia were already developed in that region in Miocene times.

But Austro-Columbia presents difficulties from which Australia is free—*Camelidæ* and *Tapiridæ* are now indigenous in South America as they are in Arctogæa, and among the Pliocene Austro-Columbian mammals, the Austro-Columbian genera *Equus, Mastodon*, and *Machairodus* are numbered. Are these post-Miocene immigrants, or præ-Miocene natives?

Still more perplexing are the strange and interesting forms *Toxodon, Macrauchenia*, and *Typotherium;* and a new Anoplotheriod mammal (*Omalodotherium*) which Dr. Cunningham sent over to me some time ago from Patagonia. I confess I am strongly inclined to surmise that these last, at any rate, are remnants of the population of Austro-Columbia before the Miocene epoch, and were not derived from Arctogæa by way of the north and east.

The fact that this immense Fauna of Miocene Arctogæa is now fully and richly represented only in India and South Africa, while it is shrunk and depauperised in North Asia, Europe, and North America, becomes at once intelligible, if we suppose that India and South Africa had but a scanty mammalian population before the Miocene immigration, while the conditions were highly favourable to the new comers. It is to be supposed that these new regions offered themselves to the Miocene Ungulates as South America and Australia offered themselves to the cattle, sheep, and horses of modern colonists. But after these great areas were thus peopled came the Glacial epoch, during which the excessive cold, to say nothing of depression and ice-covering, must have almost depopulated all the northern parts of Arctogæa, destroying all the higher mammalian forms except those which, like the elephant and rhinoceros, could adjust their coats to the altered condition. Even these must have been driven away from the greater part of the area. Only those Miocene mammals which had passed into Hindostan and into South Africa would escape decimation by these changes in the physical geography of Arctogæa. And when the northern hemisphere passed into its present condition, these lost tribes of the Miocene Fauna were hemmed by the Himalayas, the Sahara, the Red Sea, and the Arabian deserts, within their present boundaries.

Now, on the hypothesis of evolution, there is no sort of difficulty in admitting that the differences between the Miocene forms of the Mammalian Fauna and those which exist now, are the results of gradual modification; and since such differences in distribution as obtain are readily explained by the changes which have taken place in the physical geography of the world since the Miocene epoch, it is clear that the result of the comparison of the Miocene and present Faunæ is distinctly in favour of evolution. Indeed, I may go further. I may say that the hypothesis of evolution explains the facts of Miocene, Pliocene, and Recent distribution; and that no other supposition even pretends to account for them. It is, indeed, a conceivable supposition that every species of Rhinoceros and every species of Hyæna, in the long succession of forms between the Miocene and the present species, was separately constructed out of dust, or out of nothing, by supernatural power. But until I receive distinct evidence of the fact, I refuse to run the risk of insulting any sane man by supposing that he seriously holds such a notion.

Let us now take a step further back in time, and inquire into the relations between the Miocene Fauna and its predecessor of the upper Eocene formation.

Here it is to be regretted that our materials for forming a judgment are nothing to be compared in point of extent, or variety, with those which are yielded by the Miocene strata. However, what we do know of this upper Eocene Fauna of Europe, gives sufficient positive information to enable us to draw some tolerably safe inferences. It has yielded representatives of *Insectivora*, of *Cheiroptera*, of *Rodentia*, of *Carnivora*, of Artiodactyle, and Perissodactyle *Ungulata* and of opossum-like Marsupials. No Australian type of marsupial has been discovered in the upper Eocene, nor any Edentate mammal. The genera (except in the case perhaps of some of the *Insectivora*, *Cheiroptera*, and *Rodentia*) are different from those of the Miocene epoch, but present remarkable general similarity to the Miocene and recent genera. In several cases, as I have already shown, it has now been clearly made out that the relation between the Eocene and Miocene forms is such that the Eocene form is the least specialised; while its Miocene ally is more so, and the specialisation reaches its maximum in the recent forms of the same type.

So far as the Upper Eocene and the Miocene Mammalian Faunæ are comparable, their relations are such as in no way to oppose the hypothesis that the older are the progenitors of the more recent forms, while, in some cases, they distinctly favour that hypothesis. The period in time and the changes in physical geography, represented by the nummulitic deposits, are undoubtedly very great, while the remains of middle Eocene and older Eocene Mammals are comparatively few. The general facies of the middle Eocene Fauna, however, is quite that of the upper.

The older Eocene, pre-nummulitic mammalian Fauna, contains Bats, two genera of *Carnivora*, three genera of *Ungulata* (probably all perissodactyle), and a didelphid marsupial. All these forms, except perhaps the Bat and the Opossum, belong to genera which are not known to occur out of the lower Eocene. The *Coryphodon*, however, appears to have been allied to the Miocene and later Tapirs; while *Phiolophus*, in its skull and dentition, curiously partakes of both artiodactyle and perissodactyle characters. The third trochanter upon its femur, and its three-toed hind foot, however, appear definitely to fix its position in the latter division.

There is nothing, then, in what is known of the older Eocene mammals of the Arctogæal province to forbid the supposition that they stood in an ancestral relation to those of the Calcaire Grossier and the Gypsum of the Paris basin; and that our present fauna, therefore, is directly derived from that which already existed in Arctogæa at the commencement of the Tertiary period. But if we now cross the frontier between the Cainozoic and the Mesozoic Faunæ, as they are preserved within the Arctogæal area, we meet with an astounding change, and what appears to be a complete and unmistakeable break in the line of biological continuity.

Among the twelve or fourteen species of Mammalia which are said to have been found in the Purbecks, not one is a member of the orders *Cheiroptera*, *Rodentia*, *Ungulata*, or *Carnivora*, which are so well represented in the Tertiaries. No *Insectivora* are certainly known, nor any opossum-like Marsupials. Thus there is a vast negative difference between the Cainozoic and the Mesozoic mammalian Faunæ of Europe. But there is a still more important positive difference, inasmuch as all these Mammalia appear to be Marsupials belonging to Australian groups; and thus appertaining to a different distributional province from the Eocene and Miocene marsupials, which are Austro-Columbian. So far as the imperfect materials which exist enable a judgment to be formed, the same law appear to have held good for all the earlier mesozoic Mammalia. Of the Stonesfield slate mammals, one, *Amphitherium*, has a definitely Australian character; one, *Phascolotherium*, may be either Dasyurid or Didelphine; of a third, *Stereognathus*, nothing can at present be said. The two mammals of the Trias, also, appear to belong to Australian groups.

Everyone is aware of the many curious points of resemblance between the marine Fauna of the European Mesozoic rocks and that which now exists in Australia. But if there was this Australian facies about both the terrestrial and the marine Faunæ of Mesozoic Europe, and if there is this unaccountable and immense break between the Fauna of Mesozoic and that of Tertiary Europe, is it not a very obvious suggestion that, in the Mesozoic epoch, the Australian province included Europe, and that the Arctogæal province was contained within other limits? The Arctogæal province is at present enormous, while the Australian is relatively small. Why should not these proportions have been different during the Mesozoic epoch?

Thus, I am led to think that by far the simplest and most rational mode of accounting for the great change which took place in the living inhabitants of the European area at the end of the Mesozoic epoch, is the supposition that it arose from a great change in the physical geography of the globe, whereby an area long tenanted by Cainozoic forms was brought into such relations with the European area, that migration from the one to the other became possible, and took place on a great scale.

This supposition relieves us, at once, from the difficulty in which we were left, some time ago, by the arguments which I used to demonstrate the necessity of the existence of all the great types of the Eocene epoch in some antecedent period.

It is this Mesozoic continent (which may well have lain in the neighbourhood of what are now the shores of the North Pacific Ocean), which I suppose to have been occupied by the Mesozoic *Monodelphia*; and it is in this region that I conceive they must have gone through the long series of changes by which they were specialised into the forms which we refer to different orders. I think it very probable that what is now South America may have received the characteristic elements of its Mammalian Fauna during the Mesozoic epoch; and there can be little doubt that the general nature of the change which took place at the end of the Mesozoic epoch in Europe, was the upheaval of the eastern and northern regions of the Mesozoic sea bottom into a westward extension of the Mesozoic continent, over which the Mammalian Fauna, by which it was already peopled, gradually spread. This invasion of the land was prefaced by a previous invasion of the Cretaceous sea by modern forms of mollusca and fish.

It is easy to imagine how an analogous change might come about in the existing world. There is, at present, a great difference between the Fauna of the Polynesian Islands and that of the west coast of America. The animals which are leaving their spoils in the deposits now forming in these localites are widely different. Hence, if a gradual shifting of the deep sea, which at present bars migration, between the easternmost of these islands and America took place to the westward, while the American side of the sea-bottom was gradually upheaved, the palæontologist of the future would find, over the Pacific area, exactly such a change as I am supposing to have occurred in the North Atlantic area at the close of the Mesozoic period. An Australian Fauna would be found underlying an American Fauna, and the transition from the one to the other would be as abrupt as that between the Chalk and lower Tertiaries. And as the drainage area of the newly-formed extension of the American continent gave rise to rivers and lakes, the mammals mired in their mud would differ from those of like deposits on the Australian side just as the Eocene mammals differ from those of the Purbecks.

How do similar reasonings apply to the other great change of life—that which took place at the end of the Palæozoic period?

In the Triassic epoch, the distribution of the dry land and of terrestrial vertebrate life appears to have been, generally, similar to that which existed in the Miocene epoch; so that the Triassic continents and their Faunæ seem to be related to the Mesozoic lands and their Faunæ, just as those of the Miocene epoch are related to those of the present day.

In fact, as I have recently endeavoured to prove to the Society, there was an Arctogæal continent and an Arctogæal province of distribution in Triassic times as there is now. And the *Sauropsida* and *Marsupialia* which constituted that fauna were, I doubt not, the progenitors of the *Sauropsida* and *Marsupialia* of the whole Mesozoic epoch.

Looking at the present terrestrial fauna of Australia, it appears to me to be very probable that it is essentially a remnant of the Fauna of the Triassic, or even of an earlier, age; in which case Australia must at that time have been in continuity with the Arctogæal continent.

But now comes the further inquiry, Where was the highly-differentiated Sauropsidan Fauna of the Trias in Palæozoic times? The supposition that the Dinosaurian, Crocodilian, Dicynodontian, and Plesiosaurian types were suddenly created at the end of the Permian epoch may be dismissed, without further consideration, as a monstrous and unwarranted assumption. The supposition that all the types were rapidly differentiated out of *Lacertilia*, in the time represented by the passage from the

Palæozoic to the Mesozoic formation, appears to me to be hardly more credible; to say nothing of the indications of the existence of Dinosaurian forms in the Permian rocks, which have already been obtained.

For my part I entertain no sort of doubt that the reptiles, birds, and mammals of the Trias are the direct descendants of reptiles, birds, and mammals which existed in the latter part of the Palæozoic epoch, but not in any area of the present dry land which has yet been explored by the geologist.

This may seem a bold assumption, but it will not appear unwarrantable to those who reflect upon the very small extent of the earth surface which has hitherto exhibited the remains of the great Mammalian Fauna of the Eocene times. In this respect the Permian land vertebrate Fauna appears to me to be related to the Triassic, much as the Eocene is to the Miocene. Terrestrial reptiles have been found in Permian rocks only in three localities: in some spots of France and recently of England, and over a more extensive area in Germany. Who can suppose that the few fossils yet found in these regions give any sufficient representation of the Permian Fauna?

It may be said that the Carboniferous formations demonstrate the existence of a vast extent of dry land in the present dry land area; and that the supposed terrestrial Palæozoic vertebrate Fauna ought to have left its remains in the coal measures, especially as there is now reason to believe that much of the coal was formed on dry land. But if we consider the matter more closely, I think that this apparent objection loses its force. It is clear that during the Carboniferous epoch, the vast area of land which is now covered by coal measures must have been undergoing a gradual depression. The dry land thus depressed must, therefore, have existed, as such, before the Carboniferous epoch—in other words, the Devonian times—and its terrestrial population may never have been other than such as existed during the Devonian, or some previous epoch, although much higher forms may have been developed elsewhere.

Again, let me say that I am making no gratuitous assumption of inconceivable changes. It is clear that the enormous area of Polynesia is, on the whole, an area over which depression has taken place to an immense extent. Consequently a great continent, or assemblage of sub-continental masses of land, must have existed at some former time, and that at a recent period, geologically speaking, in the area of the Pacific. But if that continent had contained mammals, some of them must have remained to tell the tale; and as it is well known that these islands have no indigenous *Mammalia*, it is safe to assume that none existed. Thus, midway between Australia and South America, each of which possesses an abundant and diversified Mammalian Fauna, a mass of land, which may have been as large as both put together, must have existed without a Mammalian inhabitant. Suppose that the shores of this great land were fringed, as those of tropical Australia are now, with belts of mangroves which would extend landwards on the one side, and be buried beneath littoral deposits on the other side, as depression went on; and great beds of mangrove lignite might accumulate over the sinking land. Let upheaval of the whole now take place, in such a manner as to bring the newly emerging land into continuity with the South American, or Australian, continent; and, in course of time, it would be peopled by an extension of the Fauna of one of these two regions—just as I imagine the European Permian dry land to have been peopled.

I see nothing whatever against the supposition that distributional provinces of terrestrial life existed in the Devonian epoch, inasmuch as M. Barrande has proved that they existed, much earlier. I am aware of no reason for doubting that, as regards the grades of terrestrial life contained in them, one of these may have been related to another as New Zealand is to Australia, or as Australia is to India, at present. Analogy seems to me to be rather in favour of, than against, the supposition that while only Ganoid fishes inhabited the fresh waters of our Devonian land, *Amphibia* and *Reptilia*, or even higher forms, may have existed, though we have not yet found them. The earliest Carboniferous *Amphibia* now known, such as *Anthracosaurus*, are so highly specialised, that I can by no means conceive that they have been developed out of piscine forms in the interval between the Devonian and the Carboniferous periods, considerable as that is. And I take refuge in one of two alternatives. Either they existed in our own area during the Devonian epoch and we have simply not yet found them; or, they formed part of the population of some other distributional province of that day; and only entered our area by migration, at the end of the Devonian epoch. Whether *Reptilia* and *Mammalia* existed along with them is to me, at present, a perfectly open question, which is just as likely to receive an affirmative, as a negative, answer from future inquirers.

Let me now gather together the threads of my argumentation into the form of a connected hypothetical view of the manner in which the distribution of living and extinct animals has been brought about.

I conceive that distinct provinces of the distribution of terrestrial life have existed since the earliest period at which that life is recorded, and, possibly, much earlier; and I suppose, with Mr. Darwin, that the progress of modification of terrestrial forms is more rapid in areas of elevation than in areas of depression. I take it to be certain that Labyrinthodont *Amphibia* existed in the distributional province which included the dry land depressed during the Carboniferous epoch: and I conceive that, in some other distributional provinces of that day, which remained in the condition of stationary, or of increasing dry land, the various types of the terrestrial *Sauropsida* and of the *Mammalia* were gradually developing.

The Permian epoch marks the commencement of a new movement of upheaval in our area, which attained its maximum in the Triassic epoch when dry land existed in North America, Europe, Asia, and Africa as it does now. Into this great new continental area the mammals, birds, and reptiles, developed during the Palæozoic epoch, spread, and formed the great Triassic Arctogæal province. But, at the end of the Triassic period, the movement of depression recommenced in our area, though it was doubtless balanced by elevation elsewhere; modification and development, checked in the one province, went on in that elsewhere; and the chief forms of mammals, birds, and reptiles, as we now know them, were evolved, and peopled the Mesozoic continent, from which I conceive Australia to have become separated as early as the end of the Triassic epoch, or not much later. This Mesozoic continent must, I conceive, have lain to the east, about the shores of the North Pacific and Indian Oceans; and I am inclined to believe that it continued along the eastern side of the Pacific area to what is now the province of Austro-Columbia, the characteristic Fauna of which is probably a remnant of the population of the latter part of this period.

Towards the latter part of the Mesozoic period, the movement of upheaval around the shores of the Atlantic once more recommenced, and was very probably accompanied by a depression around those of the Pacific. The Vertebrate Fauna elaborated in the Mesozoic continent, moved westward and took possession of the new lands which gradually increased in extent up to, and in some directions after, the Miocene epoch.

It is in favour of this hypothesis, I think, that it is consistent with the persistence of a general uniformity of the directions of the great masses of land and water. From the Devonian period, or earlier, to the present day, the four great oceans, Atlantic, Pacific, Arctic, and Antarctic, may have occupied their present positions, and only their coasts and channels of communication have undergone an incessant alteration. And, finally, the hypothesis I have put before you requires no supposition that the rate of change in organic life has been either greater, or less, in ancient times than it is now; nor any assumption, either physical or biological, which has not its justification in analogous phenomena of existing nature.

I have now only to discharge the last duty of my office, which is to thank you, not only for the patient attention with which you have listened to me so long to-day; but also for the uniform kindness with which, for the past two years, you have rendered my endeavours to perform the important, and often laborious, functions of your President, a pleasure, instead of a burden. T. H. HUXLEY

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Feb. 17.—The following papers were read: "Account of the Great Melbourne Telescope from April 1868, to its commencement of operations in Australia in 1869." By Albert le Sueur. The author stated that the building in which the telescope is placed is rectangular, 80 feet long meridionally by 25 wide, with walls 11 feet high. Of the meridional length, the telescope-room occupies the north 40 feet; the next 12 feet are appropriated to the polishing machine, crane, and engine; the remaining 28 feet are divided into two rooms, one of which is at present used as an office, the other, 25 by 14, is intended for a laboratory. The moveable roof is 40 feet long, and runs on rails laid the whole length of the walls; the telescope room may therefore be completely covered in, and as completely uncovered when required, the roof in the latter case resting on the south building, which on that account has a very low permanent roof. The telescope, when housed, lies meridionally on the east side of the pier, and nearly in a horizontal direction, provision having been made to prevent the tube being lowered beyond a certain small inclination. Some trouble was experienced in removing the varnish from the specula, and they would require repolishing. Of work done, the author could not yet speak with any satisfaction since it became at all practicable to use the telescope; the history which he had to relate was a long chapter of weary heart-breaking watchings, with an occasional half hour's work. η Argûs was the first object observed for purpose of delineation; after the first night's work little (and that by snatches) was done towards it; a new inroad of workmen and a long course of extremely unfavourable weather having carried the nebula out of convenient reach. The search, which was reluctantly given up, will, however, be again soon resumed. The horseshoe nebula is a grand object, conspicuous and with shape even in the finder. It appears, however, to present no marked difference (with perhaps one exception) which may not be accounted for by the difference of aperture used. This exception is the presence of a small but conspicuous double star at the s p angle of the knot which lies between the ☋ and the bright streak; the experiment has not been tried of cutting down the aperture to approximate to an 18-inch Herschelian, but the intrinsic brightness of the principal star, and the presence in the C G H of stars not more bright (No. 3 of Herschel's catalogue is certainly less bright) go far to show, without this experiment, that the star did not exist as such with its present brilliancy at the time of the C G H and P T 33 observations. The important position of the star, and the careful scrutiny which the knot and its neighbourhood must have repeatedly undergone, forbid the assumption that it was simply overlooked by Sir John Herschel. The star β is conspicuously and beautifully double, the companion of considerable brilliancy, about 15 mag.; with its present brilliancy and elongation, the author thinks, it should be within reach of an 18-inch. The appearance of the knot is sparkling, though no discrete stars can be seen, except perhaps a second faint one, which is suspected at the s f angle; part of the streak near to the knot is also sparkling, but not in so marked a manner; the other portions appear of the ordinary milky nebulosity. The fainter nebulosity (S) of the bright streak pretty well marks out the borders of the almost vacuous lane which leads up to and past the knot; on receding from the lane it becomes very faint; nor is this faintness uniform, but the appearances are so fugitive that, after repeated and painful effort, they could not be caught. The borders, however, stretching to the stars are occasionally pretty well seen. On one or two occasions the author suspected the existence of a link between the nebulosity about the star No. 10 and the lower portion of the ☋; this, however, requires verification. At the f end, the upper and smaller semicircle is plainly marked, the lower and larger very faintly; its exact figure is, therefore, uncertain. 3570 is a small but beautiful spiral. The two brighter knots are resolvable. Of work out of the regular course, amongst other things, Neptune has been observed on some five or six occasions for figure and a second satellite, with only negative results. In the absence of a photographic apparatus to be used at the uninterrupted focus of large mirror, attempts have been made to utilise the second or Cassegrain image; an average exposure of near ten minutes on an eight-day moon produced pictures which (by no means good) were of sufficient promise to make it worth while to resume the attempt under more favourable conditions. The time of exposure is somewhat surprising, and would seem to indicate a great loss of chemical rays by a second perpendicular reflexion; but perhaps the inactivity was mainly due to absorption at the surface of the large mirror, which was then very yellow. The spectroscope arrived some time ago, but has not been much used; it is thought that for *star* work of any value some modification will be required, principally the exchange of the present collimator for one of longer focal length; a greater dispersion, moreover, seems desirable. The spectroscope was mainly designed for nebula work, is handy and compact, and will be of much service. For spectroscopic work on objects having a sensible diameter, the great telescope itself labours under some disadvantages; the enormous focal length and consequent magnification of the image is a serious inconvenience in the case of faint objects, and may be only partially remedied by a suitable condenser. This magnifying of the image may, however, in some cases be advantageous, from the possibility thereby afforded of viewing small definite portions of moderately bright objects, though unfortunately that will be seldom. Of nebulæ, Orion has been examined for purpose of practice; the three lines are plainly and conspicuously seen; the hydrogen line is comparatively much fainter than was anticipated, disappearing in the fainter portions of the nebula. 30 Doradûs shows the nitrogen line with facility, the second line certainly, but not in all positions, and always with difficulty; the hydrogen line is suspected only. No trace of a continuous spectrum could be seen. η Argûs has been observed on only one unfavourable morning; the nitrogen line was seen over a considerable space; the presence or absence of others, or of a continuous spectrum, could not be stated with certainty. With respect to future operations, it is intended that at first the routine work shall consist of a detailed delineation of the objects figured by Sir John Herschel, or any others which may prove interesting; this will take some time; for even without the impediment of cloudy weather, the delineation with any degree of satisfactory correctness, of a moderately large nebula, requires a considerable amount of work with careful and frequent scrutiny. It is hoped, however, that this work will by practice be found less painfully difficult than it is at present. The spectroscope will be used as much as possible, the moon photographed, and attempts made to photograph the nebulæ, when a photographic apparatus has beenpr ocured, and staging, photographic room, &c., added to the building. It is moreover hoped that before long a refractor, of some nine inches aperture, may be procured, to be mounted with the reflector, or, preferably, as a separate instrument. This telescope, besides being of much general use, will find much and valuable employment in determining micrometrically the chief points in the nebulæ under examination with the reflector, with more expedition and accuracy than at present; for spectroscopic work this telescope would be a valuable adjunct, especially if it be constructed of such comparatively short focal length as seems now to be practicable.

"On a distinct form of Transient Hemiopsia," by Hubert Airy. From a comparison of the different accounts of "Hemiopsia," "Half-vision," or "Half-blindness," by Wollaston, M. Arago, Brewster, the Astronomer Royal, Dufour, Sir John Herschel, Sir Charles Wheatstone, and Mr. Tyrrell, the author considers that, irrespective of the wide primary distinction between the transient and permanent forms of Hemiopsia, there are different forms of transient Hemiopsia which have all been included under the same name; Wollaston, Arago, Brewster, and Tyrrell, describing one form of the transient affection, while Sir John Herschel, Sir Charles Wheatstone, the Astronomer Royal, Professor Dufour, and the author agree in describing another. As to the actual seat of the visual derangement, the author considers that the exact agreement of the two eyes in the nature, extent, and degree of their affection, proves (assuming the semi-decussation of the optic nerves at the chiasma) the seat of the affection to be at some point behind the chiasma of these nerves. All the causes that are found to lead to transient half-blindness, point to the brain as the seat of disturbance. Still clearer is the evidence given by the loss of speech and of memory, the derangement of hearing, and the partial paralysis which sometimes follow an attack of teichopsia. Such cases as Sir John Herschel's, where the cloud passed over the whole field from left to right, can only be explained by supposing the disturbance to lie in some region of the brain where the opposite halves are in contact. The mischief may possibly be seated in the corpora quadrigemina or geniculata, or even in the cerebellum itself. The phenomena are so definite and so localised, and their course is so regular, that we can hardly avoid the conviction that their cause is equally definite and equally localised; and it is difficult to admit so vague an agent as nervous sympathy with gastric derangement, except as acting through the medium of some secondary local manifestation in the brain.

Chemical Society, February 17.—Prof. Williamson, F.R.S., president, in the chair. The following gentlemen were elected fellows:—R. T. Atcherley, T. W. Axe, A. H. Bateman, E. Francis, A. Prangley, W. Pritchard, L. B. Ross, T. G.

Rylands, T. Wills, and P. Wright. An account was given by Prof. Tyndall of his researches on "the action of light on gases and vapours," illustrated by a series of beautiful experiments. Dr. Tyndall began by remarking that it had, for the last ten years, been his endeavour to make radiant heat a means of getting an insight into the working of the atomic forces, or, in other words, into the state which is called chemical combination. Whilst pursuing his experiments with luminous waves on matter in a finely divided state, he was forced to imagine molecules and atoms; in fact, his belief in the existence of atoms is founded more upon those physical evidences than upon the considerations which are current in the chemical world. If he had to give up the notion of atoms, and to replace that conception by the abstract idea of multiple proportions, he would feel completely at a loss how to account for changes in the physical properties of matter. After these introductory remarks, the lecturer proceeded to the main subject. The apparatus which served to illustrate the statements, consisted of a glass tube about 3 feet in length, and 3 inches internal diameter, closed at each end by glass discs. This tube, after having been exhausted by an air-pump, was partially filled with dry air which had been permitted to bubble through the liquid whose vapours were to be examined. The condensed beam of an electric lamp was caused to pass through the tube from end to end. Since the aim of these experiments is to render visible the chemical action of light upon vapours, substances have been chosen, one at least of whose products of decomposion by light has so high a boiling point that as soon as it is formed it is precipitated. Nitrous oxide gas, the vapours of Alleylic Iodide, Amylic Nitrite, Benzole, &c., mixed with some air which had passed through hydric nitrate or hydric chloride, were found well suited for this purpose. In all cases, no matter what the nature of the vapours was, if it was only employed in a sufficiently attenuated state, the visible action commenced with the formation of a blue cloud, which in some instances was of the deepest azure tinge, rivalling the colour of the purest Italian sky. When a cell containing some of the liquid whose vapours are to be examined was inserted between the lamp and the tube, no clouds were formed within the tube; the luminous waves traversing the liquid had been deprived of their acting power. When polarised light was sent through the tube the blue cloud was visible only in one direction—the direction varying according to the position of the Nicol's prison; when the short diagonal of the Nicol was vertical, the blue cloud was seen when the specator's eye looked horizontally upon the tube, not otherwise; as soon as the prism was turned round its axis, the blue cloud was only seen when the line of vision fell vertically upon the experimental tube.

After concluding his account of this highly interesting subject, Prof. Tyndall showed some of the experiments bearing on his researches upon Dust, quite recently communicated at the Royal Institution.

Anthropological Society, February 15.—Dr. Berthold Seemann, V. P., in the chair. C. W. Eddy, Esq., M.A., and E. Schiemann, Esq., were elected Fellows. The following papers were read:—No. 1. "On the Aborigines of the Chatham Islands," by Dr. Barnard Davis and Mr. E. A. Welch. Mr. Welch, after discussing the history and discovery of those islands, described their conquest by the Maories and the ultimate fate of the Aborigines. Dr. Barnard Davis gave the results of a particular examination of the characters presented by the skulls and skeletons of many of the inhabitants. In three cases the cephalic indices of the skulls were stated to be ·74, ·74 and ·87. The stature of the Moriories, or Chatham Islanders, appeared to indicate a race shorter and stouter than the inhabitants of New Zealand. "On polygamy: its influence in determining the sex of our race and its effects on the growth of population." By Dr. J. Campbell. The author, who had been many years resident in Siam, gave minute details of the relative proportions of female to male births in the harems of the King and other important Siamese dignitaries. The result seemed to be that the proportions of males and females born were, as in the case of Monogamist marriages, entirely equal.—Mr. Ralph Tate described an inscribed rock on the banks of the Iguana, a tributary of the Orinoco. This presented an incised marking which the author considered to be more ancient than the present inhabitants of the district.

Royal Microscopical Society, February 9.—Annual meeting; the Rev. J. B. Reade, president, in the chair. The following gentlemen were elected officers for the ensuring year:—President, Rev. J. B. Reade; Vice-Presidents, Charles Brooke, L. S. Beale, James Glaisher, F. H. Wenham; Treasurer, Richard Mestayer; Secretaries, H. J. Slack, Jabez Hogg. The president read an address and announced his intention of presenting to the Society a copy of the Philosophical Transactions —60 vols. *in extenso*, from 1665 to 1812, and the parts from 1813 to the present time, as issued by the Royal Society.—Mrs. Holland presented the silver medal of the Society of Arts, with certificates awarded to her late husband for his "Microscopic Triplet," 1832. A micrometer ruled on silver by Mr. Barton, with some specimens of beads and bead lenses made by the late Mr. Holland, &c.—A vote of thanks was given to the president and Mrs. Holland for their presents.

Institution of Civil Engineers, February 1.—Mr. Charles B. Vignoles, F.R.S., president, in the chair. "On the statistics of railway expenditure and income, and their bearing on future railway policy and management." Mr. John Thornhill Harrison, M. Inst. C.E. From returns now made to the Board of Trade supplying definite information on most points of interest, the author had prepared a synopsis of this information for twenty of the principal railways in England and Scotland, representing about 85 per cent. of the entire capital expended in the United Kingdom. The original cost of railways, the working expenses, revenue, &c., were described, and it was shown that while the National Debt, amounting to 750 millions sterling, with a return of 26½ millions per annum, or 3½ per cent., was a burden on the industry and capital of the country, the capital expended on railways, amounting to 500 millions sterling, gave a return of 20 millions, or 4 per cent. per annum; whilst a sum nearly equal to the interest on the National Debt was annually expended in labour and materials.

PARIS

Academy of Sciences, February 14.—The greater part of the proceedings at this meeting had reference to subjects connected with mathematics and mechanics. M. de Saint-Venant presented a second part of his memoir on the determination of the pressure of incoherent soils upon walls; M. Morin an elaborate report upon a memoir by M. Tresca on the effects of punching and stamping, and on the mechanical theory of the deformation of solid bodies; M. de Saint-Venant appended to the latter a theoretical proof of the equality of the two coefficients of resistance to cutting with shears and to extension or compression in the continuous movement of deformation of ductile solids beyond the limits of their elasticity; and a report on five memoirs by M. F. Lucas, entitled investigations upon the mechanics of atoms.—M. C. Jordan communicated a paper on a new combination of the twenty-seven right lines of a surface of the third order; M. Pellet a note on the functions irreducible by means of one module, and one modular function, and M.A. Ribacour a note on the deformation of surfaces.—An extract from a letter of M. De la Rire to M. Jamin was read, referring to the observations of M. Trève on the action of magnetism upon rarefied gases.—M. Zaliwski read a note on a battery with three liquids regarded by him as superior to Bunsen's battery. The battery consists of an inner porous vessel, containing nitric acid and a plate of carbon, and an outer porous vessel containing sulphuric acid, the whole placed in a vessel containing a solution of hydroclorate of ammonia and a plate of zinc.—In a short note M. J. M. Séguin communicated some interesting observations on the accidental images of white objects.—M. A. Demoget described a new electro-magnetic apparatus, which, by an increase in the number of coils and alteration in their shape, can be made to produce a greater evolution of electricity, with less rapid revolution, than Siemens' apparatus.—M. P. Volpicelli communicated a paper containing an account of a photographic barometer, and some historical details upon lunar radiation. He noticed some modifications which he has introduced into the construction of a barometer for the Observatory at Rome, and with regard to the second subject, after citing several old writers, such as Aristotle, Thomas Aquinas, Pico della Mirandola, and Cardan as having admitted the production of calorific effects by the lunar radiation, maintains that the first experimental and incontestable demonstration of the phenomenon was given by Melloni in 1843.—A short note, illustrated with a figure, upon two solar spots now visible with the naked eye, by M. Tremeschini, was presented. The penumbras of these spots measure 0° 3′ 45″ and 0° 4′ 50″ in their greatest diameter; one of them contains a nucleus measuring 0° 0′ 45″11 in its greatest diameter.—M. J. Girard presented a note upon double crystals of snow, the formation of which he ascribes to the splitting of a drop of water too large to form a single crystal; the twin crystals are united by a small stay of a hexagonal prismatic form, having each of its edges corresponding exactly to the origin of one of the six regular branches of the two crystals.—A note by M. P. Bert on the influence of green light on the Sensitive plant, was presented by M. Claude Bernard. The author placed several young Sensitive plants in lanterns filled with variously coloured glass, and found that those exposed to green light lost their sensibility and died almost as quickly as those placed in perfect darkness.—M. A. Milne-Edwards communicated a note on some Mammalia from Eastern Thibet, which notwithstanding the rigour of the climate, is inhabited by two species of monkeys, a *Macacus* and a *Semnopithecus*.—The author noticed two forms of Insectivorous mammals forming new genera—one, which he calls *Nectogale elegans*, being intermediate between the Desmans and the Shrews; the other very nearly related to the latter, and called *Anourosorex* on account of the rudimentary state of its tail.—A singular animal, resembling a bear in general appearance, was noticed as forming a new genus, *Ailuropoda*, allied to the pandas and raccoons.—A long-snouted mole and a new flying squirrel were also mentioned.—The following notes and memoirs were communicated, but no particulars of their contents are given.—On the statistics of the therapeutical properties of the mineral waters of Baréges, Amélie-les-Bains, Vichy, and Bourbonne, by M. Champouillon; on some questions which may be referred to the theory of permanent isothermal lines, by M. E. Combescure; on staphyloraphic, and on the action of hydrate of chloral, by Mr. Lawson Tait; on the cause of the oscillatory movement of molecular granules by M. Lerique de Mouchy; on an accumulation of heat by the concentration of radiant heat through convex lenses of rock salt and the application of this heat to the production of a current of air giving rise to a continuous movement, by M. Vernier; on the production of the electric light by induction coils, by M. Delaurier; and a note on the trisection of the angle, by M. L. Vezzia.

Berlin

German Chemical Society, February 14.—A. W. Hofmann gave a new instance of the aid science derives from industry. The manufacture of chloral yields as a secondary product chloride of ethyle mixed with other chlorinated liquids. By treating this mixture with alcoholic ammonia in Frankland's digester, large quantities of the chlorides of ethylated ammonia bases are formed, while sal-ammoniac separates. This appears now to be the most reasonable method for producing ethyl-amines. The chlorinated compounds mixed with the chloride of ethyl are not acted upon by NH_3. They remain behind. These liquids commence to boil at 30° C., and seem to consist partly of dichlorinated marsh gas.—O. Liebreich reported on Suewern's disinfecting process. The bulk of the substance employed consists of lime disguised by the presence of chloride of magnesium and tar. Its utility proved to be very limited. Amongst the details given by Mr. Liebreich he mentioned that the canal water operated upon contained nitrogenous matter in extremely variable quantities according to the temperature of the air. For 59 parts of N. found in it during warm days, it contained 2 parts only while the weather was cold.—V. Meyer described a new and ingenious synthetical method for producing organic acids. This method is founded on the observation that formiate of sodium, when heated, splits into H and the group COO Na. Thus, when heated alone, the formiate yields oxalate of sodium and H_2. When heated with the potassium salt of a sulpho-organic acid such as phenyl-sulphurous acid $HKSO_3$, acid sulphate of potassium separates and COO Na takes the place occupied by the group KSO_3. In the instance mentioned benzoate of sodium is formed. Sulphobenzoate of potassium similarly treated yields isophtalic acid. The same chemist made some interesting remarks on the constitution of camphor and of camphoric acid.—Mr. Franck, the discoverer of potassium salts in Stassfurth, and the originator of the important industry founded on this occurrence, gave some details of the manufacture of bromine from the mother liquors. After describing an apparatus for pouring bromine from one vessel to another, he described his process for purifying this substance by re-distillation. This he effects by allowing the vapour to pass through a solution of bromide of iron before it passes into the condenser. The chlorine mixed with the bromine is thus retained in the shape of chloride of iron. Bromide of iron is the best material for the production of potassium. It is also well suited for transport; and a large quantity of the bromine shipped to America, goes there in the form of dry bromide of iron. Parchment-paper and clay mixed with colza oil, serve to unite the vessels used in the distilling process of bromine. The retorts are made of sandstone, and are lined with tar inside. The bromine acts on the tar, entailing the inevitable loss of sixty or eighty pounds of bromine in a new retort, and the production of brominated organic products, boiling between 60° and 400° C., but containing no bromoform. The bromine manufactured at Stassfurth contains no trace of iodine.

DIARY

THURSDAY, February 24.

Royal Society, at 8.30.—Note on Certain Lichens: Dr. Stenhouse.—Successive Action of Sodium and Iodide of Ethyle upon Acetic Ether: Dr. Frankland and Mr. Duppa.
Zoological Society,
Society of Antiquaries, at 8.30.—On the Guilds at Wymondham, Norfolk: Mr. G. A. Carthew.
Royal Institution, at 3.—Chemistry: Prof. Odling.
London Institution, at 7.30.

FRIDAY, February 25.

Quekett Microscopical Club, at 8.
Royal Institution, at 9.—On the Results of the Ordnance Survey of Sinai: Captain Wilson.

SATURDAY, February 26.

Royal Institution, at 3—Science of Religion: Prof. Max Müller.
Royal Botanic Society, at 3.45.

MONDAY, February 28.

Geographical Society, at 8.30.
Institue of British Architects, at 8.
Institute of Actuaries, at 7.—On the Proper Method of Loading the Premiums required for the Grant of Life Annuities and Assurances: Mr. W. M. Makeham.
London Institution, at 4.

TUESDAY, March 1.

Medical and Chirurgical Society, at 8.30.
Anthropological Society, at 8.—On the Circassian Slaves and the Sultan's Harem: Major F. Millingen.
Institution of Civil Engineers, at 8.—Discussion upon The Mhow-Ke-Mullee Viaduct, and The Pennair Bridge.—The Wolf Rock Lighthouse: Mr. J. N. Douglass.
Syro-Egyptian Society, at 7.30.

CONTENTS

Errata.—Page 409, first column sixth line: for "Fern Deal," read "Ferndene."—Page 410, first column, fourth line: for "29," read "19."—Page 410, second column, fortieth line: for "50," read "40."—Page 406, second column, twenty-fourth line: for "x," read "ϕ."

Professor Jevons requests us to state that the subject of the paper read by him at the Manchester Philosophical Society, though similar to that read a the Royal Society, was not the same as was inadvertently stated in our repor at p. 393.

RECENT PUBLICATIONS.

GEOLOGICAL MAPS.

LONDON.

Just published, scale, one inch to a mile; size, 36 inches by 24,

Stanford's New Geological Map of London AND ITS ENVIRONS, showing superficial deposits. Compiled from the latest authorities.

Folded in cover, 5*s.*; mounted on cloth in case, 7*s.* 6*d.*; on rollers, varnished, 9*s.*

In addition to the above, geological maps of the World, Europe, British Isles, Scotland, India, France, Belgium, &c., are published, and are always kept in Stock.

ENGLAND AND WALES.

Third Edition, with Corrections and Additions; scale, 12 miles to 1 inch; size, 36 inches by 42,

Geological Map of England and Wales. By ANDREW C. RAMSAY, LL.D., F.R.S. and G.S., Local Director of the Geological Survey of Great Britain, and Professor of Geology at the Royal School of Mines.

This Map shows all the Railways, Roads, &c., and when mounted in case folds into a convenient pocket size, making an excellent Travelling Map.

Price, in sheets, 25*s.*; mounted in case, 30*s.*; on roller, varnished, 32*s.*

Fifth Edition; scale, 28 miles to an inch; size, 18 inches by 14,

Geological Map of England and Wales. By SIR RODERICK I. MURCHISON, Bart., K.C.B., &c., Director-General of the Geological Surveys of Great Britain and Ireland.

Price, on one sheet, 5*s.*; mounted in case, 7*s.*

PUBLISHED BY AUTHORITY OF HER MAJESTY'S GOVERNMENT.

Geological Survey of England and Wales. Under the superintendence of SIR RODERICK I. MURCHISON, Bart., K.C.B., &c., Director-General of the Geological Surveys of the United Kingdom.

The Map is the Ordnance One-inch Series, specially adapted, and coloured geologically; arranged in 110 divisions, of which about 72 are published, and others are in progress. Some of the divisions are printed on a single sheet, size 27 inches by 40. Other divisions are printed on two or four smaller sheets.

Price of the large sheets, 8*s.* 6*d.*, 5*s.* and 4*s.*; of the smaller, 3*s.* and 1*s.* each.

For full particulars of the Maps, Sections, Memoirs, and other Publications of the Geological Survey of the United Kingdom, with Index Maps of England, Scotland, and Ireland, showing the published sheets, see Stanford's Geological Survey Catalogue, per post on receipt of one stamp.

IRELAND.

Scale, 8 miles to 1 inch; size, 38 inches by 31,

Geological Map of Ireland. By Joseph BEETE JUKES, M.A., F.R.S., late Director of Her Majesty's Geological Survey of Ireland.

This Map is constructed on the basis of the Ordnance Survey, and coloured geologically. It also shows the Railways, Stations, Roads, Canals, Antiquities, &c.

Price, on two sheets, 25*s.*; mounted in case, 30*s.*; on roller, varnished, 32*s.*

CANADA.

Scale, 25 miles to 1 inch; on eight sheets, size of each, 24 inches by 21.

Geological Map of Canada and the ADJACENT REGIONS, including parts of other British Provinces and of the United States. By SIR W. E. LOGAN, F.R.S., &c., Director of the Geological Survey of Canada. The Geology of Canada is derived from the results of the Canadian Geological Survey; that of the other British Provinces from the labours of Dr. J. W. DAWSON, Professors JAMES ROBB, J. B. JUKES, and others; while that of the United States is compiled under the authority of Professor JAMES HALL, from various sources mentioned in "The Atlas of the Geology of Canada."

Price, sheets, 3*l.* 10*s.*; mounted in case, or on roller, varnished, 5*l.* 5*s.*

BOOKS.

Second Edition, revised and enlarged, post 8vo. cloth, price 10*s.*,

The Coal Fields of Great Britain: their History, Structure, and Resources, with descriptions of the Coal Fields of other parts of the World. By EDWARD HULL, B.A., F.G.S., of the Geological Survey of Great Britain. With numerous Woodcut Illustrations and a Map (scale, 20 miles to an inch), showing the areas of the Coal Fields and the Extension and Depth of the Coal Formation throughout Great Britain.

"The author could not have more usefully employed his talents, and the unrivalled resources at his command, than in taking stock on these great deposits of mineral wealth."—*Spectator.*

Demy 8vo. cloth, 5*s.*,

Mount Vesuvius: a Descriptive, Historical, and Geological Account of the Volcano, with a Notice of the Recent Eruption, and an Appendix, containing Letters by Pliny the Younger, a Table of Dates of Eruptions, and a List of Vesuvian Minerals. By J. LOGAN LOBLEY, F.G.S.

Illustrated with View, Map (printed in colours), and Section.

"An exceedingly interesting account, both historical and scientific, of Vesuvius . . . . A very complete volume."—*Spectator.*

Post 8vo. cloth lettered, price 2*s.*,

Rain: How—When—Where—Why—it is MEASURED. Being a Popular Account of Rainfall Investigations, with numerous Illustrations. By G. J. SYMONS, F.M.S.

"Excellent little handbook.'—*London Review.*

One volume, demy 8vo. cloth, price One Guinea,

The Parana: with Incidents of the Para- GUAYAN WAR, and SOUTH AMERICAN RECOLLECTIONS, from 1861 to 1868. By THOMAS J. HUTCHINSON, F.R.G.S., F.R.S.L., F.E.S., F.A.S.L., H.B.M. Consul for Rosario; Author of "Niger-Tshadda-Binuë Exploration," "Impressions of Western Africa," "Ten Years' Wanderings amongst the Ethiopians," "Buenos Ayres and Argentine Gleanings," &c. With Maps and Illustrations, including a Portrait of Field-Marshal Lopez, the Paraguayan President.

"We can cordially recommend the book, both as pleasant, fresh reading, and for the quantity of sterling, reliable information it contains."—*Observer.*

Crown 8vo. cloth, price 10*s.*

Geography: Physical, Historical, and MILITARY. From the Seventh French Edition of TH. LAVALLEE, late Professor of Military History and Statistics at the Military School of Saint-Cyr. Edited, with Additions and Corrections, by Captain LENDY, F.G.S., F.L.S., &c., Director of the Practical Military College at Sunbury.

"A genuine geography."—*Spectator.*

"The work contains that admirable system and lucid arrangement which are so marked in all the educational treatises of the continent, and its advantages appear to be enhanced by the skilful treatment of Captain Lendy."—*London Review.*

Atlases, Maps, and Globes. Now ready, a New CATALOGUE of SELECTED ATLASES, MAPS, and GLOBES, comprising Atlases of Ancient and Modern Geography; Physical, Biblical, Historical, and Educational Atlases, &c.; Maps of the World, Europe, Asia, Africa, and America; Great Britain, India, and the Colonies; London and its Environs; the Useful Knowledge Society's Series; also Selections from the Geological and Ordnance Survey Maps. Free on application, or per post for one stamp.

London: EDWARD STANFORD, 6 and 7, Charing Cross, S.W., agent by appointment for the Sale of the Geological Survey and Ordnance Survey Publications and Admiralty Charts.

Printed by R. CLAY, SONS, & TAYLOR, at 7 and 8, Bread Street Hill, in the City of London, and published by MACMILLAN & Co. at the Office, 63, Bleecker Street, New York.—THURSDAY, February 24, 1870.

NATURAL SCIENCE AT THE UNIVERSITY OF CAMBRIDGE

IN endeavouring to give a brief sketch of the aids and encouragements to the student of Natural Science in this University, it will simplify matters to arrange our materials under three heads: (1) Instruction, (2) Appliances, (3) Inducements.

(1) INSTRUCTION.—This may be subdivided into (*a*) University, (*b*) Collegiate. As the relation between the University and the Colleges is often not understood by outsiders, it may be well to preface this part of our subject by a word of explanation. As it would clearly be impossible in most branches of learning for one, or even several, professors to teach the large number of students now resident in the University, the greater part of the work has to be done by the staff of tutors and lecturers in the various Colleges. Hence, in practice, a system of division of labour has grown up. The Colleges look after the general education of their students, and do the heavy work, undertaking almost the whole instruction of the rank and file in the Arts and Sciences; while the professor is held to be the representative of his particular department, whose duty is to do his best to advance its study, and be the organ by which the latest advances in it are communicated to the University at large. His work, therefore, is to fine-polish the tools which the Colleges have prepared. Hence, in one of the more frequented branches of study,—say, for example, that of mathematics,—the great mass of students never attend a professor's lecture at all; for them the instruction provided by the Colleges amply suffices; his class therefore consists of only a few of the ablest students, and he confines his instructions to those very difficult branches of mathematics on which perhaps few men besides himself can speak with much authority. In the case, however, of a branch of study followed by only a small number—say Sanscrit—the care of all the students may fall on the professor; but then, as the class cannot be a large one, this is not too heavy a burden. When, therefore, the demand for instruction in any such branch increases, the Colleges, either singly in the larger or by combination in the smaller Colleges, appoint lecturers to relieve the professor by taking charge of the average students, and by preparing the more able to attend his classes. This last is exactly the position of the Natural Sciences at the present time.

(*a*) To return, then, after this digression to the University Instruction in the Natural Sciences. At the present time, without reckoning the two purely Medical Professors, there are six Professorships in the University: that of

	Founded in	At present held by
Anatomy*	1707	Dr. Humphry.
Botany	1724	Prof. C. C. Babington.
Chemistry	1702	Prof. Liveing.
Geology	1727	Prof. Sedgwick.
Mineralogy	1808	Prof. W. H. Miller.
Zoology	1866	Prof. A. Newton.

The number of lectures given varies considerably, depending mainly on the requirements of the students; the smallest being one course of four days a week in one term, while the largest is two courses each of three days a week in every term.

(*b*) Collegiate. Trinity College has one lecturer in the Natural Sciences; St. John's College has two; and the present lecturers have made arrangements by which the lectures are common to the two Colleges: the subjects thus covered being Physics, Chemistry, Geology, and Elementary Botany. Sidney Sussex College has one lecturer in the Natural Sciences, and Downing two "in Medicine and Natural Science." We believe that these lecturers also admit to their lectures students from the neighbouring Colleges.

(2) APPLIANCES.—The University possesses various collections, &c., accessible to students. These are: the Museum of Human Anatomy and Pathology, which is strong in the latter department, but not so well supplied in the former. The Botanical Museum, containing the collections formed by the late Professor Henslow with the herbaria of Drs. Lehmann and Lindley, and considerable additions that have been made from time to time. These for many years could not be properly exhibited owing to want of space, but they have been recently established in a suite of rooms in the New Museums and Lecture Rooms Buildings, and provided with convenient cases in which they are being rapidly arranged. There is also a large Botanic Garden, with hothouses, &c. The Professor of Chemistry has a small Museum of Chemical Preparations, with Laboratories that will accommodate about forty students at once. The Geological Museum, which occupies the ground-floor rooms under a part of the Public Library, had for its nucleus the collection of Dr. Woodward, the first professor. Since then it has been constantly augmented by many valuable gifts, and by the energy and liberality of the present occupant of the chair, the venerable Professor Sedgwick. It is peculiarly rich in Palæozoic, Cretaceous, and Eocene fossils; containing, among others, collections from the Cretaceous rocks by Mr. Image and by Dr. Forbes Young, of Saurians from the Lias by Mr. Hawkins, of Dudley fossils by Captain Fletcher. There is, we believe, no Museum where the palæontology of East England can be better studied. It also contains some good sets of Continental fossils, and a remarkably fine series of rock specimens collected by the present professor. On the whole it is a collection of which the University may justly be proud. The Mineralogical Museum now occupies a suite of rooms above that of Botany, and its arrangement is almost completed. It originated in the collection formed by Dr. E. D. Clarke; but has since been greatly augmented, having received the entire collections of Mr. H. Warburton, Dr. Forbes Young, Lord Lilford, Viscount Alford, and Mr. H. J. Brooke, besides large donations from Dr. Whewell and others. Rooms for purposes of study are attached to the Museum. The Museum of Comparative Anatomy contains the nucleus of a fine collection in Comparative Osteology, numbering more than 2,000 specimens, with a collection of Invertebrata and a Physiological series. It owes much to the energy and liberality of the late Professor of Anatomy, Dr. Clark, and of his son, Mr. J. W. Clark, the present superintendent of this and the Zoological Museum. The latter Museum, now in process of arrangement, contains some good collections of birds

* The University also provides a demonstrator in Anatomy to assist the professor.

and fishes. In the Colleges, there are laboratories at St. John's, Sidney Sussex, and Downing; and we believe that Trinity College contemplates establishing one.

(3) INDUCEMENTS.—The degree of B.A. may be obtained in Natural Sciences. An examination in Honours was instituted in 1851; in 1861 the regulations were revised, and the successful candidates were declared entitled to a degree. Ninety-five students have passed this examination in the nine years since the alteration. A candidate for an ordinary degree may also select for the subject of his third or final examination one of the following subjects: Chemistry, Physics, Geology, Botany, Zoology. In the Colleges: Clare gives annually a scholarship, value 50*l.*; Caius two, value not stated, one for Chemistry, the other for Anatomy; Christ's has lately offered scholarships, from one to four in number, and from 30*l.* to 70*l.* in value, according to the merit of the candidates; St. Peter's gives annually one of the value of 60*l.*; St. John's gives annually an exhibition of 50*l.* for three years to students commencing residence; this College has also just instituted an annual examination in the Natural Sciences for its resident students, for proficiency in which prizes in books and pecuniary rewards will be given, as in the other College examinations; Trinity gives annually one foundation scholarship, tenable till the holder is of M.A. standing; Sidney Sussex, two scholarships annually, value 40*l.*, with opportunity of promotion, for Mathematics or Natural Science; Downing gives annually at least one scholarship, value 40*l.* A fuller description of these will be found in No. 6 of this periodical, p. 169.

In looking through the lists of the Natural Sciences Tripos, fourteen persons will be found to have been elected fellows, but in most cases the candidate has been not without distinction in other branches of study. In several, however, proficiency in Natural Science was the declared cause of the election.

These statements are made upon the authority of the last volume of the Cambridge Calendar, supplemented in some instances by personal knowledge.

Thus much has been done: of what remains to do it is perhaps better that one, who is a resident and engaged to some extent in the work, should refrain from speaking. On this point only I may venture to express my conviction, that the coldness and even dislike with which the study of Natural Science was once regarded here is rapidly passing away, that the number of earnest students in the various branches is annually increasing, and that the University is fully alive to the wants of the age; so that, while she can never neglect or forget those old paths of Classics and Mathematics in which many of her sons have won an almost world-wide reputation, she will heartily welcome, and will regard with no less pride, all who are among the followers of sciences of a more recent date.

T. G. BONNEY

THE MEASUREMENT OF GEOLOGICAL TIME

II.

WE have now to consider an entirely distinct set of facts which have an important bearing on the probable time elapsed since the last glacial epoch. Messrs. A. Tylor, Croll, and Geikie have shown that the amount of denudation now taking place is much greater than has generally been supposed. The quantity of water discharged by several rivers and the quantity of sediment carried down by those rivers have been measured with tolerable accuracy, and allowing for the difference of specific gravity between sediment and rock, it can be easily calculated, from the known area of each river basin, what average thickness has been removed from its whole surface in a year, since all the matter brought down by the river must evidently have come from some part of its basin. In this way it is found that the Mississippi has its basin lowered $\frac{1}{6000}$ of a foot per annum; the Ganges, $\frac{1}{2358}$; the Rhone, $\frac{1}{1528}$; the Hoang-Ho, $\frac{1}{1464}$; the Po, $\frac{1}{729}$.

But it is evident that this amount will be distributed very unequally over different parts of the basin, according as the surface is flat or sloping, whether the slopes are of loose soil or of rock, whether the rock is solid or friable. The perfectly flat alluvial plains that form a considerable part of many river basins, will not only suffer no denudation, but will generally receive deposits of sediment during floods, and all such flat lands should therefore be deducted from the area of the river. Slightly undulating lands, especially if well covered with forest, will also suffer scarcely any denudation, as is well seen in the case of the Rio Negro branch of the Amazon and other black water rivers of South America, which hardly carry down any perceptible sediment even when in full flood. Again, wherever lakes occur, they receive all the sediment from the basin above them, which portion should therefore be treated by itself, since it contributes no sediment to the main river. If we look at a physical map of North America we see that a large extent of the Mississippi basin consists of alluvial flats and slightly undulating prairie, sufficiently explaining its small proportionate denudation. Even the Rhone, which has a high rate of denudation, flows through a great extent of low lands and perfectly flat meadows, while the upper portion of its valley which produces most sediment is cut off by the Lake of Geneva. In order, therefore, to arrive at any fair estimate of the amount of denudation in the upland and mountainous portions of the Rhone valley (which is what we require for our purpose) we have considerably to reduce the area of its basin by taking away the flat lands in all its valleys, and considerably to increase the amount of sediment by adding all that is now poured into the Lake of Geneva. We shall probably not be far wrong in adding one third to its denuding powers on these grounds, which will lead us to the startling fact that the Rhone basin is being lowered at the rate of a foot in a thousand years; but even this is considerably less than in the case of the Po. Mr. Croll takes the Mississippi denudation of a foot in six thousand years as a measure for that of Europe; but for reasons above stated I conceive this to be quite out of the question, and I maintain, that if we are to use his measure of denudation for any practical purpose, we must apply that of European rivers to European phenomena, that of Alpine rivers to Alpine phenomena, and must further make the necessary corrections for alluvial flats and intercepting lakes.

Mr. Croll and Sir Charles Lyell were at first both inclined to adopt the period of high excentricity which occurred from 750,000 to 950,000 years ago as that of the glacial epoch, but Mr. Croll, in consideration of the proofs of rapid denudation above given, now believes that the period beginning about 240,000 and ending about 80,000 years ago, is the more likely one. Even this, however, offers difficulties. Denudation in Wales and Scotland must probably have gone on as rapidly as the average rate of the Rhone valley, especially during the period when the old glaciers were disappearing; and eighty thousand years will therefore imply eighty feet of average denudation over the whole surface of the country, if less in one part then correspondingly more in another; but how is this consistent with the preservation of ice-ground rock-surfaces and glacial furrows in so many situations, as well as numberless heaps of loose matter, the moraines of ancient glaciers, apparently just as they were left by the ice? There are, it is true, a few considerations that go to diminish though not to remove the difficulty. The amount of denudation is now abnormally large, because the large quantities of glacial drift left over the surface of the country, supply much of the sediment carried down by the streams of Alpine countries. Many glacial markings were at first covered up and preserved by drift or alluvium, and have been since exposed by denudation: those earliest exposed are obliterated, but new surfaces are being continually uncovered. The amount of denudation of a solid rock-surface may not be a tenth part of that which now obtains in glaciated districts; a fact which can only be ascertained by determining the amount of sediment brought down by streams the basins of which are *free from drift or gravel*, and consist almost wholly of *compact rock surfaces*. We still have to deal with the difficulty of the moraines, whose form and aspect are often so fresh that we can hardly believe them to have been much changed since the ice left them, although it is impossible to understand how they have escaped the denudation which has lowered the whole surface of the country eighty, or even a much smaller number of feet.

It is true Mr. Geikie, in his paper on Modern Denudation,* suggests that all the effects of ice-action, now visible, are merely the few examples which have been preserved owing to a concurrence of favourable conditions, while a much larger number have been destroyed; and I learn from him that there are in Scotland moraines in all stages of decay. If this be the true explanation of the difficulty, it follows that denudation must be extremely unequal, and that if one valley or hill-side has remained unaltered during 80,000 years, another must have been denuded to double the average amount.

Having thus shown the difficulty there is in accepting even the shorter period of 80,000 years for the date of the end of the glacial epoch in Europe, let us see what other modes of measurement are available. In Sir Charles Lyell's "Antiquity of Man," 2nd ed., p. 28, we have three different calculations of the age of the bronze and stone periods in Switzerland, which would place the latter at about from 5,000 to 7,000 years ago. At page 321 of the same work, we have an estimate of the age of the upper delta of the Tinière by M. Morlot. The lower delta (by the presence of Roman remains in one of the upper strata) is calculated with tolerable certainty to be 10,000 years old, while the upper delta, 150 ft. above the lake, is ten times as large as the lower one, and is therefore supposed to be 100,000 years old. From its fossil remains it is believed to be post-glacial; but it is evident that, during the melting of the ice, the torrent might have been more powerful, and have accumulated a delta much more rapidly than now. The peat mosses of Denmark, indicating that the present beech-tree vegetation of that country, which was also characteristic of it in the Roman period, was in the Bronze age replaced by oaks, and in the still earlier Stone age by fir-trees, imply a very long lapse of time; yet this only takes us back to the Neolithic age, when all the shells and all the mammalia were of existing species. The 8,000 or 10,000 years of the Swiss Stone age may, however, have sufficed for this change. There seems to be no doubt, that the time which elapsed from the close of the glacial epoch (when man used the rudest flint weapons, and was coeval with many extinct animals, when, moreover, the climate and physical features of the country were considerably different from what they are now) up to the Neolithic age, was much greater than from the latter date to the present day, but how much greater it is impossible to determine. The position of many of the tool-bearing gravels shows that rivers then flowed at much higher levels, but from the known rate of denudation, a valley might be deepened even 50 or 100 ft. in as little as 50,000 years, since it is in valleys that the effects of denudation would be greatest; and the extinction of the various animals might certainly take place in an equal time under such conditions as are not unlikely to have occurred at a period of great climatic change.

* Transactions of the Geological Society of Glasgow, vol. iii. p. 153.

It does not appear, therefore, that any of the estimates of time founded on an actual basis of observed change in a known period, require us to assume more than 80,000 years since the close of the glacial epoch, while the measurement of the existing rate of denudation renders it almost certain that it was less rather than more. We may fairly assume, that even if a large excentricity has been an essential condition of a glacial epoch, the ice would maintain itself into a period of less excentricity than would be required to bring one on. Now 74,000 years ago the excentricity was about double what it is now, and the winter of the northern hemisphere then occurred in *aphelion*, so that the glacial epoch would at that time probably have been in full force, and we may assume that it might continue 3,000 or 4,000 years longer. But when we come to 65,000 years back, we find the excentricity scarcely more than it is at present, and winter nearly in *perihelion;* so that we must conclude, if excentricity has anything to do with it, that the last glacial period came to an end not less than 70,000 years ago.

Now it is most important to observe that, for the last 60,000 years, the excentricity has been very small—for three-fourths of the time less than it is now. During this time the opposite phases of precession, each lasting 10,500 years, will have produced scarcely any effect on climate, which in every part of the earth will have been *nearly uniform for that long period.* But this is quite an exceptional state of things; for the curve of excentricity shows us that, during almost the whole of the last three million years, the excentricity has been high—almost always twice, and sometimes three and four times as much as it is now. If, therefore, Mr. Croll's theory be correct, there will have been a change each 10,500 years during this vast period (in all the extra-tropical regions at least) from a very cold to a very mild climate. This will necessarily have caused much migration both of plants and animals, which would inevitably result in much extinction and comparatively rapid modification. Allied races would be continually brought into competition, altered physical conditions would induce variation, and thus we should have all the elements for natural selection and the struggle for life, to work upon and develop new races. High excentricity would therefore lead to a rapid change of species, low excentricity to a persistence of the same forms; and, as we are now, and have been for 60,000 years, in a period of low excentricity, *the rate of change of species during that time may be no measure of the rate that has generally obtained in past geological epochs.* Thus we should have explained the extraordinary persistence of organic forms during the historical period as well as during the preceding Neolithic age, although slight changes of climate and of physical geography have undoubtedly taken place; and it would prove to be not so much the *usually* slow rate of organic change, as the fact of our living in the midst of an *exceptionally uniform climatic epoch*, that has hitherto prevented us from obtaining a measure of the average duration of species.

These considerations have an important bearing on our estimate of the duration of the glacial epoch itself, and on our calculation of geological time from the change of species since its commencement. If it terminated 70,000 years ago, and if each 10,500 years before that date, there was alternately a warm period and a glacial epoch, there would necessarily occur a series of northern and southern migrations of animals and plants, and thus deposits formed at times not geologically remote, might contain very distinct groups of animals. These might even meet and be confounded in the same strata, and thus lead to that extraordinary mixture of northern and southern forms which occurs in some of the more recent formations, like the hippopotamus and mammoth in the Norfolk crag and the lower brick-earths.

Geologists seem hardly to have attached sufficient importance to the great gap that intervenes between the Palæolithic and Pre-historic ages. Mr. Boyd Dawkins has shown, from a careful study of their mammalian remains, that the whole of the post-glacial river deposits and cave-beds of this country (148 in number) are of the same age, being characterised by about twenty species of extinct or arctic mammalia, and this was the age of Palæolithic man. In the Pre-historic or Neolithic age all these have disappeared, while the sheep, goat, dog, and *Bos longifrons* are first met with. Now, on the theory that this Palæolithic age was entirely post-glacial, and that the climate and physical geography of Britain have been since slowly approaching their present condition, how is this great gap to be accounted for? The large number of places where remains have been found, shows that the conditions requisite for preserving them very frequently occurred, and there must therefore have been some special cause which has prevented any record being left of the long period during which they were becoming extinct. Mr. J. Scott Moore* maintains that they were all pre-glacial, and that the gap was the glacial epoch itself. He adduces in corroboration the striking fact that none of the supposed post-glacial gravels ever rest on the boulder clay, but always on an older rock, which could hardly have been the case in every instance were they all post-glacial. Again, Mr. Boyd Dawkins tells us that the identity of such a large proportion of the species of pre-glacial and post-glacial mammals "forbids the idea of the existence of any gap or lacuna which would warrant the classification of the one as tertiary and the other as quaternary." But if we admit the occurrence, during the last glacial epoch, not only of one or two, but of a series of alternate cold and warm periods, we may make the Palæolithic age *inter-glacial*, and suppose it to have occupied several of these alternations of climate. If we further place the last submergence which separated Britain from the Continent, during one of the later phases of extreme cold, when most of the extinct mammalia, as well as man, had migrated southwards, we shall sufficiently account for the great gap that intervenes between the Palæolithic and Pre-historic ages.

* Pre-glacial Man and Geological Chronology. Dublin, 1868.

In the "Principles of Geology," 10th ed., vol. i. p. 300, Sir C. Lyell has given an estimate of the duration of geological epochs, from the proportionate change in the species of marine mollusca, taking as a basis a million years since the beginning of the glacial epoch. Of the marine shells then living, six per cent. have become extinct, while at the close of the glacial epoch they were all of existing species, but this does not necessarily imply that the former are many times older than the latter. The glacial period itself may have been the cause of their extinction independently of mere time; so that the Bridlington beds, where the above-mentioned proportion of extinct species occurs, need not on this account be more than twice as old as those glacial or post-glacial drifts which contain only living species, or, according to our previous estimate, about 140,000 years. The Norfolk crag, which contains eleven per cent. of extinct shells, may be from 40,000 to 60,000 years older; this will allow for two or three alternations of warm and cold periods, which, at a time of such high excentricity, must have been strongly contrasted, and have led to a correspondingly rapid change of species. From these considerations it becomes evident that the time, measured by the occurrence of five per cent. of extinct species of marine shells, is not necessarily the whole number of years which has elapsed since they existed, but only that number *minus* the last 60,000 years of uniform climate and specific immobility; and we may be even too lavish of time if we allow so much as 100,000 years for this amount of change under the influence of those repeated alternations of climate which have characterised the last three million years and which have probably more or less characterised all past geological time. If now we take this number as our datum instead of a million years, all Sir Charles Lyell's figures will be reduced to a tenth, and will stand thus: the time elapsed since the beginning of the—

Lower Miocene . . .	2,000,000	years.
Eocene	6,000,000	,,
Cretaceous	10,000,000	,,
Triassic	14,000,000	,,
Permian	16,000,000	,,
Carboniferous	18,000,000	,,
Devonian	20,000,000	,,
Silurian	22,000,000	,,
Cambrian	24,000,000	,,

These figures will seem very small to some geologists who have been accustomed to speak of "millions" as small matters; but I hope I have shown that, so far as we have any means at present of measuring geological time, they may be amply sufficient. Taking Sir William Thomson's allowance of a hundred million years for the time during which the earth can have been fit for life, it yet allows Mr. Darwin, for the process of development from the primordial germ, three times as many years anterior to the Cambrian epoch as have elapsed since that date, an amount of time which, I believe, will fully satisfy him, by whatever scale we may measure it.

The evidence of the rapidity of denudation would indeed tend to the still further shortening of the estimate here given; and it is not impossible that a concurrence of geographical conditions might have brought down the glacial epoch into a period when the excentricity was no greater, or even less, than it is now. This, however, is hardly probable, and I am inclined to think that the considerations already alluded to will, to a considerable extent, explain how it is that so many signs of glacial action still remain, in spite of such denudation. The only argument I consider new in this paper, is that derived from the uniformity of climate during the last 60,000 years, and the alternations of heat and cold for a long time previously, leading to a slower change of species since the glacial epoch than at any former period, thus allowing us to suppose change of form in the organic world to go on more rapidly than we had before thought possible. If this be a sound deduction, it will, I believe, more than anything else, enable us to bring the period required for the development of the whole organic world within that which modern natural philosophy assigns as the age of the habitable earth.

Much of the force of my argument appears to depend upon the accuracy of Mr. Croll's view, that, during a time of great excentricity, there will be in each hemisphere alternately a glacial epoch for about 10,500 years, and a perpetual spring or summer for about an equal period. But Sir Charles Lyell argues, with great force, for the opposite view, that the cold of one period would be continued through the other, and that during the whole continuance of a phase of high excentricity both hemispheres would be in a state of glaciation. Supposing this view to be the true one, it will not very materially affect my argument, for the diagram shows many comparatively rapid alternations from a very high to a very low excentricity, which would also be from a glacial to a temperate climate and would certainly tend to comparative rapidity of specific change; while in each 10,500 years there would, no doubt, be some retreat and advance of the snow line, followed by a less amount of migration, competition, and variation. During the last 60,000 years, on the other hand, the change of excentricity has been hardly perceptible, and the change of organic forms may be supposed to have been far below the average.

ALFRED R. WALLACE

FRESHWATER CRUSTACEA OF NORWAY

Histoire Naturelle des Crustacés d'eau douce de Norvège; by George Ossian Sars. Part I. Malacostraca. With 10 plates. (Christiania, 1867.)

SOME few years ago, much interest was excited amongst naturalists by the announcement of the occurrence, in the great Swedish lakes Venner and Vetter, of certain Crustacea, heretofore known only as marine species inhabiting the Arctic and Baltic Seas. The author of this discovery was Professor Lovèn; and the explanation of it appeared to be, that the gradual elevation of the Scandinavian peninsula had cut off these originally marine creatures from their natural habitat, and that they had been able to accommodate themselves successfully to altered conditions of life.

In the volume now under notice, we have an elaborate —we may say almost an exhaustive—contribution to the natural history of these and other fresh-water crustacea of Norway. The species here treated are *Mysis oculata*, var. *relicta; Gammarus neglectus; Pallasia cancelloides*, var. *quadrispinosa; Gammaracanthus loricatus*, var. *lacustris; Pontoporeia affinis*; and *Asellus aquaticus.* One notices with surprise the absence of the most abundant freshwater Amphipod of our own country, *Gammarus pulex*, and its replacement by the very closely allied *G. neglectus.* The well-shrimps (*Niphargus*) seem also to be unnoticed as yet in Norway; neither do we find any mention of another group, inhabiting chiefly brackish water, but in some districts of England reaching into situations which, though affected more or less by tides, are yet of quite fresh-water character; e.g. *Palæmon varians* and *Mysis vulgaris.*

The anatomy and physiology of all these animals, and their points of variation from the typical marine forms, are most carefully and elaborately worked out. The following interesting remarks occur respecting *Pontoporeia affinis.* The males of this species are numerous, having their antennæ either imperfectly developed or presenting a very peculiar form, except in some individuals, where, towards the end of autumn, the antennæ take on their fully developed form; in both cases, the animals being perfectly fertile. This phenomenon is analogous to some already observed in the Cumacea and Tanaidæ. The great likeness between this and the Greenland species, *P. femorata*, led the author at one time to consider the two as presenting only varietal differences, the Norwegian species exhibiting a permanent arrest of development such as he shows to be the case with the variety *relicta* of *Mysis oculata.* This supposition, however, he was compelled to dismiss; one important fact tending to a contrary opinion being that the secondary appendage of the superior antenna contains in *P. affinis* a larger number of joints than in *P. femorata.*

We would commend the dredging of our deeper lakes to the attention of English naturalists. Nothing in that direction has, so far as we know, been done in this country; and it is worthy of remark, that only in the very greatest depths of the Scandinavian lakes were the abnormal species found. That this field is not unlikely to prove a productive one near our own doors we fully believe, inasmuch as we have ourselves found, and elsewhere published, some interesting instances of the occurrence of truly marine microscopic crustacea in fresh water in the west of Ireland.

It should be added, that the plates illustrating M. Sars' work are admirable specimens of the engraver's art, and leave nothing to be desired as to copiousness and accuracy. The work is altogether well produced; the expenses, which we fear are scarcely likely to be repaid, having been generously borne by the publisher, M. le Réviseur d'Etat Johnsen.

G. S. B.

THE THREE KINGDOMS OF NATURE

The Three Kingdoms of Nature, briefly described. By the Rev. S. Haughton, F.R.S., M.D. Dubl., D.C.L. Oxon, &c. (London: Cassell, Petter, and Galpin.)

THIS little work resembles a modern novel in one particular: it is written with an idea.

The learned author, in his preface, lays down the law that "the faculties of our mind are developed in succession as we advance in age, each of them reaching its maximum and then gradually diminishing. In childhood the senses acquire their greatest development; in boyhood and youth, the memory and imagination; in early manhood, the purely reasoning faculties; and in adult life, the judgment." He accordingly draws the conclusion that "the child should be instructed mainly through his sensations; the boy should learn languages, ancient and modern, and natural history, so far as it depends on observation; the youth should cultivate mathematics and logic; while studies such as ethics, physiology, and politics should be reserved for the more mature period of life:" and offers this work as a text-book on Natural History.

We must confess that the above law seems to us to be barely a half-truth. We admit that the senses are relatively strongest in childhood, but not absolutely. So far from their attaining their maximum development at that age, and then gradually diminishing, we believe that the senses of the truly fashioned man are at their height when he is in the prime of life; and that in the properly trained man, memory, imagination, reason, and judgment, all flourish at the same time.

We are apt to forget into what a wretchedly cramped and artificial condition so many generations of schoolmasters have bred us. Each of us, generation after generation, has very early been made to put Chinese shoes on most of the feet of his mind.

We all see the sportive, elastic, quick, sharp, unwearying work of the senses of a little child. We do not all of us bear in mind to how fearful an extent those senses are bruised and deadened by the pedantry of our pedagogues. Men who cultivate those sciences in which success is inseparable from agile sense, know at what cost and labour, in later life, sometimes even in their full prime, they have had to go back and undo all that their schoolmasters have done, have had to become little children again for the sake of a sharper eye and a quicker ear. To ourselves, there is nothing more disheartening than to study a little boy, of eight or ten years of age, who has never been to school, tracing out in his mind with ease nascent scientific capabilities; then to know the same little boy after he has enjoyed for two or three years the great advantages of a grammar or a commercial school, or a private academy, and to find his mind as blank and as deadened as his moral nature.

We do not feel inclined, then, to accept the physiological law laid down by Dr. Haughton, but we are not thereby prevented from agreeing with him that "Natural History (as a school study) is inferior to no other study, not even language, as a means of cultivating the memory and observation," or from accepting his brief description of the three kingdoms as a capital instrument of teaching.

The first part contains, besides an introductory and extremely lucid chapter on Crystallography, a detailed but succinct description of the various minerals found in Nature; the chemical composition, physical characters, crystalline forms, geological and geographical distribution of each being briefly given.

The second part treats of the Vegetable kingdom; dealing somewhat fully with the anatomy, more briefly with the physiology, of plants, and devoting only some dozen pages or so to classification.

The third part, comprising nearly half the volume, describes the Animal kingdom, beginning with mammalia and working down to protozoans. In each subdivision a brief anatomical history precedes the classification, which is given pretty fully. Formal definitions in italics, of classes and orders, are relieved by popular descriptions of the habits and features of species and individuals; and the whole work is largely illustrated by many excellent woodcuts.

Although so large a field is gone over, the matter is on the whole eminently exact and truthful; and the author has probably given an indication of the judgment of the mature period, by hesitating to place in a dogmatic text-book views on various points which are certainly recent, and may turn out to be raw. We may congratulate Dr. Haughton on having compressed a vast amount of information into a small compass. But is only right to add one more observation: the book is very formal, even to exceeding toughness. Though quotations from the poets, Aristotle, and Scripture appear here and there, the general reader would, we fear, find it very dry. As a text-book in the hands of a teacher, it will commend itself to every one; we doubt if any but very strong-minded persons would choose it for self-instruction, except with the fear of an examination before them. M. F.

OUR BOOK SHELF

Baillon's Cæsalpineæ.—*Histoire des Plantes:—Monographie des Legumineuses Cæsalpinées.* Par H. Baillon. (Paris: Hachette, 1869. London: Williams and Norgate.)

WE have so recently reviewed the first volume of Baillon's "History of Plants" (see NATURE, No 2, p. 52) and discussed his mode of treating the subject, that we need scarcely more than mention the publication of his monograph of the important order or sub-order of *Cæsalpineæ*. The boundary-line between this sub-order and the *Papilionaceæ* is very difficult to be accurately laid down. M. Baillon describes the *Cæsalpineæ* to be, in general terms, those *Leguminosæ* which have a straight embryo and the æstivation not vexillary in the bud; but neither of these diagnostics can be relied on as absolutely constant. All the other characters dependent on the regularity or irregularity of the corolla, the cohesion of the stamens, the number of seeds, the presence or absence of albumen, &c., are still more uncertain. There are even species so far removed from the normal type of the order as to have undivided leaves, indefinite stamens, diclinous flowers, and herbaceous stems. A. W. B.

Ueber die Fortpflanzungs-Geschwindigkeit des Schalles in Rohren. Von Adolf Seebeck. (Göttingen, 1869.)

IN this inaugural dissertation, Herr A. Seebeck, the inheritor of a name famous in physical science, gives an account of his experiments on the velocity of the propagation of sound in pipes. The results are extremely interesting and important.

In 1867, Professor Kundt, of Zurich, proved that the velocity of sound in pipes depends on their cross section, and attributed the result to the loss of heat in the friction of the gases on the enclosing wall. Kirchhoff deduced the consequences of this theory mathematically, and pointed out that the diminution of velocity must vary inversely as the square root of the number of vibrations in the sound propagated; that is to say, that the velocity of sound could not be uniform for different notes. Seebeck shows that the loss is inversely as the cube of the square root of the number of vibrations; so that we can scarcely attribute the result entirely to the loss of heat by friction of the enclosed gas on the walls of the tube. On the other hand, his results completely establish the fact of a difference in the speed with which different notes of music are propagated in tubes.

The magnificent and laborious work of M. Regnault on the velocity of sound in pipes, appeared while Seebeck was occupied in these investigations. He points out, that since the sounds which Regnault studied, such as explosions of gunpowder and so on, are due to violent and complicated disturbances, however important it may be to study them in a practical view, they are not likely to give us accurate and delicately differenced results. Where the sound contains a mass of irregular notes, no effect due to difference of note can be observed. The method of generation compels the air to move at first in all directions in the tube. Such sounds fall into the sea of air like a mass of stone dropped from a great height into the water. The waves which they generate can only reduce themselves to regularity at some distance from the disturbance and their propagation must be irregular till that distance is reached. On the other hand, a regular pulsation, such as would be produced by the timed advance and retrogression of a piston at the end of the cylinder, gives waves which are regular and regularly propagated from the beginning. It is in consequence of this delicacy in the character of his experiments that Seebeck has attained his results.

He makes one of König's tuning-forks sound at the open mouth of a cylindrical pipe, the other end of which is stopped by a moveable piston. A short distance from the mouth of this pipe there is an opening, connected with an indiarubber tube which can be carried to the ear. If, by the motion of the moveable piston, this opening be made to correspond exactly to a "ventre" in the standing wave which is generated in the air of the tube, it is easy to measure, with great accuracy, the length of that standing wave, which corresponds to the precise number of vibrations of the tuning-fork. The extreme difference in fifty experiments for the same note, appears to have been about one five-hundredth of the whole amount.

The results are the following, the velocities being reduced from the experiments to those at 0° C.:

	Diameter of pipe in millimetres.	Velocities reduced to 0°, in metres per second.				Number of vibrations per second in note sounded.
1.	3·4	322·90	318·86	317·26	——	512, 384, 320, 256
2.	9·0	328·44	327·68	327·22	325·63	
3.	17·5	330·92	329·86	329·24	327·82	
4.	29·0	326·10	326·72	325·36	324·54	

If we compare these numbers with that for the speed of propagation in free space, as given by Schröder von der Kolk, which is 332·77, we see (1) that they are *uniformly* and considerably *less*; (2) the divergence *is greatest in narrow tubes*, with the exception of that where the tube was 29 millimetres in diameter, which was in all probability too wide to have the mass of air at its end uniformly affected by the vibrating tuning-fork; (3) the notes which travel slowest are the *low notes*. This difference is by far the greatest in the case of the narrow tube of an eighth of an inch in diameter, amounting to nearly 1 in 60 of the whole amount for the notes e and c_2.

The author discusses the further question, whether the nature of the enclosing tube produces any effect. In a tube, the inside of which is sheet copper, which has nearly 17 mm. diameter, the velocity is as low as it is in a glass tube of 9 mm. Where the friction is raised to a maximum by coating the inside wall of the tube with flannel, the velocity is reduced to 293·7 metres per second in a tube of 13 mm. diameter.

The same subject is treated fully by Herr Schneebeli, in a series of experiments published in Poggendorff's *Annalen* in February of last year; but those which we have described appear to us to have conducted their author to more valuable and interesting results.

WILLIAM JACK

An Introduction to the Study of Chymistry. Written for the People by Cuthbert C. Grundy. Pp. 108. (London: Simpkin, Marshall, and Co.)

WE remember when at school being called upon to admire the beauties of Schiller's *Wilhelm Tell.* Our impressions of that play were then by no means complimentary to some of the principal personages: so far as we could see Melcthal, Stauffacher and the rest of the members of the three Cantons apparently did nothing but meet clandestinely (when the weather was favourable) to talk much treason and fine sentiment, generously leaving most of the hard work to be performed by Tell (who being lowly-born was perhaps not so free of speech). All this was doubtless wrong and absurd; but we are reminded of these early impressions by the character of much of what is being said and done in reference to the education of the masses in the present movements. There is a wonderful disparity in the proportion of Tells to our ideal Melcthals and Stauffachers. Possibly, if certain noisy persons would but show their earnestness in the practical manner of Mr. Grundy, the wheels of progress would not drag so heavily.

In a modest little preface, Mr. Grundy informs us that his book is mainly intended for those among the great body of the people who desire knowledge, but have little time and only limited means for acquiring it. Occasionally, for example, when defining and illustrating the phenomena of latent heat, the author lays himself open to the charge of sacrificing precision of knowledge to clearness of statement. This fault is not unfrequently met with in manuals of this character: surely the two are not incompatible. Why does Mr. Grundy prefer the more antiquated form of styling the science? The generally accepted word is undoubtedly more correct: Kopp has satisfactorily shown this in his recently published "Beiträge zur Geschichte der Chemie."

On the whole, however, we can congratulate Mr. Grundy on having succeeded in explaining in clear and simple language the fundamental principles of chemical philosophy.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

On Professor Tyndall's Exposition of Helmholtz's Theory of Musical Consonance

IN the course of a re-perusal of Helmholtz's "Ton-empfindungen," it occurred to me to compare the theory of consonance and dissonance, there propounded, with the exposition of that theory presented in the Lectures on Sound of Professor Tyndall. The result of the comparison is the present paper, in which I shall endeavour to show that Professor Tyndall's version of the theory is radically different from the original, and erroneous.

Helmholtz determines the consonances of two *simple* tones by reference to their combination-tones. That of the first order suffices for the *octave;* those of the first and second order determine the *fifth* and *fourth*. The remaining consonances—*major and minor sixth* and *major and minor third*, do not, according to him, admit of determination from two simple tones and their combination-tones, but require the addition of a third primary simple tone.

* "Ton-empfindungen," pp. 301-303, 306-307. I shall in the following references use "H." to denote this work, and "T." for Prof. Tyndall's lectures.

Professor Tyndall * undertakes to determine the consonances of the *octave, fifth, fourth*, and *major third* for two simple tones, without employing combination-tones. He writes as follows :—

"Bearing in mind that the beats and the dissonance vanish when the difference of the two rates of vibration is 0; that the dissonance is at its maximum when the beats number thirty-three per second; that it lessens gradually afterwards and entirely disappears when the beats amount to 132 per second—we will analyse the sounds of our forks,† beginning with the *octave*. Here our rates of vibration are—

512 – 256; difference = 256.

It is plain that in this case we can have no beats, the difference being too high to admit of them.

"Let us now take the *fifth*. Here the rates of vibration are—

384 – 256; difference = 128.

This difference is barely under the number 132, at which the beats vanish; consequently the roughness must be very slight indeed.

"Taking the *fourths*, the numbers are—

384 – 288; difference = 96.

Here we are clearly within the limit where the beats vanish, the consequent roughness being quite sensible.

"Taking the *major-third*, the numbers are—

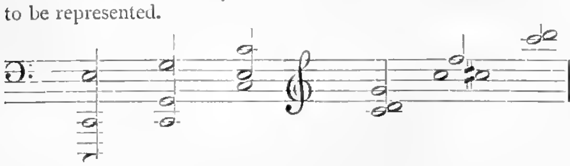
320 – 256: difference = 64.

Here we are still further within the limit, and accordingly the roughness is more perceptible. Thus we see that the deportment of our four tuning-forks is entirely in accordance with the explanation which assigns the dissonance to beats." ‡

It will not be difficult to test the value of the above reasoning. Starting from the rate of 256 vibrations per second selected by Prof. Tyndall, all that can be deduced from his definition of beats and dissonance at the head of the extract is that the maximum of dissonance will fall on the interval 256 : 256 + 33, *i.e.* 256 : 289; and that all intervals larger than 256 : 256 + 132, *i.e.* 256 : 388, will be free from dissonance. These numbers indicate almost exactly a whole tone and a *fifth* respectively. Each of these results is contrary to experience: the dissonance of a whole tone is less harsh than that of a half tone; and intervals greater than a fifth are by no means equally free from dissonance. Moreover, it follows that the determination of the octave by this reasoning is delusive, for the process would bring out, as perfect consonances, a *seventh* or a *flat ninth*, which are extreme discords, just as readily as an octave. If we apply the same method to other parts of the scale than that to which Prof. Tyndall has restricted himself, the results are even more remarkable. Thus starting from the higher octave of 256, viz. 512, the maximum roughness falls on 545, a half-tone, and dissonance ceases after 644, which lies between a *major third* and a *fourth*. For the next octave, *i.e.* starting from 1,024, dissonance ceases before we reach the interval of a whole tone. If we take lower positions on the scale we obtain opposite results. With 128 as our fundamental note, the maximum dissonance falls on 161, slightly above a *major third*, while roughness extends to 260, just beyond an *octave*.

With 64 the worst discord is at 97, just above the *fifth*, and roughness reaches 196, another *octave* higher. Starting from 32 the worst dissonance 65 is just above the *octave*, and roughness is not got rid of until 164, *two octaves and a major third* from the fundamental note.

The following octave exhibits at one view the results we have reached. The lowest note of each triad represents the fundamental note, the middle one the position of maximum dissonance, and the highest the limit of roughness. The middle note necessarily falls out of the last triad, as it lies too near the fundamental note to be represented.



Prof. Tyndall's method leads to the following conclusions :—The interval of an *octave* from the 16-foot C is the harshest possible dissonance; so is that of a *fifth* from the 8-foot C; so is that of a *major-third* from the lower C of a baritone voice. On the octave above the high C of a soprano voice, all the intervals beyond D are perfect consonances, while in the 16-foot octave there are no perfect consonances at all.

* T. p. 296.
† Tuning-forks produce, of course, *simple* tones.
‡ T. pp. 296, 297.

These conclusions are so utterly at variance with facts, that the method by which they have been obtained must be pronounced erroneous. In fact, Prof. Tyndall is himself a witness that this is so; for, in speaking of the *octave*, he remarks that if this interval be slightly impure, *beats of the fundamental tone are heard*.* Now this does not square with his own theory; for suppose two simple tones with 513 and 256 vibrations per second, which would form an impure octave: the difference is 257, which is as much "too high" as 256 was in the case of the pure octave. This interval should, therefore, give no beats, and an impure octave be as harmonious as a pure one. But according to Helmholtz's view, the first combination-tone of 513 and 256, viz. 257, will produce one beat per second *with the fundamental tone*, as stated, but not satisfactorily explained † by Professor Tyndall. This amounts to a practical admission by him that the beats of two simple primaries are not adequate for the determination of their consonances, and that recourse must be had for this purpose to combination-tones.

I claim to have shown that the method by which Prof. Tyndall appears to determine the consonances of simple tones is erroneous, and the determinations themselves fallacious. I proceed to point out the defect which vitiates his reasoning. He enunciates but one condition for the production of audible beats, that their number should not exceed 132 per second. Helmholtz lays down a second, quite as important—that the tones producing them should not differ too much in pitch. "These beats," he writes, "are *powerful when their interval amounts to a half-tone or a whole tone, but weak and audible only in the lower portions of the scale, when it is equal to a third, and they diminish in distinctness as the interval increases*." ‡ Here we see at once the reason why it is futile to attempt to determine consonances of a fifth or octave by the beats of two simple primaries—viz. that for these wide intervals the beats are imperceptible.

Let us now proceed to Prof. Tyndall's theory of consonance for *composite* sounds. Taking the octave C′, C″ or 264 : 528, he writes :—"With regard to the octave C′, C″, its two fundamental tones and their over-tones answer respectively to the following rates of vibration :—

		1	:	2	
Fundamental tone		264		528	Fundamental tone
Over-tones . .	1.	528		1056	
	2.	793		1584	
	3.	1056		2112	
	4.	1320		2640	
	5.	1584		3168	
	6.	1845		3696	
	7.	2112		4224	
	8.	2376		4752	
	9.	2660		5280	

"Comparing these tones together in couples, it is impossible to find, within the two series, a pair whose difference is less than 264. Hence, as the beats cease to be heard as dissonance when they reach 132, dissonance must be entirely absent from the combination. This octave, therefore, is an absolutely perfect consonance." § The same process is then applied to other intervals. For the *fifth* 264 : 396, the lowest difference between any two overtones being 132, the interval is "all but perfectly free from dissonance." For the *fourth*, 264 : 352, the least difference, 88, makes it "clearly inferior to the fifth." Similarly the *major third*, 264 : 330, with least difference 66, is "less perfect as a consonance than the *fourth*, and the *minor third* 264 : 316·8, with least difference 53, "inferior as a consonance" to all the previous intervals.‖ In each case the "least difference" is precisely equal to the difference between the vibration-rates of the fundamental tones; so that, in spite of the array of figures, *nothing is added by this process to that employed by Prof. Tyndall to fix the consonances for simple tones*. Inasmuch, therefore, as that method has been proved erroneous, these determinations cease to have any validity.

Here, again, the neglect of the second condition for the production of audible beats is at the root of the error. Helmholtz

* T. p. 297.
† Professor Tyndall's attempted explanation depending on *difference of phase* between the two primaries is at once refuted by the general principle that *difference of phase in partial-tones has no effect on quality*. See H. p. 193. A note and the octave above may obviously be treated as the groundtone and first overtone of a composite sound.
‡ H. p. 302. § T. p. 299. ‖ T. p. 299—301.

does not only consider the differences of the vibration-rates of pairs of over-tones, but inquires also whether they are *within beating distance* of each other. In the former case alone can they become a source of dissonance. The interval of an *octave* is a perfect consonance, because every partial-tone of the higher sound coincides with one of those of the lower; and thus any slight deviation in pitch will produce beats between each adjacent pair.

The interval of a *fourth* is less consonant than that of a *fifth* —not, as Prof. Tyndall represents it, on account of its 66 beats which, but a single octave below that in which he has placed it, ought to become the worst possible dissonance—but because the second partial-tone of the higher sound comes within beating distance (a whole tone) of the third partial-tone of the lower, as shown on the stave—

when the fundamental tones are written in minims, and the over-tones in crotchets.

I may as well notice that a diagram given by Helmholtz * to illustrate various degrees of dissonance, and copied by Prof. Tyndall, † is accompanied by the latter with an explanation giving a wrong idea of its meaning. The diagram, as explained by its author, is intended to represent to the eye the degrees of roughness attaching to intervals greater than one octave, and not exceeding two. Prof. Tyndall having evidently missed the remark of Helmholtz ‡ that C′, *not its octave* C″, "is to be the constant fundamental tone of all the intervals," has represented the diagram as "beginning with the unison C″—C″" and going up to the octave intead of beginning with the octave C′—C″ and going up to the double octave C′—C‴. The diagram as it stands in Prof. Tyndall's lecture is calculated to convey an impression as unlike its author's meaning as it is contrary to fact.

The Valuation of Liquid Town Sewage

THOUGH I consider it highly unbecoming for one member of a committee, charged with an important inquiry, to criticise publicly and in a controversial manner, views expressed by another member of that committee in regard to the subject it has to investigate, still some of the remarks made by Mr. Hope at the Society of Arts last Wednesday seem so unmistakeably to refer to the article which appeared in NATURE on the 23rd December last, that I feel constrained, as the writer of that article, to reply to them. The statement objected to by Mr. Hope was an expression, not of individual opinion, but of the fact—long accepted as beyond question—that the practical value of liquid town sewage as manure, that is to say, its value to the farmer, cannot be computed *solely* from the amount of manure material it may contain, and that, in forming such an estimate, the positive element afforded by chemical analysis must be controlled by the negative element introduced by extreme dilution, and varying under different local circumstances. This fact has been recognised by authorities too numerous to name, and so decisively, that Mr. Hope's assertion as to the value of the ammonia in sewage being affected only in a very minor degree by the amount of water mixed with it, seems to have no other merit than that of being "sensational." I am at a loss to conceive what ground Mr. Hope could have for objecting to the statement that "it is a great mistake, and likely to prove a very ruinous one," to estimate the value of dilute sewage by calculation solely from the amount of manure material it may contain. Yet this is what Mr. Hope characterises as a "strange paradox." Why it has puzzled him, as he admits, I will not stop to inquire; but I must protest against his representing "the obligation of applying water to crops at all times of the year, whether they want it or not," as having been one of the reasons given for the statement he objects to. In doing that he has at least fallen into a great error, and he has at the same time evaded the point to which attention was directed in the article, viz., the agricultural difficulty attending the "continuous daily application of sewage to land." That is a difficulty not to be disposed of *ex cathedra*—it would obtain whether the land destined to receive sewage were under crops or lying fallow. In the one case the application of sewage might be inadmissible during great part of the year; in the other case the land under fallow would be unproductive meanwhile. Indeed the need for applying sewage to fallow land, which Mr. Hope seems to suggest, would enhance the difficulty of disposing of sewage by irrigation, since it would involve the want of a still larger area of land for its reception, day by day throughout the year. Such a mode of application might well necessitate an area of twenty-five acres for every 100 persons, and that necessity, if it existed, would be, I imagine, a very serious matterin the case of many towns.

I will not attempt to occupy your space by considering the question whether leaving land under fallow is to be regarded as a feature of progress in agriculture; nor will I venture an opinion as to whether water be the "best dung-cart," further than to express my surprise that, in regard to this question, Mr. Hope should have recourse to a chemist's opinion while declaring that its decision is not within the province of the chemists.

The case put by Mr. Hope, with an air of anticipatory triumph, of a man who applies to his land an excessive and useless amount of manure, seems to me an exact parallel to the use of liquid sewage in many instances, for whether it be the fancy or the folly of the farmer, or some other circumstance, which impels him to use manure in such a way that the possible effect cannot come up to the amount of manure applied, I should imagine it to be obvious that, to the user, the value of the manure must be gauged by the practical effect likely to be realised. I should expect this view to be appreciated even by the bucolic intellect which Mr. Hope seems disposed to contemn.

As stated by the chairman at the Society of Arts meeting, the views held by Mr. Hope on the general subject of town refuse are clear and precise. There is no doubt what those views are, but it is not my intention to enter upon any discussion of them. At the same time, as a member of the British Association Committee, and having individually entertained the expectation that Mr. Hope's co-operation would be of material service in the inquiry it has to make, I cannot avoid expressing my regret that he declares himself a partisan of one particular solution of the town-refuse problem. There are, probably, few questions of the day which demand more careful and impartial consideration than this one—few that less admit of being dealt with for the promotion of a project at any price. For my own part, therefore, I deem it a misfortune that the value of Mr. Hope's well-known ability and extensive knowledge of this subject should be limited by his avowal of a foregone conclusion.

February 28. BENJAMIN H. PAUL

Weeds in Newly Turned Ground

FROM a recent address of Mr. Bentham, the President of the Linnæan Society, it would appear to be still uncertain whether the weeds which appear spontaneously on ground which has been newly turned over, spring from seeds hidden in the ground, or from seeds accidentally carried on to the new surface. Could not this question be decided by a simple experiment, namely, by turning over some suitable ground and covering parts of it by gardener's glass frames, so as to prevent the importation of any seeds? So far as the weeds are the same both within and without the frames, it is certain that they must spring from seeds previously contained in the earth. It is true that there will be a difference of temperature beneath the glass and in the open air, but it would not prevent us from learning what seeds are really contained in the earth. A frame covered with fine muslin would serve instead of glass if the muslin be fine enough to prevent the passage of any seeds.

J.

Skeleton Lectures on Science

I HOPE you will allow me, through your valuable pages, to suggest what I have no doubt would be a most powerful and successful means for promoting scientific knowledge throughout the length and breadth of the land. There are hundreds of persons with the desire and a sufficient taste and general knowledge of science, who now devote themselves to penny readings, who would be too glad to give popular lectures on scientific subjects, if they could only be aided by *skeleton lectures*, and the loan, on moderate terms, of simple apparatus, diagrams, &c., to illustrate the same. It certainly would well remunerate any scientific instrument maker to loan out apparatus for such lectures.

Skeleton sermons are enormously in request, why not skeleton lectures on science? W. L.

ANCIENT BRITISH LONG BARROWS

I.

THERE are many hopeful signs that the number of persons to whom all knowledge of nature is dear for its own sake is steadily on the increase ; but it is, unfortunately, true that science still requires some adventitious aid to secure the attention of the general public. We must, therefore, look upon it as a matter of congratulation that even the Irish Question has been found to have a scientific aspect, and has recently awakened some general interest in so obscure a subject as that of the ethnology of England and Ireland.

It is not our present intention to enter upon the long-standing controversy as to the physical characters of the so-called Kelts, as we think that the materials for a satisfactory solution of the various questions involved are still very insufficient, notwithstanding the large amount of really trustworthy evidence collected of late years by Broca, Pruner Bey, and others in France, and by Barnard Davis, Thurnam, Beddoe, and Wilson in our own country. Few persons have any idea of the time, skill, and patience necessary for any satisfactory investigation either of the ethnic composition of existing populations, or of the characters and affinities of the earlier races whose works and remains have come down to us. It may seem surprising that we should be long in doubt on matters apparently so easily settled as the average stature, prevailing head-form, and distribution of colour of hair and eyes, in various districts of our own and neighbouring countries ; but it must be remembered that the number of persons interested in this branch of inquiry is extremely small, and that the collection of anthropological statistics by inaccurate or improperly instructed observers is very much to be deprecated. If the scientific study of existing populations is surrounded with difficulties and can reckon but few votaries, still more is this the case with the investigation of the character and affinities of the races inhabiting Western Europe at the dawn of history and in pre-historic times. We have had innumerable riflers of grave-mounds and endless discussion of the scraps of information handed down by Greek and Roman authors ; but of thorough and extended investigation of pre-historic monuments of any one class or of any given district, with a view to elucidating the ethnography and early history of the country rather than with the object of collecting specimens for the museum, we have all too little to show.

The late Mr. Bateman devoted considerable attention to the pre-historic archæology of Derbyshire and the adjoining counties, but his extensive investigations do not appear to have been conducted with the care or described with the accuracy necessary for scientific purposes. The important researches for remains of our early ancestors, made by Sir Richard Hoare and Mr. Cunnington in the richest district in all England, were undertaken so long ago as the beginning of the century ; and although the explorations are recorded in full detail in Sir Richard's great work, "Ancient Wiltshire," the general results have not hitherto been fully and satisfactorily worked out. This want has, however, at length been supplied in a memoir* recently communicated to the Society of Antiquaries by Dr. John Thurnam, a gentleman who possesses the rarely combined qualifications of classical scholarship, antiquarian knowledge, and familiarity with scientific method, and who is well known as one of the authors of the "Crania Britannica," undoubtedly the most valuable contribution to the ethnology of this country which has yet been published. The memoir in question is not a mere analysis of the labours of the Wiltshire baronet and his coadjutor; it is to a large extent a record of original explorations, more especially of a class of monuments somewhat neglected by Sir Richard Hoare, but to which the greatest interest attaches now that the advances in certain departments of anatomical knowledge enable us to turn to due account the evidence afforded by human remains.

Fig. 1.—A Long Barrow (after Sir Rd. Hoare)

Fig. 2.—Vessel with Primary Interment. Norton Bavant, Long Barrow (scale 2/8 linear)

* On ancient British Barrows, especially those of Wiltshire and the adjoining counties. Part I. Long Barrows. From the "Archæologia," vol. xlii. 1869

The monuments to which we refer are the huge grave-mounds known as Long Barrows, and chiefly occurring in Wiltshire and the adjoining counties.

Only the first part of Dr. Thurnam's memoir has as yet been published—that, namely, relating specially to the Long Barrows; but this part is of sufficient importance to demand separate notice at our hands.

The chief result of the examination of the Ancient British barrows of the south-west of England is their division into two great classes—(1) the Long Barrows, the primary interments of which have yielded implements of stone and bone only, and which are, therefore, confidently assigned to the Stone Age; and (2) the Round Barrows, affording implements of bronze as well as of stone, and occasionally, though rarely, of iron. The round barrows vary considerably in form, and Dr. Thurnam thinks that these variations are not to be attributed to the individual fancy of the builders. He recognises three primary forms of round barrow—the bowl-shaped, the bell-shaped, and the disc-shaped; each of these three having again its three modifications. The long barrows are of two kinds—the simple barrows of South Wilts and Dorset, consisting merely of earth, chalk, and flints; and the barrows of North Wiltshire, Gloucestershire, and Somersetshire, containing chambers or cists built of large stones.

Wiltshire is, *par excellence*, the county of long barrows, one district consisting of about 150 square miles, containing, on an average, one of these huge mounds in every six miles. The distribution of these monuments is a point of great interest. Unlike the round barrows, which usually occur in clusters, they are almost without exception solitary—generally two or three miles apart—and situated in some prominent position, usually the highest points of the hills, commanding extensive views over the downs. The immense size of the mounds of the South Wilts and Dorsetshire long barrows, and the imposing stone structures of those of North Wilts, Gloucestershire, and Somersetshire, would alone be sufficient, notwithstanding the rude character of the implements contained in them, to lead one to conclude that we have here the graves of the chieftains of the primitive people of these districts. The situations chosen for the grave-mounds, and the evidence, hereafter to be alluded to, of the immolation of slaves, and perhaps wives and children, seem strongly to confirm this supposition.

It will be convenient in the remainder of our notice to treat separately of the unchambered and chambered barrows; that arrangement having been followed in the memoir in the "Archæologia." The following is Dr. Thurnam's account of the external form of the simple or unchambered barrows:—"The long barrows are for the most part immense mounds, varying in size from one or two hundred to three and even nearly four hundred feet in length, from thirty to fifty feet in breadth or upwards, and from three to ten or even twelve feet in elevation. (See Fig. 1.) Along each side of the whole length of the tumulus is a somewhat deep and wide trench or ditch, from which trenches no doubt a great part, or sometimes even the whole, of the material of the mound was dug, but which it is very remarkable are not continued round the ends of the barrow. . . . . In by far the greater proportion of long barrows the mound is placed east and west, or nearly so, with the east end somewhat higher and broader than the other. Under this more prominent and elevated extremity the sepulchral deposit is usually found at or near the natural level of the ground." The great infrequency of manufactured objects in these barrows and their rude character is very remarkable. Some "delicate

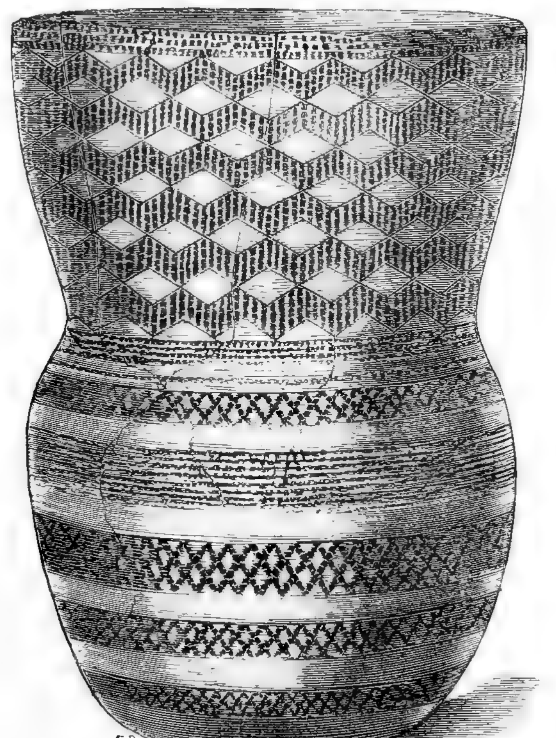

Fig. 3.—Drinking Cup with Secondary Interment. Figheldean, Long Barrow (scale ½ linear)

and beautifully-chipped leaf-shaped arrow-heads" have been found in one or two instances, and this type of arrow-head, which is unbarbed, is the only one yet discovered. In no case has any trace of metal been found with the primary interments. Fragments of a coarse black pottery are occasionally met with, and in one barrow, that of Norton Bavant, Dr. Thurnam was fortunate enough to discover a tolerably perfect vessel of extremely rude construction, and utterly devoid of the ornamentation usually found in the pottery from the round barrows. Thanks to the courtesy of the Society of Antiquaries, we are enabled to reproduce Dr. Thurnam's drawing of this vessel. We are likewise indebted to the same Society for the other figures which illustrate this paper.

Remains of oxen of the ancient small species, *Bos longifrons* or *Bos brachyceros*, are often found in long barrows not far from the human remains; antlers and bones of the red deer are still more frequent. Tusks and bones of swine have also been discovered. It would appear that oxen were slaughtered at the funeral feasts, and that the heads and feet (the bones of which parts are more frequently found), not being used for food, were buried in the barrow, perhaps as offerings to the gods or to the spirits of the dead.

Secondary interments in the upper portion of long barrows are not infrequent, and afford valuable evidence of the antiquity of these tumuli. Some of these interments are assigned without hesitation to the Anglo-Saxon period; others, again, undoubtedly belong to the Ancient Britons of the bronze age, being sometimes burials after cremation, sometimes interments of entire skeletons in the contracted posture characteristic of the round barrows. In the latter case the remains are frequently associated with pottery undoubtedly of the round-barrow period. In order to show the difference between this pottery found with secondary interments in long barrows, and part of the long-barrow period itself, we reproduce (Fig. 3) an elegantly ornamented drinking-cup found at Figheldean, and now in possession of Dr. Thurnam.

In the present article we have only touched upon some of the most interesting of Dr. Thurnam's researches. It still remains for us to notice the chambered long barrows, and the most important evidence of all, that derived from the skeletons disinterred in both chambered and unchambered barrows. We have been able from the archæological evidence to gain some idea of the state of barbarism in which these primitive people lived; but still further information is to be obtained even on this point from the very bones of the people themselves; and from these sad relics alone can we obtain any ray of light as to the relation of these most ancient Britons to the population of more civilised times.

HOW LARGE SEEMS THE MOON?

IN a communication addressed to the Association Scientifique, M. Viguier remarks on the linear dimensions which ordinary observers employ to define the size of celestial objects. They seem to imagine that they are really pointing out the size of a meteor, for instance, when they state that it was a yard in diameter, or the like Of course, such a statement is absolutely without meaning to the astronomer; while the seemingly less precise mode of speaking which compares the size of a meteor to that of the moon, is in reality much more valuable. It is true that when an observer says a meteor was as large as the moon, he makes a wider error than when he says it was a yard in diameter; but the astronomer knows what one statement means, whereas he can form no real estimate even of the meteor's apparent size from the other.

If every observer formed the same estimate of the linear dimensions of a celestial object, one might indeed interpret a statement of the linear dimensions of a meteor. But this is not the case. As M. Viguier justly remarks, the short-sighted or the far-sighted person each forms his own estimate of the moon's real size, the position of the moon affects the judgment, nay, even the state of the weather influences our instinctive estimate.

But it is interesting to consider what is really implied by such a statement as that the moon is a foot in diameter. This is a size often assigned to the moon, I may remark, though many judge her to look larger. The moon subtends an angle of about half a degree, so that this estimate makes half a degree of the celestial sphere one foot in length. Thus the circumference becomes about 720 feet, and the radius about 115 feet. This, at any rate, is the distance which the estimate assigns to the moon. And this last view is the more correct, since the varying estimates made of the moon's dimensions according to her position, suffice to show that the mind instinctively assigns to the celestial vault a somewhat flattened figure, the part overhead seeming nearest to us. In fact, a common opinion that the moon's diameter looks about twice as large when she is on the horizon as when she is nearly overhead, would assign to the celestial dome the figure of a segment of a sphere, less than a fifth of the sphere's surface being above the horizon.

It is worth noticing, though M. Viguier does not consider the point, that we can conclude from the estimated size of the moon *as compared with the intervals separating certain stars*, that the mind intuitively assigns to the moon a distance considerably greater than that of the fixed stars. For example, I find that if, when the moon is below the horizon, an observer be asked whether the distance separating the three stars in Orion's belt (ζ from ϵ, or ϵ from δ, I mean) be greater or less than the moon's diameter, the answer is that it is about equal to that dimension. In reality, the moon's apparent diameter is but about one-third of the distance between these stars. It follows that the mind estimates the distance between the stars on a scale one-third only even of the small scale according to which it measures the moon; in other words, that it regards the distance of the fixed stars as about one-third that of the moon.

It may be, however, that the result of this comparison merely indicates that the mind assigns to the celestial sphere as seen on a moonless night a distance equal to only one-third of that which separates us from the faintly seen stars of a night on which the moon is full.

RICHD. A. PROCTOR

NOTES

WE are informed that her Majesty's Government has determined to issue a Royal Commission to inquire into the present state of Science in England. This step will be hailed with the liveliest satisfaction on all sides, and much good will certainly follow from such an inquiry, especially at a time when the arrangements for the prosecution of Science in this country are acknowledged on all hands not only to be "chaotic," but positively detrimental to the national interest. We learn that some of the commissioners have already been designated, but as their number is not yet complete, we withhold the names.

WE have been favoured with a copy of the report just issued by the Rivers Pollution Commissioners on the Mersey and Ribble basins. We hope to return to this subject shortly.

THE first Royal Society's Soirée of this Session will take place on Saturday evening next.

MR. E. RAY LANKESTER has been elected by examination to the Radcliffe Travelling Fellowship at Oxford.

WE have received the third part of Vol. I. of the Transactions of the Edinburgh Geological Society, containing the communications made to that body during its session 1868-1869. These are numerous, and testify to the activity of the members of the society. The most important are Mr. Powrie's description of the fish remains of the Old Red sandstone rocks of Forfarshire; Mr. Robert Brown's paper "On the geographical distribution and physical characteristics of the coal-fields of the North Pacific coast;" and Mr. Croll's notice of two river channels buried under drift. Mr. Powrie's paper is illustrated with five plates of roughly executed, but tolerably characteristic figures. The part also contains a biographical notice of the late Prof. J. D. Forbes.

The American Gaslight Journal and Chemical Repertory states that Professor Loomis, who claims to have discovered a way to transmit messages by electrical air currents without the aid of wires, wants to be appointed Consul to some European port, that he may experiment on the summit of Mont Blanc.

FOR many years it has been a query whether the electric current might not be brought so far under man's control as to take the place of steam as a motor for machinery, and success has at last crowned the persevering efforts of scientists. At the last exhibition of the American Institute, there was seen an elliptic lock-stitch sewing machine, driven by a small electric engine which might easily be put into a common hat box. A series of eight magnets are set on the periphery of a circle, and around these revolves an armature of steel, which is continuously propelled by the magnetic action, and thus operates the machinery that moves the needle. Connection with this motor is had by means of a small slide within easy reach of the operator, at whose will the current may be cut off entirely, or the speed of the needle graduated as may be desired. The use of this motor, if it becomes general, cannot fail to prove of the utmost benefit to ladies, especially to machine operators, as it does away entirely with the necessity for using the feet, as is now the case, and must be highly conducive to the health of females, who suffer from many diseases that are generated by the constant strain on the pedal and limb muscles. The inventor of the engine in question is Charles Gaume.

A LARGE chemical laboratory is projected at Harvard. The library building is also to be greatly enlarged.

WE regret to learn that a wing of the Emperor's Palace in Pekin has been burned, containing the Imperial printing-office, with large stores of books and block-types. The books printed at the Imperial cost for the last two centuries have issued from this printing office.

Prof. W. H. Miller, of Cambridge, has been elected a correspondent of the French Academy of Sciences, in place of Prof. Fournet, of Lyons. The other candidates were MM. Abich; G. Bischoff; A. Boué; Dana; v. Dechen; Domeyko; J. Hall; v. Hauer; v. Helmersen; C. T. Jackson Kjerulf; v. Kokscharow; F. Romer; Scacchi; A. Sismonda; Studer, and Sir W. Logan.

THE Cleveland correspondent of the *Engineer* states that operations are in progress for working upon a large scale the salt deposits underlying Middlesborough.

WHATEVER may be the case in our own country, it is gratifying to see that there exists in France considerable sympathy between scientific and literary men. Professor Sars, the late eminent zoölogist at Christiansen, left a large family in very impoverished circumstances; and an appeal for their relief was made in our columns by Mr. Gwyn Jeffreys, from his personal knowledge of the case, to the naturalists and geologists of Great Britain. This appeal was seconded in France by M. Alglave, in his *Revue des Cours Scientifiques;* and the result has been highly successful in both countries. It must tend to foster and increase the sentiment allied to that of freemasonry which animates men of science everywhere without regard to nationality. But in France this charitable movement has not been confined to scientific men. M. Emile Girardin, in *La Liberté*, has advocated it with his usual ability and energy; and in the list of French subscribers to the fund are the names of his Excellency M. Segris, the Minister of Public Instruction, M. Villemessant, the Chief Editor of *Figaro*, Alexandre Dumas, fils, the Society "des amis des lettres" at Paris, the Stanislaus Literary Society at Nancy, Clery the painter, *L'Echo de la Sarbonne*, and many others of a similar kind. Let us hope that science, arts, and letters may be associated here also on the same friendly footing, each promoting the objects of the other, and all working together although placed in different grooves of the machine.

AT the annual general meeting of University College, London, Mr. George Grote presided, and the following students of the College, who had "passed distinguished examinations for University degrees," some at London alone, others at Cambridge as well as at London, were admitted Fellows of the College on the nomination of the Council:—in Arts, Mr. Numa Edward Hartog, Mr. Alfred Slater West, Dr. Richard Francis Weymouth, and Mr. Augustus Samuel Wilkins; in Medicine or Science, Dr. Henry Charlton Bastian, Mr. Marcus Beck, Dr. Frederick George Finch, and Dr. Edward Lloyd Harries Fox.

DR. J. H. GLADSTONE will bring the subject of "Indices of Refraction" before the next meeting of the Chemical Society.

THE Board of Trinity College, Dublin, has nominated the Rev. T. Leslie, F.T.C.D., to the Professorship of Natural Philosophy in Trinity College.

THE President, vice-Presidents, and Committee of the Quekett Microscopical Club have issued cards for a conversazione on Friday evening the 11th, at eight o'clock.

WE learn with much regret that the celebrated botanist, Prof. Fr. Unger, died suddenly on February 13th, at Gratz.

WE hear that the number of candidates for the place of Assistant-Registrar about to be created at the University of London is very great. Among them are men of high position and attainments, who are perhaps desirous to obtain a footing in London. They will know their fate ere long, for the choice of the Senate is to be made in the course of this month.

WE hear that the "Ladybirds" which excited so much curiosity last autumn, have reappeared in large numbers in the neighbourhood of New Wandsworth. So early an appearance will surprise most of us who have been wont to regard these visitors as summer guests.

WE learn from the *Athenæum* that the Société de Géographie has awarded the Empress's new prize of 10,000 francs to M. de Lesseps, and that he has given the money as a contribution to the Society's projected expedition into equatorial Africa.

THE *Pall Mall Gazette* reports that all the medical men connected with the case of the Welsh fasting girl were to appear last Monday before the justices at Llandyssil, to answer the charge of "wilfully killing and slaying" Sarah Jacobs, the prosecution being instituted by the Government.

NOTICE is given that at the annual election of fellows to be held in October next at the University of Cambridge, one fellowship will be given for proficiency in the natural sciences. The examination will be held in the latter half of the month of September, on days hereafter to be fixed. The subjects for examination will be those appointed for the natural sciences tripos. The competition for this fellowship will be open to any member of the University who shall have attained the degree of B.A., B.L., or M.B., and whose standing after such degree shall not exceed three years.

WE have received from the Canadian Government Emigration Office the Year Book and Almanac of Canada for 1870, containing statistics and other useful information relating to British North America, and a map showing the railways and their principal connections.

THE current number of the *Revue des Cours Scientifiques* contains a translation of Mr. Carruthers' lecture at the Royal

Institution, on the Cryptogamic forests of the coal period, and a continuation of the report on the Anthropological Congress at Copenhagen.

Cosmos states that the cavern of Montesquieu-Avantès (Ariége) has been recently explored by M. F. Regnault, of Toulouse, who discovered, on the surface of a hearth covered with stalagmite, bones of ruminants and human bones, the latter consisting of fragments of skulls, leg and arm bones. The whole were sent to M. F. Garigou, who declares that both kinds of bones are broken in the same manner, and each bears indications of a smashing instrument and of a sharp tool that has scratched them. These bones are said to be exactly similar to those which were regarded as furnishing decided proof of cannibalism, at the Anthropological Congress in 1867. M. Garigou writes that he has no hesitation in agreeing with MM. Spring, Dupont, Schaffausen, Broca, Carl Vogt, Steenstrup, &c., that primitive man was, like modern savages, anthropophagous.

Les Mondes also reports that Prof. Capellini of Bologna, has discovered remains of man and of animals in a cavern in the island Galmeria, the access to which is difficult and dangerous. In excavating he found many implements of flint and stone, the working of which showed that they belonged to the most remote stone age. Besides objects referrible to the hand of man, he found many which had been carried there by the human inhabitants of the cave, and a considerable quantity of animal bones, mixed with the human bones. The condition of the latter indicated that the cave had been inhabited by cannibals. At the centre of the cave were traces of a hearth.

DR. BERTHOLLE has communicated to the Société Médico-Chirurgicale the particulars of what he believes to be a case of spontaneous combustion, which recently came under his notice, the subject being a woman who was an habitual spirit drinker frequently suffering from *delirium tremens.*

THE *Siècle* states that M. Combes has declined to act on the commission charged with the temporary direction of the Paris Observatory, and that his place has been filled by M. St. Claire Deville.

WE have received the prospectus of a new series of the "Zeitschrift für die gesammten Naturwissenschaften," edited by Dr. C. G. Giebel and Dr. M. Siewert, of Halle. One of the main features of the journal is to be the publication of monthly reports of the progress of astronomy and meteorology, physics and chemistry, geology, mineralogy, palæontology, botany, and zoology.

Cosmos reports the death of M. Florent Prevost, assistant-naturalist at the Museum of Natural History, and known for his useful work in connection with the agronomic applications of zoology.

WE have received from the Chairman of the Technological Commission of Victoria, a report on the promotion of technical and industrial instruction, by lectures and otherwise, among the working classes of Victoria.

THE Food Committee of the Society of Arts had recently before them a specimen of meat treated by Professor Gamgee's process. A joint of mutton—stated to be part of a sheep slain on December 28th, and to have been, since the treatment, simply hung up in Professor Gamgee's premises—was roasted and tasted by the Committee, who pronounced it very satisfactory; but the Committee considered that a test over a longer time and at a warmer period of the year, was necessary before any decided opinion as to its success could be given. Another joint—from a sheep slain on the 22nd December—was ordered to be placed in charge of the Secretary, to be tested at a future time. Mr. Tallerman also exhibited specimens of meat imported from Australia, and showed it both cooked and uncooked. He explained the plan he had adopted, by means of which cheap dinners were prepared from it for the use of the people. Specimens of raw meat from Australia, preserved in tins by Manning's process, were brought before the Committee. The meat consisted of beef steaks, which were cooked and tasted by the Committee. The meat, though sound, was not considered satisfactory in flavour.

Cosmos reports the death of M. Foucou at New York, shortly after establishing himself at Oil Creek, where he intended to carry on the working of petroleum, to the industrial application of which he had given much attention.

MR. HARTNUP, astronomer at Liverpool, has published his annual report to the Marine Committee Mersey Docks and Harbour Board, and is no doubt not a little gratified at dating it from a new Observatory. The old building having been swept away by dock improvements, a new site was found on the left bank of the river, on the top of Bidston Hill, about a mile to the rear of Birkenhead Docks, and two hundred feet above the mean sea-level. The new building occupies about five hundred square yards in an acre of land set apart for the use of the Observatory. Underground rooms, with arrangements for elevating the temperature at pleasure, are provided for the testing of nautical instruments. In each hot-air chamber one hundred chronometers can be placed at once for examination. Two octagonal, domed rooms, twenty feet in diameter, rise at opposite angles of the building, one being occupied by the transit, the other by the equatorial instrument. In the words of the report, "The site is remarkably favourable for astronomical and meteorological observations." We may, therefore, hope to hear of much good work being accomplished at the Liverpool Observatory. To facilitate comparison of chronometers without the trouble of carrying them to the Observatory, a time-gun has been placed on the river brink near the landing-stage at Birkenhead. This gun is fired every day at one o'clock by a galvanic current sent from the standard clock on Bridston Hill, and masters of vessels lying in the port thus get the true time. Besides the observations of transits required for the service of the establishment, the usual meteorological observations have been taken, comprising daily and hourly readings of the barometer, the velocity and direction of the wind, the amount and duration of windfall, and the mean daily temperature of evaporation. All these results, collected into tables, are published at the end of the report, and thereby add to its utility. The site of the old Observatory was in latitude 53° 24′ 48″ N., and longitude 3° 0′ 1″ W. from Greenwich: the new Observatory is 17·04 seconds farther to the west.

ACCORDING to the Sydney Correspondent of the *Times* the production of sugar in Australia appears to be progressing rapidly and successfully.

WE learn from the *Society of Arts Journal*, that at a recent meeting held at the Town Hall, Reading, it was decided to accept the offer made by the Hon. Auberon Herbert, and to establish a free library.

FOR many years past the French physician, M. Burg, has been engaged in investigating the effect of copper as a preservative and curative agent in cholera. In support of his theory, M. Burg instances the immunity enjoyed by workers in this metal from cholera. He has obtained from the Prefect of the Paris police, certain statistics which go to prove that this immunity in the case of copper-workers has a real existence. In the instances of jewellers, engravers on metal and clockmakers, out of a population of 11,500, there were 16 cases of cholera, or 1 in 719. Engravers in copper, makers of metal eyelet-holes, jewellers working with copper, had, in a population of 6,000, 6 cases, or 1 in 1,000. Founders, tap-makers, chisellers, turners in bronze, lamp-makers, and workers in counterfeit gold, had, in a population of 14,000, 7 cases, or 1 in 2,000. Opticians using copper, mathematical instrument makers, musical instrument makers, stampers, metal polishers, &c., out of a population of 5,650, had not a single case of cholera.

BOTANY

Movements of Chlorophyll

ACCORDING to observations recently made by the French botanists, MM. Prillieux and Roze, the grains of chlorophyll in the leaves of plants assume different positions according as they are exposed to light (either natural or artificial) or to darkness. In darkness these grains, together with protoplasmic threads to which they are attached, are in contact with the walls which divide the cells from one another; under the influence of light they gradually change their position from these to the upper or under walls which form the surfaces of the leaf. M. Roze believes that this motion originates in the protoplasmic threads, which are the vital and animating part of the cell. (*Comptes Rendus.*)

Dependence of the Distribution of Plants on that of Animals

PROF. HILDEBRAND continues in the *Botanische Zeitung* his account of Delpino's investigations on the Dependence of the Geographical Distribution of Plants on that of Animals (see NATURE, No. 9, p. 246). In passing from the tropics to the temperate regions, we observe a general falling off in the number of species of native plants, caused by the disappearance of those animals which are needful for their fertilisation. Thus a large number are lost whose impregnation depends upon humming-birds. Roses and pæonies disappear where the larger Coleoptera are no longer found. The greater number of *Sileneæ*, and especially the night-flowering species of *Silene* and *Lychnis*, find their limits where nocturnal Lepidoptera cease. In the Arctic zone those plants only can be found which are fertilised by the agency of Hymenoptera, Diptera, or the wind. This law is illustrated by the flora of Nova Zembla lying between 71° and 76° N. lat., and Spitzbergen, between 76° and 80° N. lat. Out of 124 species of flowering plants constituting the phænogamous flora of Nova Zembla, six belong to the tribe *Pedicularineæ*, which are neither self-fertilised, nor by the agency of the wind, but entirely by the help of Hymenopterous insects. The inference is drawn that, notwithstanding the severity of the climate (the mean temperature of August, the hottest month in the year, not rising above 5° C. or 41° F.), some insect of this class must find its home there. Accordingly Spören records observing a single beetle and a ground-bee, with a few flies and midges. The insect described as the ground-bee is probably the widely-diffused *Bombus terrestris*, one of the most active of insects in the fertilisation of plants. Prof. Delpino thus classifies the 124 flowering plants of Nova Zembla: 16 dichogamous, fertilised by Hymenoptera; 84 dichogamous or homogamous by Hymenoptera or Diptera; 24 dichogamous by the wind. Out of 91 flowering plants found in Spitzbergen, 2 may be described as fertilised by Hymenoptera, 63 dichogamous or homogamous by Hymenoptera or Diptera, and 26 by the wind. In neither country are there any plants dependent on Lepidoptera for their fertilisation.

A. W. B.

M. JOSE DI CANTO has successfully introduced, on an experimental scale, the cultivation of *Cinchona officinalis* into the Azores.

SCIENTIFIC SERIALS

The last number of Poggendorff's *Annalen der Physik und Chemie* (vol. cxxxviii. part 4), contains the following papers:—(1.) "Thermo-chemical Investigations, Part iii." by Julius Thomsen (pp. 497 to 514). This communication relates to the calorimetric behaviour of the acids of sulphur and selenium when neutralised with bases. The author's numerical results differ considerably from those of Favre and Silbermann. This difference is ascribed by him to the use, by those investigators, of the mercurial calorimeter, which he considers to be "altogether inapplicable for accurate determinations." (2.) "Mineralogical Communications" (ninth part), by G. vom Rath (pp. 515 to 550). (3.) An addition to a previous communication "On the crystalline forms of salts of certain sulpho-acids derived from phenol," by the same author (pp. 550 to 553). (4.) "Experiments on Irradiation," by Wilhelm von Bezold (pp. 554 to 560). This paper contains a description of experiments whereby the imperfect achromatism of the eye is made strikingly evident, and also of a method of producing analogous effects objectively upon a screen by means of a simple unachromatised convex lens. (5.) "On the vibrations of a plate of air corresponding with those of a solid plate," by E. H. Vierth (pp. 560 to 563). Two Chladnis plates were fixed by means of a clamp parallel to each other, and one about a millimeter above the other, a disk of cork being placed at the centre to prevent them touching. The upper plate being thrown into vibration by means of a fiddle bow, the distribution of nodes and loops in it and in the stratum of air between the plates, was ascertained by strewing sand upon each plate. The sand figures formed, respectively, upon the upper plate by its own vibrations and upon the lower plate by the vibration of the stratum of air, were markedly different, but, nevertheless showed a distinct correspondence. (6.) "On the corrosion-figures and asterism of Iceland spar," by Heinrich Baumhauer (pp. 563 to 565). (7.) "Reply to the critical remarks of Mr. L. Boltzmann," by R. Most (pp. 566 to 570). In this paper, which is entirely mathematical, the author maintains the accuracy of a demonstration of the second fundamental theorem of the mechanical theory of heat communicated by him to a previous number of the *Annalen*. (8.) "Experimental investigation into the influence of temperature on electromotive force," by L. Bleekrode (pp. 571 to 604). Solutions of salts of various metals were placed between precisely similar electrodes of the same metal in each case as that contained in the salt employed, and the electrodes were connected by a metallic circuit of great resistance, containing a delicate reflecting galvanometer. When the liquid in contact with one of the electrodes was heated, a current was obtained in most cases of such a strength as to indicate a change of electromotive force between the metal and liquid approximately proportioned to the change of temperature. The experiments seem to show that the currents observed were of the nature of thermo-currents, but they are not quite conclusive on this point. (9.) "On new Sulpho-salts" (third communication), by R. Schneider (pp. 604 to 628). (10.) "Experiments on combinations of Mica" (from the Proceedings of the Berlin Academy, July 1869), by E. Reusch (pp. 628 to 638). If a number of thin plates of biaxal mica are superposed, so that the principal section of each makes an angle of 60° with that of the preceding one, the combination has the optical properties of a uniaxal crystal causing rotation of the plane of polarisation to the right or left, according to the direction in which each plate of mica is turned relatively to the preceding one. (11.) "On the separate perception of an Over-tone simultaneously with the Fundamental tone," by C. B. Greiss (pp. 638 to 640). This paper contains nothing new, except that it ascribes to Prof. Tyndall a well-known experiment of Helmholtz's. (12.) "Reply to Dr. Mohr," by A. Von Lasaulx (pp. 640 to 642), respecting the formation of basalt. (13.) "On the motion of the light of the negative inductive discharge in rarefied air," by J. C. Poggendorff (pp. 642 to 644). When the discharge of an induction coil is allowed to pass between two fine platinum wires, the ends of which are within one millimetre of each other, the well-known negative glow recedes from the end of the negative wire, in proportion as the air in which the discharge is taken is more and more rarefied; and at the same time the position of the greatest evolution of heat by the negative discharge recedes similarly.

The Ibis, a quarterly journal of Ornithology, New Series, No. 21, January 1870. (Van Voorst.) The papers contained in this number are—(1.) "Notes on the Birds of the Peninsula of Sinai," by C. W. Wyatt. (2.) "On the Sun-birds of the Indian and Australian regions," by Lord Walden—an article showing an extraordinary acquaintance with the literature of the subject. (3.) "On a fourth collection of birds from the Fantee country," by R. B. Sharpe. (4.) "A list of the birds of Turkey," by Captain Elwes and Mr. T. E. Buckley—the first attempt at a compilation of all the available information respecting the ornithology of one of the least known European countries, including that acquired by the authors during a tour through various parts of the Turkish dominions. (5.) "On the Ornithology of Hainan," by Consul Swinhoe, hitherto well known by his successful researches in the sister island of Formosa—an article containing results quite as remarkable as those furnished by the writer's former explorations. (6.) "Notes on the birds of the Island of St. Helena," by J. C. Melliss. (7.) "Additional notes on Mr. Lawrence's list of Costa-Rican birds," by O. Salvin. (8.) "Notices of recent Ornithological publications," English, German, Finnish, Italian, Portuguese, and Australasian, wherein more than thirty works are briefly reviewed; and (9.) "Letters from Mr. Allen Hume, Drs. Jerdon and Malmgren, Captain Shelley, Messrs. Gurney, Harting, and Sharpe, Dr. Salvadori and Mr. Swinhoe." The number also contains four well-drawn and coloured lithographic plates, by Mr. Keulemans, representing seven species of birds, all but one hitherto unfigured.

STAR-DRIFT

WITH reference to the accompanying account of my paper on this subject, recently communicated to the Royal Society, it is to be remarked that the interest, if any, attaching to my results must be founded on the way in which they bear on received theories respecting the distribution of the fixed stars. It is quite evident that according to the views usually accepted, the stars which appear in any part of the heavens must be regarded as situated at very different distances from the eye; the faintest nine or ten times farther from us, at the very least, than the brightest, and the different stars altogether too far apart to exert any influence on each other. Indeed, whatever theory we may hold respecting stellar distribution, regarded generally, we must be prepared to recognise in the stars seen towards any part of the sky, objects which lie at very different distances. And regarding these objects as severally in motion, we must be prepared to find in general the utmost diversity, not only as respects the direction of the apparent motions of the stars, but also as respects the magnitude of these motions. It is only when one has adopted the theory that the stars are grouped according to special laws of aggregation, that one would be led to anticipate that here and there, almost as by accident, so to speak, some indications of their grouping might be discoverable in the characteristics of the stellar proper motions. Although I had become firmly convinced that the stars are not distributed throughout space with any approach to that general uniformity insisted on by many astronomers, I had very little hope that a suggestion I threw out a year ago in the pages of the *Student*, that the stellar proper motions if examined carefully might afford evidence in favour of my views, would be confirmed in any very distinct manner if the method I had pointed out should ever be applied. I knew that a certain community of motion in the constellation Taurus had led Mädler to important, but as I judged incorrect conclusions as to the nature of the stellar motions; but I also knew that that community of motion was one which could only be appreciated by the few who had convinced themselves of what was to be *expected* if the stars were uniformly distributed. I had an impression at that time that Mädler had examined the stellar proper motions over the whole of the northern hemisphere, and that it was the exceptional community of proper motion in Taurus which had led him to form his well-known theory respecting a central sun. It was only when I was reminded that he had in fact examined the stellar proper motions in the neighbourhood of Taurus alone, having been led by independent considerations to regard that neighbourhood as that within which a central sun was to be looked for, that I was encouraged to map down all the recognised proper motions. To my surprise I found that in Gemini, Cancer, and Leo, a community of motion far more striking than that noticed by Mädler in Taurus was to be recognised; and further, that though in other directions, as I had expected, stellar motions belonging to different depths in space were intermixed, it was yet possible to trace out laws of association indicating the existence of drifting star-groups in these directions also.

I lay very little stress on the indications which have led me to name the great double cluster in Perseus as more likely to be an important centre of motion than the Pleiades. But it is worthy of mention that Mädler required a star on the Milky Way as the centre of the galaxy, and Alcyone does *not* lie on the Milky Way; he required his centre to lie ninety degrees from the apex of the solar motion, and Alcyone does *not* lie ninety degrees from the mean of the last determinations of that point. The great cluster in Perseus fulfils both conditions in the most perfect manner.

RICHARD A. PROCTOR

A careful examination of the proper motions of all the fixed stars in the catalogues published by Messrs. Main and Stone (Memoirs of the Royal Astronomical Society, vols. xxviii. and xxxiii.) has led Mr. Proctor to the conclusion that in parts of the heavens the stars exhibit a well-marked tendency to drift in a definite direction. "In the catalogues of proper motions, owing to the way in which the stars are arranged, this tendency is masked; but when the proper motions are indicated in maps, by affixing to each star a small arrow whose length and direction indicate the magnitude and direction of the star's proper motion, the star-drift (as the phenomenon may be termed) becomes very evident. It is worthy of notice that Mädler, having been led by certain considerations to examine the neighbourhood of the Pleiades for traces of a community of proper motion, founded on the drift he actually found in Taurus his well-known theory that Alcyone (the *lucida* of the Pleiades) is the common centre around which the sidereal system is moving. But in reality the community of motion in Taurus is only a single instance, and not the most striking that might be pointed out, of a characteristic which may be recognized in many regions of the heavens. In Gemini and Cancer there is a much more striking drift towards the south-east, the drift in Taurus being towards the south-west. In the constellation Leo there is also a well-marked drift, in this case towards Cancer.

"These particular instances of star-drift are not the less remarkable, that the stars are drifting almost exactly in the direction due to the proper motion which has been assigned to the sun, because the recent researches of the Astronomer Royal have abundantly proved that the apparent proper motions of the stars are not to be recognised as principally due to the sun's motion. Mr. Stone has shown even that we must assign to the stars a larger proper motion, on the average, than that which the sun possesses. Looking, therefore, on the stars as severally in motion, with velocities exceeding the sun's on the average, it cannot but be looked upon as highly significant that in any large region of the heavens there should be a community of motion such as I have described. We seem compelled to look upon the stars which exhibit such community of motion as forming a distinct system, the members of which are associated indeed with the galactic system, but are much more intimately related to each other. In other parts of the heavens, however, there are instances of a star-drift opposed to the direction due to the solar motion. A remarkable instance may be recognised among the seven bright stars of Ursa Major. Of these, the stars β, γ, δ, ϵ, and ζ are all drifting in the same direction, and almost exactly at the same rate towards the "apex of the solar motion," that is, the point *from* which all the motions due to the sun's translation in space should be directed. If these five stars, indeed, form a system (and I can see no other reasonable explanation of so singular a community of motion), the mind is lost in contemplating the immensity of the periods which the revolutions of the components of the system must occupy. Mädler had already assigned to the revolution of Alcor around Mizar (ζ Ursæ) a period of more than 7000 years. But if these stars, which appear so close to the naked eye, have a period of such length, what must be the cyclic periods of stars which cover a range of several degrees upon the heavens? In like manner the stars α, β, and γ Arietis appear to form a single system, though the motion of α is not absolutely coincident either in magnitude or direction with that of β and γ, which are moving on absolutely parallel lines with equal velocity. There are many other interesting cases of the same kind." The author hopes soon to be able to lay before the Royal Society a pair of maps in which all the well-recognised proper motions in both hemispheres are exhibited on the stereographic projection. In the same maps also the effects due to the solar motion are exhibited by means of great circles through the apex of the solar motion, and small circles or parallels having that apex for a pole. The star-drift described by Mr. Proctor serves to explain several phenomena which had hitherto been thought very perplexing. In the first place, it accounts for the small effect which the correction due to the solar motion has been found to have in diminishing the sums of the squares of the stellar proper motions. Again, it explains the fact that many double stars which have a common proper motion, appear to have no motion of revolution around each other; for clearly two members of a drifting system might appear to form a close double, and yet be in reality far apart and travelling, not around each other, but around the centre of gravity of the much larger system they form part of. While mapping the proper motions of the stars, Mr. Proctor has been led to notice that the rich cluster around χ Persei falls almost exactly on the intersection of the Milky Way with the great circle which may be termed the equator of the solar motion; that is, the great circle having the apex of the sun's motion as a pole. This circumstance points to that remarkable cluster, rather than to the Pleiades, as the centre of the sidereal system, if indeed that system has a centre cognisable by us. When we remember that for every fixed star in the Pleiades there are hundreds in the great cluster in Perseus, the latter will seem the worthier region to be he centre of motion. The author is disposed, however, to regard the cluster in Perseus as the centre of a portion of the sidereal system, rather than as the common centre of the Galaxy.

SOCIETIES AND ACADEMIES

Royal Society, February 24.—The President in the chair. The following papers were read: "Note on certain Lichens." By John Stenhouse. Usnic acid extracted from *Usnea barbata* by dilute solution of carbonate of soda was found to have the formula $C_{18} H_{18} O_7$, and the sodium salt $C_{18} H_{17} Na O_7$. This result accords with that of Hesse and differs from that of Knop, Rochleder, and Heldt, whose analysis give the formula $C_{19} H_{18} O_7$. Usnic acid was also obtained from *Evernia prunastri* as well as evernic acid. Tetrabrom-evernic was got by the action of bromine on evernic acid. Its formula is $C_{18} H_{12} Br_4 O_7$. The acid extracted from *Cladonia rangiferina*, though possessing the same composition as usnic acid, was observed by Hesse to have a different melting-point (175° C.) from ordinary usnic acid (203° C.) He proposed, therefore, to call it β-usnic acid, as it so closely resembled ordinary usnic acid in its general character. The author has found that ordinary usnic acid, melting at 203° C., obtained from *Evernia prunastri*, *Ramalina calicaris*, and the various *Usneas*, does not yield a trace of β-orcin when distilled, whilst, on the contrary, the acid extracted from *Cladonia*, on being subjected to the same treatment, yields β-orcin; thus showing a marked difference in the products of its decomposition from ordinary usnic acid, as well as in its melting-point. Under these circumstances, therefore, he proposes to name the acid from *Cladonia rangiferina* "Cladonic Acid," instead of β-usnic acid, as proposed by Hesse. He intends to continue the study of this acid.

"On the successive action of Sodium and Iodide of Ethyl upon Acetic Ether." By Prof. Frankland and Mr. B. F. Duppa. The authors, referring to a paper by Mr. Wanklyn, wherein it is stated that their interpretation of the nature of the reaction between sodium and acetic acid must be erroneous because it involves the disengagement of hydrogen, remarked that Mr. Wanklyn's opinion is founded upon experiments which differ essentially from their own, and not warranting the conclusion which he has drawn from them. The authors allowed all evolved gas freely to escape, while Mr. Wanklyn operated in sealed tubes under great pressure. M. L. Cailletet has recently shown that the evolution of hydrogen from zinc and hydrochloric acid is gradually diminished and finally stopped under increasing pressure, while the evolution of hydrogen from sodium-amalgam and water is diminished and finally stopped in a sealed tube. Since pressure retards or even interrupts a reaction in which a permanent gas is evolved, whilst it is known to exercise little or no influence upon other chemical changes in which no evolution of gas takes place, the authors consider this influence of pressure affords an explanation of the difference between the results of Mr. Wanklyn's experiments and their own, as regards the evolution of hydrogen during the action of sodium upon acetic ether. They confirm his observation that sodium dissolves in valeric ether, under ordinary atmospheric pressure, without the evolution of any gas; adding that since a reaction, whatever its nature may be, which thus proceeds readily with ethylic valerate, can scarcely be impossible with its homologue, acetic ether, it is probable this reaction goes on side by side with those which they have described, but that when the pressure is moderate those changes chiefly take place which involve the disengagement of hydrogen, whilst under the great pressure arising in sealed tubes, those changes being more or less suppressed, the reaction observed by Mr. Wanklyn comes into prominence. The authors reserve their observations upon Mr. Wanklyn's views regarding the changes which take place when sodium acts upon acetic, butyric, and valeric ethers, until the publication of the experimental data upon which those views are founded.

Ethnological Society, February 22.—Prof. Huxley, president, in the chair. Mr. E. Backhouse was announced as a new member.—By the courtesy of Dr. Lockhart, a calva from China was exhibited by Prof. Busk, in illustration of a former paper on an ancient calvaria which had been assigned to Confucius. The skull is mounted in copper, and was formerly supported on a tripod and furnished with a lid.—"On discoveries of archæological interest in recent deposits in Yorkshire." By Mr. C. Monkman, of Malton. The author described the discovery of worked flints in the clay of Kelsea Hill, in the East Riding of Yorkshire. This was formerly regarded as belonging to the Hessle clay—a post-glacial deposit unconformable to the true boulder clay of Holderness—but it is probably only a derivative clay washed from the Hessle deposits on Kelsea Hill. It may, therefore, be of comparatively recent origin. Large finds of implements of Neolithic type are reported to have been made in the York sands. Many stone implements have also been found in the old river deposits in the Vale of Pickering, chiefly turned up in the prosecution of land-drainage works. The paper was illustrated by a fine collection of specimens.—"On the Natives of Naga, in Luzon, Philippine Islands." By Dr. Jagor. The author described in detail the manners and customs of the Bicol Indians who inhabit this locality. Dr. Campbell inquired whether there was any connection between the name of this place and the Sanskrit *naga*, a snake.

Entomological Society, February 21.—Mr. Alfred R. Wallace, president, in the chair. Professor Schiödte and Siebold were elected honorary members. Messrs. B. J. Lucas and G. T. Porritt were elected annual subscribers.—Mr. J. Hunter exhibited a moth captured in the New Forest, and supposed to be *Plusia ni*.—Mr. Albert Müller exhibited galls formed in the florets of the tansy by *Dipterous* larvæ.—Mr. Pascoe exhibited a beetle from King's George's Sound, the *Nepharis alata* of Castelman—*Hicketes thoracicus* of King, which latter name sinks.—Mr. A. G. Butler read a paper "On butterflies recently received by Mr. Swanzy from West Africa." Three new species were described of the genera, *Romalcosoma*, *Philognoma*, and *Mycalesis*.

London Mathematical Society, February 10.—Prof. Cayley, president, in the chair. Mr. A. Ramsay was elected a member. The president gave an account (second communication) of his paper on "Quartic Surfaces."—Mr. Walker made some further remarks on the subject of his paper on the "Equations of Centres and Foci, and conditions of certain Involutions," read at the January meeting of the society.—The condition that a quadric (v) should determine a pair of corresponding points in one of the three involutions given by a quartic (u) is the vanishing of the cubic invariant of $\overline{12}\, uv$. When u and v are the Jacobian and quadric covariants of two cubics the preceding condition expresses that the two cubics determine an involution. When one of the two cubics (v) is the cubic covariant of the other (u) the two determine four distinct involutions; and the Hessian of u determines the foci in one of the four—viz., that in which the points harmonically correspondent are also correspondent in the involution. The other three involutions are not analytically distinguishable one from another.—Mr. Clifford read a paper "On a case of Evaporation in the order of a Resultant." In it he established the two following theorems:—"Let it be required to eliminate x between two equations homogeneous in x, and certain other variables $y, z, \ldots$ in which equations, however, x only occurs in virtue of the occurrence of a quantity $w = x^{\alpha} y^{\beta} z^{\gamma}, \ldots$ where $\alpha + \beta + \gamma + \ldots = \mu$; let, also, m, n be the orders of the equations, and h, k the remainders after division of m and n respectively by μ; then the order of the resultant is

$$= \frac{m\, n - hk}{\mu}."$$

Theorem 2. "Let it be required to eliminate $\kappa - 1$ variables $x, y, \ldots$ from k equations homogeneous in these and certain other variables, in which equations, however, x, y, only occur in virtue of the occurrence of $k - 1$ quantities $u, v, \ldots$ all of the same order μ; let also $m_1, m_2, \ldots m_\kappa$ be the orders of the equations, and $m_i = p_i \mu + h_i$, $h_i < \mu$; then the order of the resultant is

$$\Pi p \left(\Sigma \frac{h}{p} + \mu\right)."$$

Mr. Perigal presented to the Society a copy of his "Geometric Maps and Contributions to Kinematics."

Meteorological Society, January 19.—Charles V. Walker, president, in the chair. The Rev. J. Crompton, Dr. C. Fox, and Mr. E. J. Sykes were elected Fellows. The following papers were read: "On the Temperature and Humidity of the Air at the Heights of 22 feet and 50 feet above the ground, in comparison with the Temperature and Humidity of the Air at the Height of 4 feet." By Mr. Glaisher. Our knowledge of the temperature and humidity of the air near the surface of the earth is almost entirely confined to within 4 or five feet above the earth. The theory that the temperature was always lower at higher elevations was proved not to be at all times true, and the theory of the decline of 1° of temperature in every increase of 300 feet of elevation, was proved to be erroneous. The author stated the results of his observations in the great Captive Balloon, at Ashburnham Park, Chelsea, which M. Giffard kindly placed at his disposal for the purpose. This balloon could ascend to the height of 200 feet on a calm day; its rate of ascension could be regulated at will; it could be kept stationary at any elevation, and experiments could be repeated several times in the day. From these results the author considered it to be evident that observations, even up to 50 feet, give more information than could be obtained by the use of either a free or captive balloon, as to the temperature and humidity of the air at moderate elevations. If carried through an entire year, this would give the seasonal as well as diurnal changes; such experiments are in progress at present, and several months' observations have already been made, the results of which will be placed before the Society at a future time.—"Rainfall at Jerusalem during the Rainy Season of 1868-69." Dr. T. Chaplin.

MANCHESTER

Literary and Philosophical Society, February 8.—Mr. J. P. Joule, president, in the chair. Mr. Binney, referring to his previous notice of stray boulders without traces of clay, high up the western slopes of the Pennine chain, about 1,000 feet above the level of the sea, said that Mr. A. H. Green and his colleagues had stated, in their valuable memoir on the carboniferous limestone, yoredale rocks, and millstone grit of North Derbyshire and adjoining parts of Yorkshire, just published by the Geological Survey, that they believed the eastern plain from Sheffield through Chesterfield down to Belper, to be in the main free from drift. Mr. Binney had often searched for boulders in the neighbourhood of Chesterfield. The only foreign rock which he met with in that district was a large block of greenstone several hundred pounds in weight, above the valley of the Hippei near Spring Bank and below the waterworks station, Chesterfield. The stone was well rounded and polished. He mentioned the fact to direct the attention of observers to this subject on both the eastern and western slopes of the Pennine chain. Probably they have only to be more diligently sought for in order to be found in greater abundance.

"On Convertent Functions." By Sir James Cockle. This was a supplement to the author's paper "On convertent functions." The convertent equation (3) contains in substance only one disposable arbitrary, and the sign of summation Σ does not increase, and may be expunged from it without diminishing, its generality. Consequently the process would fail to convert the Boolian integral for the cubic and lead only to illusory results. But a recognition of this failure had led him to another form of convertent equation. And first, if to the several dexters of (2) and (3) we add a term h, then the conversion will be possible, even though h be not a perfect differential co-efficient, provided only that $\int hdu$ be assignable within the limits of the integration.

Mr. Spence repeated the experiment he had made at the Exeter meeting of the British Association, showing that the temperature of saturated saline solutions could be raised to their boiling points by merely passing them through ordinary steam at a temperature of 212°. Thus, a solution of chloride of sodium was raised to a temperature of 221°, and one of chloride of calcium to 248°.

"On the Natural Ropes used in packing Cotton Bales in the Brazils." By Mr. Charles Bailey. Most of the cotton bales which reach this country from the Brazils are corded with the long stems of climbing plants growing in profusion in the forests bordering on the cotton districts. In their fresh state these stems are exceedingly pliant and of remarkable strength, so that they serve admirably for cordage purposes, but by the time that the cotton reaches the mills of Lancashire they become dry and rigid, and as no further use can be made of them, they are burned for firewood. Being very long, they are very troublesome to put on the boiler fires, and most millowners are glad to get rid of them. These objects are invested with singular interest when examined in regard to their structure, for although the external form of many of them is extremely curious, their chief interest centres in their remarkable internal organisation. Although they reach this country in immense quantities, they are not often to be met with in our museums or colleges, and the names of the plants which produce them are for the most part unknown. The *Bignoniaceæ* stands pre-eminent as the natural order most largely used for supplying lianas for packing purposes, both as regards the quantity of ropes, and the largest number of species. *Malpighiaceæ*, *Sapindaceæ*, *Leguminosæ*, *Aristolochiaceæ*, and *Ampelidæ* also yield these ropes. There are many other species found amongst these ropes which belong to other natural orders, such as the *Menispermaceæ*, *Gnetaceæ*, *Asclepiadaceæ*, &c., but our knowledge of them is too limited to assign them to their respective orders. Most of the author's specimens have come from bales of Santos cotton. The whole of these lianas furnish beautiful objects for the microscope.—Mr. Forrest suggested that useful dyes might be obtained from the plants described by Mr. Bailey.—In reply to a question from the Rev. Brooke Herford, Mr. Bailey stated that owing to a difference in the structure and general appearance of some of the stems in his possession, he had been led to suspect that they were aërial roots of some of the plants he had exhibited and described.

CAMBRIDGE

Philosophical Society, February 21.—The following papers were read:—"The antiquity of some of our familiar agricultural terms." By Mr. Paley (St. John's). After some general remarks upon the English language, and the fact that agricultural life was peculiarly favourable to the preservation of old words, Mr. Paley called attention to the fact that while in our language the generic names of animals are usually of Saxon origin, the words denoting their application are usually of classic origin. Words which are not generic, but particular and descriptive, are also generally of classic origin. He then proceeded to discuss the derivation of a large number of familiar agricultural terms in illustration of the above remarks.—"Proof that every rational equation has a root," and "The space theory of matter," both by Mr. Clifford (Trinity.)

GLASGOW

Natural History Society of Glasgow, January 25.—Prof. John Young, president, in the chair. "On the claims of Natural History as a branch of education" By J. W. Allan. The author advocated the teaching of zoology and other branches of natural history in schools, also that zoology should occupy a more important place in the curriculum in all universities. At its close Prof. Young made some remarks bearing on the different aspects of the question.—"On the introduction of the wild turkey (*Meleagris Gallopavo*) into Argyleshire." By John Gilmour. The author of this paper mentioned having received three specimens of this beautiful bird—a male and two females—from the southern extremity of Lake Huron, in Canada, in the summer of 1866, since which time various broods had been successfully reared in the neighbourhood of Ardlamont, where the birds had been allowed their full liberty in the woods. Mr. Gilmour concluded his paper with a description of the wild bird as compared with domestic breeds, remarking that it possessed greater symmetry with a more compact form, standing higher on its legs, and exhibiting other characters more like those of a game bird than one of the gallinaceous order. Mr. Gray mentioned that there are now supposed to be three different species of *Meleagris* besides the *M. ocellata* of Honduras and other parts of Central America, namely, *M. Americanus*, which is probably peculiar to the eastern half of North America; *M. Mexicana* of Gould, a species belonging to Mexico and extending along the table lands to the Rocky Mountains, the Gila and the Llano Estacado; also the *M. Gallopavo* of Linnæus, or domesticated bird. This last species was perhaps originally indigenous to one or more of the West India Islands, whence it was taken in a tamed state to various parts of North America, and thence to Europe about the year 1520. The domesticated bird differs from the nearly allied wild species in having a largely-developed dewlap extending from the base of the under mandible down the fore part of the neck to its base, and it cannot yet be said to be a settled question as to the precise original stock from which the valuable barn-yard breeds have descended.—"Notes on the genera of extinct fossil shells—*bellerophon* and *porcellia*; their classification amongst the mollusca, and their distribution in the silurian and carboniferous strata of the west of Scotland." By John Young. Mr. Young stated that at one time this interesting group of shells had been placed by palæontologists among the cephalopods, the highest division of the mollusca, and regarded as fossil representatives of the recent *argonautidæ*, which possess a symmetrically coiled shell as in *bellerophon* and *porcellia*, but, like them, not chambered as in the genus *nautilus*. In the more recent classification of the mollusca, *bellerophons* and *porcellia* are now placed amongst the gasteropods, and in that division termed the *neucleobranchiata*, which consist of entirely pelagic animals, some having shells, others none, and, according to Woodward, swimming at the surface instead of creeping on the bed of the sea. Prof. Owen believes, however, that it can scarcely be insisted all were necessarily floaters on account of their organisation. In recent seas the extinct genera are represented by the genus *Atlanta* and the sub-genus *oxygyrus*. In palæozoic times the genus *bellerophon* commenced its existence, so far as is known, in the lower Silurian, and became extinct in the carboniferous period.

NEWCASTLE-UPON-TYNE

Chemical Society, November 25, 1869.—I. Lowthian Bell, president, in the chair. "On the estimation of Peroxide of Manganese in Manganese Ores," by E. Sherer and G. Rumpf. The authors showed that the method of Fresenius and Will is open to the objection of giving results which do not always agree with those obtained in the practical use of manganese for producing chlorine. They recommended Bunsen's method of testing as better adapted for the valuation of manganese ore.

BRIGHTON

Brighton and Sussex Natural History Society, February 10. The president, Mr. T. H. Hennah, in the chair. The hon. sec., Mr. T. W. Wonfor, exhibited a collection of *galls*, found on British plants, made by Mr. W. H. Kidd, and read a description of each one of the insects producing them, drawn up by the same gentleman. The collection is intended for the Brighton Museum. Mr. Wonfor then read a paper on Seeds. Commencing with the first appearance of the ovule in the unexpanded flower-bud, as a pimple consisting of an aggregation of cells, its gradual development and the impregnation by the pollen, together with its coeval parts, were traced until the perfect seed, ready for dissemination and containing within it the embryo of the future plant, was fully formed. The various modes by which the seed is scattered, the numbers produced by some plants, the power possessed by some of resisting heat and cold, and the wonderful property possessed by others of preserving their vitality, under apparently very adverse circumstances, for long periods of years, were each discussed. On the subject of artificial selection, it was shown what has been done, notably by Mr. F. Hallett, of Brighton, with cereals in increasing both the size and number of grains in an ear; something similar might be done with other plants. Seeds, as objects for the microscope, were next discussed. From a long series of examinations of wild and cultivated seeds, spread over several years, while unwilling to lay down any law of classification by their microscopic appearance, yet often in the case of unknown seeds he had been able to determine the family to which they belonged from certain peculiarities common to many plants of the same family. Seeing how varied and beautiful they were, and how little preparation they required, he considered they were not attended to by microscopists so much as they deserved. The paper was illustrated by a large collection of seeds and microscopic preparations.

VIENNA

Imperial Academy of Sciences, January 7.—Memoirs were communicated "On some constituents of the fruit of *Cerasus acida*, Borkh.," by Professor H. Rochleder, and on a spiral valve in the portal vein of the Rodentia, by Professor J. Hyrtl. —Herr von Haidinger presented a note by Dr. S. Meunier on the victorite or enstatite of the meteoric iron of Deesa, in Chili, which was said to be perfectly colourless and transparent and to contain no trace of iron. He also made some remarks on the study of meteorites, regarding them as the last step in the development of our planetary system.—Professor F. Unger communicated a memoir on the occurrence of Typhaceous plants (*Typha* and *Sparganium*) in tertiary deposits.—Prof. E. Mach presented a preliminary communication on an apparatus constructed by him for the observation of sound-movements.—Dr. Samuel Kónya communicated an account of his investigation of the mineral water of Wielutza, near Jassy, in Roumania. He obtained about 0·9 per cent. of solid constituents, of which 0·574 was sulphate of soda, and nearly 0·18 sulphate of magnesia. The water also contained chloride and carbonate of magnesia.—A memoir by MM. J. Rumpf and F. Ullik, on the Ullmannite of Waldenstein in Carinthia, was presented by Professor Peters. —Professor Graber communicated an account of the Orthoptera of level districts among the Austrian Alps.

January 13.—A report was communicated from Dr. von Scherzer upon the proceedings of the scientific members of the East Asiatic Expedition. The following specimens were specially noticed:—Three Chinese and three Japanese skulls, a collection of freshwater fishes from Osaka in Japan, and a number of Chinese drugs.—A memoir "On nexus of curves," by Dr. Emil Weyr, was presented.—M. Haidinger communicated the contents of a series of letters from Professor W. H. Miller, relating to meteorites.—M. A. Waszmuth forwarded a memoir on a new method of determining the reduction-factor of a tangent compass. —Herr J. Effenberger announced that he had succeeded, upon scientific principles, in producing violins which in power of tone approached those of the old makers.—Professor Reuss presented a memoir on Upper Oligocene corals from Hungary, in which he described 16 species of corals from the beds in the neighbourhood of Gran, which contain abundance of *Nummulites Lucasana* and *perforata*, and were formerly regarded as of Eocene age: half the species are new; of the other half, seven have occurred in the beds of Castel-Gomberto and Oberburg.—A memoir by Dr. Leo Levschin, containing a description of the structure and vessels of the intestine of *Salamandra maculata*, was presented by Professor Langer.—Herr. F. Unferdinger communicated a memoir on the transformation and determination of a certain triple integral.—M. H. Obersteiner read a paper on some lymphatic spaces in the brain: and Dr. S. L. Schenk presented a memoir on the amount of nitrogen in the flesh of various mammals, in which he stated that this quantity is variable, ranging from 3·06 to 4·21 per cent.

PARIS

Academy of Sciences, February 21.—At this meeting M. Becquerel communicated a memoir on the production of electrocapillary currents in the bones, nerves, and brain.—M. de Saint Venant presented a report on a memoir by M. Boussinesq, relating to the theory of periodical liquid waves, and another on a supplement by M. Tresca to his memoir read on the 27th of November, 1864, on the flowing of solid malleable bodies pressed out of a cylindrical vase through a circular orifice.—The astronomical and physical communications were:—A notice of a direct and easy method of effecting the development of the perturbative function and of its differential coefficients, by Mr. S. Newcomb; and a note by M. A. Martin on the method adopted by Léon Foucault, to ascertain whether the surface of a mirror is strictly parabolic.—The following papers were read on chemical subjects:—A note on synthesis of aromatic acids, by M. A. Wurtz, in which the author described a series of acids produced by the action of amalgam of sodium upon mixtures of brominated toluene and chloride of benzyle, with chloroxycarbonic ether.—A paper containing facts relating to the stability as chemical species of normal propylic, butylic, and amylic alcohols, by MM. J. Pierre and E. Puchot. The authors described a series of observations made upon these substances under various conditions, from which they concluded that the three alcohols were specifically different. They remarked that amylic alcohol is the only one of the three which exerts any sensible action upon polarised light.—A memoir on the artificial digestion of feculent bodies by maltine, by M. L. Coutaret, in which he stated that the action of maltine or vegetable diastase upon cooked starchy matters is precisely analogous to that of the salivary diastase, and recommended the use of the former in cases of dyspepsia.—A note by M. A. Lamy on a new kind of thermometer, founded on the principle of "dissociation," that is to say, on the determination of the amount of gas given off by a solid body at different temperatures. The substance employed by the author is a double chloride of calcium and ammonia. The author regarded his method as particularly applicable to the determination of temperatures low down in the earth or in deep soundings. M. Becquerel remarked that for temperature-observations at various depths in the earth, he had several years ago proposed a method which gave good results.—A note by M. Reboul on combinations of the hydroacids with brominated ethylene and propylene.—A note by M. A. Colley on the action of the free haloids and of some chlorides upon glucose, in which he described a new compound obtained by the action of chloride of acetyle upon glucose, which he proposes to name *acetochlorhydrose* ($C^6H^7(C^2H^3O)^4Cl$).—A notice of a new phosphuretted compound by MM. Darmstädter and Henninger. This body, which the authors named *cyanethylphosphide*, was obtained by the action of an etherial solution of phosphuretted hydrogen upon chloride of cyanogen. And, lastly, a chemical and therapeutical investigation of the thermal water of the solfatara of Puzzoli, by M. S. De Luca; the water contains free sulphuric acid. The only purely mathematical communication was a memoir by M. Halphen on algebraical left curves.—General Morin presented a memoir by M. Goldenberg describing improvements introduced by him in the ventilation of the grinding and polishing works at Zorrhoff, near Saverne.—M. H. Sainte-Claire Deville communicated some further remarks by M. A. Schafarik, on the diamonds discovered at Dlaschkowitz in Bohemia, in which it was stated that fragments of the stone have been burnt, for the purpose of demonstrating its identity with diamonds from other localities.—A note from M. Liebreich on the use of strychnine as an antidote for chloral, was presented by M. Wurtz. The physiological action of these two substances was stated to be so antagonistic, that either of them may be employed with more or less effect as an antidote to the other.—M. Duchartre communicated a memoir by M. Prillieux on the formation of small masses of ice in the interior of plants. These masses, which occur in many plants, when exposed to severe frosts, were described by the author as composed of numerous prismatic needles closely applied to each other, and formed in lacunæ between the cells of the living tissues.—M. A. Chatin presented a second note on the causes of the dehiscence of anthers, in which he described the part taken in the production of this phenomenon by the second membrane or mesothecium.—M. F. Lenormant continued his notes on animals known to the ancient Egyptians, with an account of the domestication of some species of antelopes under the old empire, especially the fourth and fifth dynasties—Of the following communications no particulars are given. A memoir by M. Delaurier on a new general theory of the production of static and dynamic electricity,—an *electro-thermic theory*; a memoir on the pathology and therapeutics of cholera, by M. J. de Zycki of Wilna; a note by M. G. Adeline on the influence of copper as a preservative from cholera; a note by M. Allegret in continuation of his remarks on the geometrical representation of the elliptical function of the first kind with an arbitrary modulus, &c.; a note on the theory of magic squares, by M. Marie; a letter on the formation of ice, and a note on a case of catalepsy from Mr. Jackson Davis.

New Zealand

Wellington Philosophical Society, November 13, 1869.—Mr. W. L. Travers, F.L.S., in the chair.

Dr. Hector called attention to two live specimens of the mud fish from Hokitika, *Neochanna apoda* of Gunther. The specimens were swimming actively in clear water, and had perfect vision, although their eyes are small, so that the undeveloped state of the eye in the specimen previously received must have been exceptional. The Hon. Mr. Fox remarked that these mud fish were not peculiar to Hokitika. Five years ago he remembered seeing a fish dug up from a gravelly-clay ten feet below the surface at Rangitikei, and he believed that it was identical with the fish exhibited.

A remarkable meteor, observed in Wellington on the 8th inst. at 11.30 P.M., was described by the Rev. Mr. Stock. It was observed in E.S.E. and descended almost vertically with three distinct coruscations, attended by showers of sparks and bright prismatic colours. The brightness was equal to that of Venus. Mr. Kebbell and Mr. Gillon corroborated Mr. Stock's observations. A description of three additions to the New Zealand flora, with specimens, was laid on the table, and Dr. Hector gave a short abstract of a report by Mr. Kirk, of Auckland, on the botany of Cape Colville peninsular. This paper gave the results of a survey that had been made for the Geological Department for the purpose of obtaining an accurate record of the original vegetation, as it was undergoing rapid modification by the gold diggers. Several new species of plants were described, of which specimens were exhibited.

The next paper was a description of the mechanical apparatus employed in raising the *Taranaki*, by Mr. J. T. Stewart. Dr. Hector directed attention to a collection of the marine animals that were found on the vessel, among which are three species of *anomia*, two of *mytilus*, *ostrea*, *pecten*, *serpula*, *balanus*, and *teredo*. He remarked that some of these animals are usually confined to depths only slightly below low water. Their occurring so well-grown within a year at the depth of 100 feet, seemed to indicate that depth of water did not so much control their existence as a supply of nourishment, which was probably abundant near the wreck.

Mr. Skey showed that the temperature obtained by the common blowpipe, with proper precautions against conduction of heat, was at least 5,100° Fahr., as it is capable of fusing fine points of platinum, and described a new process to facilitate the analysis of supposed auriferous quartz, when sulphides were present in large quantities. Iodine or bromine is used as the solvent, and a rapid test is obtained by dipping filter paper in the solution and burning it with due care, when if gold be present a very characteristic purple hue is imparted to the ash. By this test the presence of gold in the proportion of one dwt. in the ton can be detected with great economy and certainty.

Dr. Hector described the bones of a fossil penguin recently discovered on the west coast of Nelson, and presented to the museum by Mr. Dingan. The discovery is interesting, as a fossil bone found by Mr. Mantell in the Oamaru limestone of Otago in 1849, was pronounced by Prof. Huxley to belong to a gigantic penguin five feet in height. The fossil bones found by Mr. Dingan, appeared to be those of a bird not larger than penguins that still exist in antarctic seas. The fossil shells sent from the same formation as the bones, indicate that they belong to a lower pliocene period.

Mr. Hamilton read a paper on the educational system.

DIARY

THURSDAY, March 3.

Royal Society, at 8.30.—Results of Monthly Observations of Dip and Horizontal Force made at Kew Observatory: Dr. Balfour Stewart.—Spectroscopic Observations made with the great Melbourne Telescope, Nebula in Argo, and the Spectrum of Jupiter: A. Le Sueur.
Chemical Society, at 8.—Indices of Refraction: Dr. Gladstone.
Linnean Society, at 8.—Hybridism among Cinchonæ; Mr. J. Broughton.
Pathological Society, at 8.
Royal Institution, at 3.—Chemistry of Vegetable Products: Prof. Odling.
Society of Antiquaries, at 8.30.—Monastic Inventories: Rev. M. S. C. Walcott.
London Institution, at 7.30.

FRIDAY, March 4.

Geologists' Association, at 8.
Philological Society, at 8.15.
Royal Institution, at 9.—Iron-built Ships: Mr. E. J. Reed, C.B.
Archæological Institute.

SATURDAY, March 5.

Royal Institution, at 3.—Science of Religion: Prof. Max Müller.

MONDAY, March 7.

London Institution, at 4.
Medical Society, at 8.
Entomological Society, at 7.
Society of Arts, at 8.—Cantor Lecture: Dr. Paul.
Royal Institution, at 2.—General Monthly Meeting.

TUESDAY, March 8.

Photographic Society, at 8.
Ethnological Society, at 8.—On the opening of a Cairn in North Wales: Col. A. Lane Fox.—On the Earliest Phases of Civilisation: Hodden M. Westropp.
Institution of Civil Engineers, at 8.—The San Paulo Railway, Brazil: Mr. D. M. Fox, M. Inst. C.E.
Medical and Chirurgical Society, at 8.30.
Royal Institution, at 3.—Plant Life: Dr. Masters.

WEDNESDAY, March 9.

Society of Arts, at 8.—Street Tramways: W. B. Adams.
Archæological Association, at 8.
Royal Microscopic Society, at 8.—1. On the Comparative Steadiness of the Ross and Lister Models under Trying Circumstances; 2. On the Shell Structure of Fusulina; 3. On the Microphyle of the Fish's Ovum; 4. On the Reparation of the Spines of Echini: Dr. W. B. Carpenter.
Geological Society, at 8.—On the Structure of a Fern-stem from the Lower Eocene of Herne Bay, and on its allies, recent and fossil: Mr. W. Carruthers, F.L.S., F.G.S.—On the Oolites of Northamptonshire: Mr. Samuel Sharp, F.G.S.—On the Geology of the district of Waipara River, New Zealand: Mr. T. H. C. Hood, F.G.S.

THURSDAY, March 10.

Royal Institution, at 3.—Chemistry: Prof. Odling.
Royal Society, at 8.30.
Mathematical Society, at 8.
Zoological Society, at 8.30.—On Dinornis: Professor Owen.—Description of a new species of *Ampullaria*: Dr. J. C. Cox.—On the Birds of Veragua: Mr. O. Salvin.—On new birds from the Yantze-kiang: Mr. R. Swinhoe.
London Institution, at 7.30.

SCIENCE EDUCATION IN GERMANY

II. THE POLYTECHNIC SCHOOLS

THE "Polytechnicum" is an institution peculiar to Modern Germany. It has for its object the teaching of all branches of the sciences of experiment and observation, not only in their principles, but in their applications to the industrial arts; these applications not being merely treated as illustrations of science, but regarded as the main subjects for instruction, for the sake of the understanding of which systematic courses on theoretic science are given.

The Polytechnica are altogether independent of the science departments of the Universities, but like these latter the Polytechnica are State institutions, the Professors (ranking generally somewhat below those of the University) are Government servants, and the current expenses are defrayed by State grants.

As a type of this interesting class of Science schools I may cite the two celebrated schools of Carlsruhe and Zurich, beginning with the Carlsruhe school with its 600 students.

In the original programme the school was declared to consist of *one* general and *seven* special departments. The general department, called the *Mathematical*, furnished instruction in mathematics, in natural science, and in modern languages and literature. It was viewed as preparatory to the special schools, and also as adapted for those who proposed to become teachers of mathematics and natural science. The seven special schools were of (1) civil engineering; (2) mechanical engineering; (3) architecture; (4) forestry; (5) manufacturing chemistry; (6) commercial studies; (7) civil service (*Postschule*). This constitution is in the latest programme, so far modified that (1) the general department is no longer treated in form as introductory to the rest, though it still appears to be so virtually; (2) the last two of the special departments enumerated above are omitted, while an agricultural department is added. The schools are, therefore, now seven, viz.:—

	Duration of complete course.
1. Mathematics	2 years
2. Civil Engineering	2½ ,,
3. Mechanical Engineering	2 ,,
4. Architecture	4 ,,
5. Chemistry	— ,,
6. Forestry	3 ,,
7. Agriculture	2½ ,,

The teaching staff consists of twenty-four professors with sixteen assistant lecturers and laboratory assistants. The appliances comprise five laboratories, viz. chemical, physical, mineralogical, and one for forestry and agriculture; a library; and twelve different cabinets or collections. In the department of natural philosophy, as many as 120 students attended the lectures of Professor Wiedemann in the summer semester of 1868. The cabinets are large and well-arranged. In the physical laboratory there were in the above year fourteen students, who went through the course of instruction in groups of four; most of these become teachers of the subjects in *Real-Schulen*; some get important posts in large mechanical workshops.

In Zürich exist both a University and a Polytechnic School; and although the university is a cantonal, and the school a federal institution, they are so far allied that they share one magnificent building, and many students of the university are, at the same time, pupils in the school. The total expense to the State for the maintenance of the Polytechnic School is 12,000*l.* per annum, whilst the original cost of the stately building itself was 160,000*l.* The professors of the two institutions, moreover, work to a certain degree in concert. For instance, Dr. Bolley is Professor of Chemistry in the school, and Dr. Städler, Professor of the same subject in the university. They have each a laboratory; but Professor Städler's is an analytical, and Professor Bolley's a technical laboratory. About 40 students work in the former, and 50 in the latter on an average.

There is less freedom allowed to pupils of the school, as to the classes to be attended, than is customary at the university. Definite courses are laid down; but relaxations are freely granted.

The most important department of this Polytechnic School is that of mathematics and engineering; there are also departments of forestry and agriculture, and an important department for teachers—a sort of technological seminary.

The Professor of Technical or Applied Chemistry, Dr. Bolley, lectures three or four times weekly throughout the session. He makes four or five sub-divisions of his course; —thus he lectures on the Chemistry of Colour; of Heating and Lighting; of Materials of Nourishment; and of Agriculture. Before entering this class, the student is required to have attended a course of theoretical lectures on chemistry, and an elementary experimental course.

Dr. Zeuner, the Professor of Engineering, gives about fifty or sixty lectures yearly on the Mechanical Theory of Heat; and he lectures six times a week for two semesters, on the Theory of Machines. The character of his courses is very high and rigorous; he insists on a knowledge of the differential calculus as a condition of entering his classes, and he remarked to the writer on the generally inadequate mathematical preparation of English students of engineering, mentioning his conviction that Professor Rankine, for whose works he expressed an unbounded admiration, must find the sphere of his efficiency as a teacher seriously limited by reason of the want of due preparation on the part of his students.

The following extracts from the prospectus of the lectures in the engineering department of the Zürich school, show how much more complete is the scheme of instruction there than has at present been found possible in England.

B. *Department of Civil Engineering.* (Duration of course, 3½ years.)

1st year.—Differential and Integral Calculus. Descriptive Geometry. Principles of Construction. Practice in Construction. Drawing. Experimental Physics. Experimental Chemistry.

2nd year.—Differential Equations. Technical Mechanics. Geometry of three dimensions. Perspective. Technical Geology. Topography. Drawing. Descriptive Mechanical Construction. Surveying.

3rd year.—Theoretical Mechanical Construction. Astronomy. Geodesy. Construction of Iron Bridges, Railways, and Iron Roofs. Drawing.

In addition to these courses there are similarly extensive programmes for (A) the department of Architecture, and (C) the department of Mechanical Engineering. The number of regular students in the year 1867, was in these subjects (A) department of Architecture, 33; (B) department of Civil Engineering, 103; (C) department of Mechanical Engineering, 87.

That the Polytechnic system of science education finds favour, at any rate, with the German State Governments, and therefore probably also with the people, is apparent from the fact that large institutions of the kind have just been built in Prussia (at Aix-la-Chapelle), in Austria (at Vienna), and in Bavaria (at Munich). In this latter city no less a sum than 125,000*l.* has been expended on the building of the new Polytechnicum, erected in a very costly style of architecture, and covering five acres of ground, whilst distinguished men from all parts of Germany have been called to fill the newly-founded professorships. The cost of the buildings at both Vienna and Aix-la-Chapelle will probably not be far short of the above amount, and it must be remembered that labour and material are very much (probably one-half) lower in Germany than with us. The expenses of education at the Polytechnica are very small; at Carlsruhe attendance on the regular courses of lectures costs 5*l.* 10*s.* for the session of nine months; the fee for chemical laboratory practice for the same length of time is 3*l.* 15*s.* to regular students, and 5*l.* to occasional students. At Zürich the fees are even lower, as any of the regular courses of the distinct departments or schools can be attended for the payment of 109 francs, or about 4*l.* 4*s.* for the session of nine months.

The age for entrance into the Polytechnic Schools is one year younger than that for the German Universities, viz. seventeen: the duration for study is the same, three years. Here, too, evidence of fitness is vigorously exacted of those who propose to enter as *regular students*, in the shape of an adequate school certificate, either from a gymnasium, a real-gymnasium, or a *Real-Schule;* or, in default of that, an entrance examination must be passed. A much higher mathematical preparation is demanded than is needed for entering the University, a knowledge at least up to, and in some schools including, the differential calculus being required. Persons of all ages, however, and not possessing such qualification, are admitted freely and without examination, as *occasional* students in the several departments. Many of these occasional students are often poorly prepared; but it is considered that the gain to such auditors, and to society through them, is great; and that, whatever tendency might arise from this practice towards the lowering of the standard of instruction could be guarded against by rigidly keeping up the standard of admission for regular students.

To many of the Polytechnica is attached a preliminary school, in which those who are not ripe for the full studies of the Polytechnicum can supply their deficiencies. The age for entrance to this *Vorschule* is sixteen.

In all the Polytechnica with which the writer is acquainted, it is the schools of civil and mechanical engineering, building construction, and architecture which really flourish. These departments of applied science are not represented in the German university system, whereas the study of chemistry in its various divisions, and of mechanics and physics in their numerous branches, forms a portion of every university course. Indeed, as a rule, the lectures delivered in the Polytechnic Schools on chemistry and physics differ very slightly, if at all, in character and scope from those which the University professor delivers. The fact is that the teaching of special technical chemistry in the Polytechnica has been found to be impossible. All that can be done in any school is, in the first place, to teach the groundwork of the science without regard to its applications, and then to point out the scientific principles upon which certain technical processes depend. No system of theoretical school instruction will fit a man to be a dyer or a calico-printer, or even a chemical manufacturer. These arts can only be learnt by practice on the large basis of practical experience, and all that Polytechnic Schools can do is to prepare the ground for a proper reception of that practical experience by a sound training in scientific principles.* This scientific training is, however, just as much the special work of the University as of the Polytechnicum, and there appears to be no valid reason for the separate existence, often side by side in one town, of a University and a Polytechnic School. On many grounds the absorption of the Polytechnicum by the University appears advisable. In the first place there is room to fear that a due supply of thoroughly good teachers, especially in science—at least in the higher positions—cannot be secured for institutions perpetually growing in number, while, on the other hand, a great waste of power is caused where such institutions exist side by side, as many of the professorships, being common to Universities and Polytechnic Schools, are thus twice represented.

Again, serious harm must come from the tendency which this separation of the Polytechnic School from the University has to foster the narrow one-sidedness already so strong in the extreme partisans of the one and the other group of studies. The Universities would suffer by the weakening in them of those branches of pure and applied science which have always been and must continue to be studied there. The Polytechnic schools would suffer (and already do suffer) from the tendency, thus encouraged, to neglect the *educational* aspects of science in considering its practical applications. How great the gain has been to the branches of the liberal arts and sciences from their alliance in Universities, the history of Universities from their first foundation abundantly shows: and it is difficult to see any sufficient reason why the applied sciences, such as Engineering, in their professional aspect should not have their proper place in the organisation of the University, exactly as Theology, Law, and Medicine have long had their place, to the great advantage both of these studies themselves and of the non-professional studies with which they have been brought into contact.

Signs are already observable in Germany, according to the highest authorities, that the zeal for teaching science in its application to the practical arts is encroaching on the domain of science proper, and that science will be deteriorated without, at the same time, industry being advanced. The true work of institutions,

* This is clearly admitted in certain cases by the Polytechnic authorities themselves. Thus I find in the regulations of the Carlsruhe Agricultural School the following words printed in large type:—"This school is concerned with the cultivation of the mind of the student, not with learning the technical operations of agriculture."

founded with the special aim of fostering the industrial arts, should be to insist on teaching *principles* systematically, and not in their isolated applications. To treat of the applications of the science is, of course, necessary, even for the sake of science itself; and under certain circumstances, some of these applications may wisely be dwelt on more than others; but this is quite a different thing from pretending to teach as *science* detached *fragments* of science in their application to this or that art.

The following extract from a well-known essay by Liebig, written so long ago as 1840, clearly shows that his views on this question coincide with those above expressed:—

"The teaching of science in the laboratories of the Trade—and Polytechnic—Schools is, in most places (in Prussia), very deficient. A system of true scientific instruction should fit a student for each and every possible application of science; for these applications become easy, and follow as a matter of course, from a knowledge of scientific principles. Nothing is more deleterious or dangerous than when utilitarianism is made the foundation of a system of tuition in a school, or when institutions, whose true aim ought to be experimental instruction in scientific principles, are employed to convert mere children into soap-boilers, brandy-distillers, or sulphuric acid makers. All this entirely destroys the true purpose of the institution.

"I have found, in all those attending my laboratory who intended to pursue a technical course of study, a general predisposition to devote themselves to some branch of applied chemistry. It is only with feelings of fear and trepidation that they consent to follow my advice, and give up the time they thus waste on mere drudgery to making themselves acquainted with the methods by which pure scientific problems are soluble, and by which alone they can be solved. . . . . There are many of my pupils, now at the head of many departments of manufacturing industry, who, having had no previous acquaintance with the processes, were in half an hour perfectly *au fait* with all the details of the manufacture, whilst in a short time they saw and introduced all sorts of necessary reforms and improvements. This power they had gained by being accustomed in their laboratory work to obtain the most accurate and precise knowledge of all the substances which came into their hands in their work; they had to learn the conditions necessary for avoiding errors, they investigated the properties of the products of decomposition formed, and thus became acquainted with the sources of error, with the means of avoiding losses; they were able to improve their apparatus, and to amend their processes. All this can never be learnt when the work is conducted according to cut-and-dry methods."

There are, no doubt, certain obstacles in the way of the proposed amalgamation in Germany; but in the old English Universities, and in the science colleges which we hope soon to see established in various parts of England, the difficulty would not arise at all. Apart from questions of tradition and historical routine, there can be no reason why students of applied science, led by their probable destination to manufacturing industry, should not study systematic science in the same class-rooms with students of the same subject who may have other aims: and if such students require minute practical and experimental instruction, there is no reason why they should not obtain this in physical and mechanical, as they do already in chemical, laboratories. In such a technical department, future teachers of science and leaders of manufacturing industry would be trained in the application of science to the most important branches of art and manufacture—so far, that is, as these are fit subjects for academic treatment; so far as they are not, they must be left to the workshop.

H. E. ROSCOE

VON SCHLICHT ON FORAMINIFERA

Die Foraminiferen des Septarienthones von Pietzpuhl. By E. von Schlicht. 4to. With 38 lithographic plates. (Berlin, 1870. London: Williams and Norgate.)

SINCE the appearance of D'Orbigny's "Foraminifères Fossiles du Bassin Tertiaire de Vienne," no work has been issued on the Foraminifera in their geological or palæontological relations, with pretensions at all corresponding to those of the newly-published monograph, the title of which stands at the head of the present article. We do not use the word *pretensions* in an offensive sense, for the author is careful to apprise his readers of the limitations of the treatise; but rather to indicate the sort of impression produced by the dimensions of the book and its profuse illustration. A quarto volume containing, in addition to the letter-press, thirty-eight large plates devoted to the Foraminifera of a small division of the Tertiary system of North Germany, and confined to a very limited district, or, as we might put it, 1,192 drawings of microscopic shells from the clay of a single brickyard, ought to show in its results a very evident *raison d'être* to save it from the imputation of labour thrown away. We need not require the expression of new or startling philosophical views to bring such a work within the scope of things worth doing; but we may fairly expect from so large an expenditure of labour and cost, some real and definite addition to our scientific knowledge. Whilst a smaller book might pass unnoticed, or at least without critical examination, one like this cannot escape without an inquiry as to what it contains of novelty, either in observation or theory,—in facts or their arrangement; and on the reply dictated by a patient study of its contents, the verdict as to its value must depend. To frame an answer to these questions which will serve to give an idea of the work, it will be necessary to offer a few preliminary observations and to epitomise the labours of previous observers in the same field.

In the Tertiary system of Belgium, and Northern and Central Germany, there occurs a thick bed of clay, containing nodules of argillaceous limestone, with radiating cracks or fissures in their interior, which have become filled with calc-spar. These nodules are termed "septaria," and they are regarded as sufficiently characteristic of the deposit to give it a name, though possibly a somewhat indefinite one. As used by German authors, the term "Septarienthon" includes the Rupelian clays of Rupelmonde and Boom, near Antwerp, the brick-clays of the neighbourhood of Berlin, together with similar beds in the valleys of the Maine and Elbe, and in many other localities between the Baltic and the centre of Germany. These beds are of Lower Miocene or Upper Eocene age, and belong to a group of transition strata, associated by continental geologists under the name "Oligocene," which are scarcely represented in Great Britain. Possibly the fluvio-marine beds of the Isle of Wight are the nearest equivalent to be found in the Tertiaries of this country.*

The exact geological position of the Septaria-clay is of less consequence to our present purpose than the general fact that it was deposited some time during that earlier or middle Tertiary period in which the Foraminifera, as a zoological group, had their most conspicuous development. It is not surprising that so promising a field should have been diligently worked by German rhizopodists, and it may be questioned whether any single bed, or group of beds, has received so large an amount of attention in respect to its microzoa. The particular locality to which Herr von Schlicht's researches refer, is the estate or manor of Pietzpuhl, which lies at the highest point of a Tertiary ridge, commencing at the river Elbe, a little north of Magdeburg, and extending in an easterly direction above Möckern to Loburg,—a course of eighteen or twenty English miles. The clay-bed is worked at Pietzpuhl for bricks or some other economical purpose, and being open to-day, the investigation of its fossil fauna presents no preliminary difficulties.

Attention was first directed to the microzoa of the Septaria-clay just twenty years ago, in two letters from Herr Reuss (then of Bilin) to Herr Beyrich, on "Foraminifera in Clay, from Hermsdorf,"† which appeared in the Journal of the German Geological Society. These communications contained little beyond a list of the genera represented; but a year later, a third letter was published,‡ containing a good deal of supplementary information, and in 1851 Professor Reuss published a more elaborate paper "On the Fossil Foraminifera and Entomostraca of the Septaria-clays of the neighbourhood of Berlin,"§ containing the results of the examination of the beds described by Prof. Beyrich, together with a tabular comparison of the species obtained at Hermsdorf and Freienwalde with those of other well-known Tertiary deposits, such as the Miocene of the Vienna Basin and the sub-Appenine Pliocene clays. The table presents a series of sixty-five species, and of these, fifty-three are described and figured as "new." All except four of them were obtained from Hermsdorf. We will not enter into any analysis of the catalogue, else we might be tempted to exceed our bounds, in criticism on the new species.

Another letter from Prof. Reuss‖ gave similar particulars respecting two fresh localities, viz:—Gorzig near Köthen, and the excavations of Fort Leopold at Stettin. Shortly afterwards, appeared an elaborate paper by Dr. J. C. Bornemann of Leipsic on the "Microscopical Fauna of the Septaria-clay of Hermsdorf, near Berlin** containing much of novelty and interest, and adding forty-six more "new species" of Foraminifera to an already extensive list. The figures of many of these show curious modifications of the simpler types, those of the genus *Polymorphina* being especially instructive. In 1858 Prof. Reuss contributed a further instalment to the literature of the subject in his paper "On the Foraminifera of Pietzpuhl," †† and this concerns our present purpose more directly, as it is stated to be the first result of the author's examination of the specimens in Herr von Schlicht's collection. It is, however, little more than a catalogue, and introduces by name seventy-two more "new species," without either figures or descriptions.

Six years later Prof. Reuss published in the Reports of the Vienna Academy his researches "On the Foraminifera of the Septaria-clay of Offenbach"* near Frankfort, figuring therein forty-four more new species; and finally, in 1866, amongst the memoirs presented to the same scientific body appears an elaborate monograph by Prof. Reuss, entitled "The Foraminifera, Anthozoa, and Bryozoa of the German Septaria-beds,"† one of the most instructive, as well as one of the most beautifully illustrated of the author's many contributions to the history of the fossil Protozoa and Cœlenterata. This paper is not devoted, like its predecessors, to the description of new species, but is rather an epitome of the facts already known, with additional information as to distribution. It is supplemented by a comparative table of the geological and geographical relations of 228 reputed species, which is a sort of concentrated essence of the whole. Without compromising our radical objection to the system of sub-dividing and renaming, time after time, forms having the same essential characters, on account of minute and very variable peculiarities, or of regarding a slight difference in geological age as a reason for constituting a new species in cases where zoological characters fail to show ground of distinction, we may cheerfully yield to Prof. Reuss our tribute of admiration for his final summary of what was known of the microzoa of the Septaria-clay.

These bibliographical details have appeared necessary because the field of research to which they refer is one with which British palæontologists have little opportunity of becoming practically acquainted; and our object in respect to Herr von Schlicht's work is half accomplished now that we have indicated the amount of labour previously expended on the same subject.

Herr von Schlicht introduces his monograph by a preface of seven pages, comprising the readable matter of the volume. This introductory essay deals in generalities rather than new truths, and the apology of the author constitutes its chief novelty. After a few preliminary paragraphs he mourns the shortcomings of the work in respect to classification, nomenclature, and other important matters. Of the systems of classification, Prof. Reuss's, as last amended, is alone spoken of with much commendation; that of Prof. Max Schultze receives bare mention, as do also the views of British rhizopodists. "After all," asks the author, "do we know enough yet about the Foraminifera to invent any classification of them? Some people think not; and so, on the whole, although the early D'Orbignyan arrangement is the worst, it is pretty well known, and it will be the least trouble."

It may be that the systematic scheme laid down by Prof. Reuss is faulty: in this we should agree with Herr von Schlicht, though on different grounds; but it has a basis of natural relationship in its larger groups, wholly wanting in that of D'Orbigny. That a general harmony should exist between its sub-divisions and those indicated

by the independent researches of Dr. Carpenter and his colleagues in this country, is surely strong evidence in its favour; and the fact of its having been used in the latest publications on the particular subject of the work, gave it a strong claim for introduction, in spite of the alleged possibility of subsequent modification.

The author further laments the imperfection caused by his omission of specific or trivial names. In the prospect of a new and better classification, with the possible employment of different criteria for the separation of genera and species, every new specific name would, he thinks, only serve to increase the present confusion in nomenclature, and to augment the difficulties of future observers; besides, hints the author shrewdly, "thereby I have spared to myself a notable piece of labour." So the honour of appending specific names is willingly bequeathed to the future systematist who shall investigate the new forms, and who, we agree with Herr von Schlicht, will not be overpaid for his trouble.

Thus we are warned at the outset that, so far as nomenclature is concerned, no advantage is taken of the mass of plates which occupies half the volume. And yet, oddly enough, the author does name *one* of his figures—an attenuated, slightly curved, costate Nodosarian, with broad, clear, somewhat irregular sutures and pointed ends. This he calls *Dentalina edelina n.s.*, a name that might very well have been spared.

Notwithstanding the absence of trivial names, *genera* are recognised, and detailed descriptions are given of the specimens figured, with references to the plates. Thirty-two genera are adopted (two of them new), and *numbers* from 1 to 556, are appended to the descriptions instead of *names*. Some of the old generic terms employed are already regarded as untenable by those who had been in the habit of using them, and the two new ones are certainly needless. One of them, "*Atractolina*," represents a mixed lot of forms, some of them possibly compact fusiform *Polymorphinæ*, the remainder doubtful *Nodosarinæ*. In the case of two generic types which inosculate in their feebler varieties, as these most certainly do, we are ready to admit the difficulty of determining to which group a number of the intermediate forms belong; but to make a fresh sub-division for them cuts the knot rather than unties it. The other new genus, "*Rostrolina*," has no better foundation, based as it is on the mere shape of the terminal orifice—a straight or curved slit in the mucronate terminal chamber, instead of the circular or radiate aperture usually found. Specimens with this peculiarity have long been known, but have been regarded as mere individual modifications, and no previous writer has thought it necessary to invent even a specific name for them.

A good deal of criticism might be expended on the subdivisions and their arrangement, but we content ourselves with the passing remark that Reuss's type *Chilostomella* is out of place amongst the *Polymorphinidæ*, and that *Bolivina* is far separated by the author from *Bulimina*, which is its nearest ally.

We may sum up in a few sentences. Notwithstanding the work falls far short of what it might have been in many important particulars, it is of considerable value. The omission of any attempt to simplify the nomenclature, with the opportunity the large number of plates offered for doing so excellent a service, is inexcusable. It may be doubted whether a single new specific name would have been needed, and the plates might have been made the basis of a large reduction in those already in use. The best point of all about the book is the completeness of many of the series represented,—the consecutive links in the chain between a number of reputed species being in many cases all figured. It more than once occurred to us in turning over the plates, there must be something of dry humour about an author who could suggest that anyone who named the new forms would deserve all the honour he could get out of them, and that the fasciculus of plates was intended to demonstrate that the system of species-splitting could not be carried further than it had been carried by some previous authors, short of naming every specimen. On the other hand, from the large number of drawings devoted to the illustration of the minute morphological variations of a few simple types, the work affords valuable testimony to the truth of the views enunciated by Mr. W. K. Parker in his earliest paper on the Miliolitidæ of the Indian Seas, as to the impossibility of sub-dividing these lowest classes of animals by hard lines corresponding to the specific limits of more highly organised creatures; that a long series of forms presenting an extraordinary range of morphological variation may be grouped round sub-types, several of which merging at their edges into each other, and without any perceptible lines of demarcation between them, find in their turn a common central type, and that this type more nearly than any minor division represents what we are accustomed to term a species. If we regard Herr von Schlicht's volume from this point of view, we may easily see how it may possess considerable value, though not exactly of the sort that was intended by its author.

We should just add, that though the paper and letterpress are excellent, the plates are scarcely equal in solidity and clearness to the lithographic work we have been accustomed to see in German memoirs on the Foraminifera.

H. B. BRADY

ENCKE THE ASTRONOMER

Johann Franz Encke: sein Leben und Wirken. Von. Dr. C. Bruhns. (Leipzig, 1869. London: Williams and Norgate.)

FOUR years have passed since Encke died. Even those four years have witnessed notable changes in the aspect of the science he loved so well. But we must look back over more than fifty years if we would form an estimate of the position of astronomy when Encke's most notable work was achieved. At Seeberge under Lindenau, Encke had been perfecting himself in the higher branches of mathematical calculation. He took the difficult work of determining the orbital motions of newly discovered comets under his special charge, and Dr. Bruhns tells us that every comet which was detected during Encke's stay at Seeberge was subjected to rigid scrutiny by the indefatigable mathematician. Before long a discovery of the utmost importance rewarded his persevering labours. Pons had detected on November 26, 1818, a comet of no very brilliant aspect, which was watched first at Marseilles, and then at Mannheim, until the 29th December. Encke next took up the work and tracked the comet until January 12. Combining the observations made between

December 22, and January 12, he assigned to the body a parabolic orbit. But he was not satisfied with the accordance between this path and the observed motions of the body. When he attempted to account for the motions of the comet by means of an orbit of comparatively short period, he was struck by the resemblance between the path thus deduced and that of Comet I, 1805. Gradually the idea dawned upon him that a new era was opening for science. Hitherto the only periodical comets which had been discovered, had travelled in orbits extending far out into space beyond the paths of the most distant known planets. But now Encke saw reason to believe that he had to deal with a comet travelling within the orbit of Jupiter. On February 5, he wrote to the eminent mathematician, Gauss, pointing out the results of his inquiries, and saying that he only waited for the encouragement and authority of his former teacher, to prosecute his researches to the end towards which they already seemed to point. Gauss, in reply, not only encouraged Encke to proceed, but counselled him as to the course he should pursue. The result we all know. Encke showed conclusively that the newly discovered comet travels in a path of short period, and that it had already made its appearance several times in our neighbourhood.

From the date of this discovery, Encke took high rank among the astronomers of Europe. His subsequent labours by no means fell short of the promise which this, his first notable achievement, had afforded. If, as an astronomical observer, he effected less than many of his contemporaries, he was surpassed by few as a manipulator of those abstruse formulæ by which the planetary perturbations are calculated. It was to the confidence engendered by this skill that we owe his celebrated discovery of the acceleration of the motion of the comet mentioned above. Assured that he had rightly estimated the disturbances to which the comet is subjected, he was able to pronounce confidently that some cause continually (though all but imperceptibly) impedes the passage of this body through space, and so, by one of those strange relations which the student of astronomy is familiar with, the continually retarded comet travels ever more swiftly along a continually diminishing orbit.

Bruhns' life of Encke is well worth reading, not only by those who are interested in Encke's fame and work as an astronomer, but by the general reader. Encke the man is presented to our view, as well as Encke the astronomer. With loving pains the pupil of the great astronomer handles the theme he has selected. The boyhood of Encke, his studies, his soldier life in the great uprising against Napoleon in 1813, and his work at the Seeberge Observatory; his labours on comets and asteroids; his investigations on the transits of 1761 and 1769; his life as an academician, and as director of an important observatory; his orations at festival and funeral; and lastly, his illness and death, are described in these pages by one who held Encke in grateful remembrance as "teacher and master," and as "a fatherly friend."

Not the least interesting feature of the work is the correspondence introduced into its pages. We find Encke in communication with Humboldt, with Bessel and Struve, with Hansen, Olbers, and Argelander; with a host, in fine, of living as well as of departed men of science.

R. A. PROCTOR

OUR BOOK SHELF

Elementary Introduction to Physiological Science. (London: Jarrold and Sons.)

ANY one may teach the higher branches of science; none but masters should dare to give elementary instruction. The truth of this fundamental article of the teacher's creed is very strikingly confirmed by this little book, which professes to give uninstructed persons some elementary knowledge—first, of the chief chemical products of animal and vegetable life; secondly, of vegetable physiology; and lastly, of animal physiology. One of the rules of teaching which a real teacher has soonest and most forcibly brought home to him says, "Never use an illustration if you can do as well without it." The practice of the author of this work is evidently, "Never miss a chance of using a metaphor, or simile, or image, or illustration that occurs to you. If it is 'striking' or 'homely,' use it as often as you can." The author possibly understands his subject; we cannot tell for certain whether he does or no, for we cannot disentangle the real things from his striking illustrations of them. We never know whether he is speaking soberly or in metaphor, and we are perfectly sure that a lad of lively imagination, reading this book by way of an introduction to biology, would get into his head such fearful and vivid ideas of what was going on inside plants and animals, that no subsequent teaching could ever set him right, and life would ever afterwards be a burden to him.

Compendium der Physiologie des Menschen. Von Prof. Julius Budge. Zweite Auflage. (Leipzig: Günther. London: Williams and Norgate.)

VERY truly called a compendium, an account of as many as possible of the facts of human physiology being compressed into about three or four hundred pages. To a reader ignorant of physiology, the book would probably be wholly unintelligible; to a German student about to undergo an examination in physiology, it would doubtless be very acceptable, for by it he might refresh his memory on every point about which he is likely to be questioned. Perhaps after all, however, it is well for the English student that we have nothing like it in the English language. The author, in the second edition, has done his best to bring the work up to the level of the most recent knowledge. Unfortunately, however, science will not stop while an author is correcting proofs; and this, like all works professing to give the latest results, records not the ultimate but the penultimate researches. This is not, however, of very great importance; for, as in so many German physiological investigations the ultimate result is the exact opposite of the penultimate, it is very easy to calculate out the former from the latter, and add it on.

Chenes de l'Amerique Tropicale.—*Iconographie des Espèces nouvelles ou peu connues. Ouvrage posthume de* F. M. Liebmann, *achevé et augmenté d'un aperçu sur la Classification des Chênes en général, par* A. S. Oersted. Copenhagen, 1868. 1 vol. folio, 29 pp. Tabb. 57.

LIEBMANN was occupied at the time of his decease in 1856 with a monograph of the American Oaks. He left behind him a number of folio copper-plate engravings which he intended for the illustration of his work, and brief descriptions of fifty-two new species. These were entrusted for publication to Prof. Oersted, who has put all in proper train, drawn up a valuable essay on the classificatory characters of the genus, prepared an analysis of many of the species, and added ten plates of leaves of various species of oak in physiotype,—making altogether an important contribution to illustrated botanical literature, and a worthy memento of his friend. Liebmann died comparatively young, about thirteen years after returning from his botanical expedition in Mexico, where he amassed very fine collections, which are still in course of determination and distribution by the Danish botanists. A short sketch of his life precedes Prof. Oersted's memoir, the substance of which had been already published in a scientific journal of Copenhagen.

The principal novel feature in Prof. Oersted's arrangement of the numerous species of oak—a genus including about 160 species in the Old World, and 120 in the New,—consists in the importance, for classificatory purposes, attributed to the form of the style and stigmatic surface. Upon these organs the sub-genera are chiefly based. We have had no opportunity of testing these characters, which it is unfortunate were not investigated by M. Alph. de Candolle, when preparing the *Cupuliferæ* for the "Prodromus," published in 1864. The omission of a Species-Index to the genus *Quercus* in the "Prodromus," makes it very tedious to ascertain how many of Liebmann's species are included in that work. Let us express the hope that in the final volume of this great work, yet to be published, we may be spared this annoyance in the case of the larger genera.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Prismatic Structure in Ice

OF late years attention has not unfrequently been called to this singular structure in ice, of which a number of instances are collected by the Rev. G. F. Browne, in his valuable book on the "Ice Caves of France and Switzerland" (chap. xviii.) In August, 1865, I had the opportunity of examining in his company some of these curious caverns; and since then have been on the look out for other instances of this structure. In January, 1867, I found it very well exhibited on a pond in Cambridge, an account of which may be found in the Proceedings of the Cambridge Philosophical Society, Part IV. and (more briefly) in my "Alpine Regions," pp. 94, 334. I again saw it last summer in a block of river or lake ice, which was brought on board a steamer at Christiansand (Norway) from an ice house. This block was about 8 inches thick. The prisms were rather irregular in form, the area of their ends varying from about a quarter of a square inch to one square inch, the sides being usually five or six in number. The prisms were at right angles to the planes of freezing, which were well marked.

These two were the only cases in which, from the first date until a few months back, I had succeeded in finding this prismatic structure clearly exhibited, but the present winter has proved very favourable to its development. I have seen it several times; in fact, after every severe frost; and under circumstances which have led me to suspect that I have often overlooked it on former occasions. In almost all the cases which I have lately noticed, the prisms were small, the area of their ends being generally about one-sixteenth of an inch. Hence, frequently the structure could not be detected without very close examination; as it was masked on the surface exposed to the air by the usual layer of disintegrating ice; and even when the under and unmelted side of a slab was examined, it had to be partly dried, before the delicate reticulation produced by the jointed structure could be observed by allowing the light to fall obliquely on it. The simplest mode of detecting it was to break the slab across, when instead of the usual conchoidal fracture of ice, a columnar structure was distinctly shown. Not unfrequently the first hint of its presence was given by the presence of a number of small holes in the under side of the slab. These, of course, were formed by water, which had trickled down from the thawing upper surface between the angles of the prisms, and had thus drilled itself a small tube. In one case—during a frost after a partial thaw—I found the structure mapped out, as it were, on the surface of the ice, but quite obliterated internally, except where some vertical lines of air bubbles marked the position of a tube or wider joint. In one of the cases above described, I totally obliterated the internal columnar structure by placing the ice in a freezing bath. I have often looked for, but never found it in glacier ice. I am therefore inclined to think that, though the large and strongly marked prisms are of comparatively rare occurrence, this finer structure may be found, if looked for, in every tolerably gradual thaw. Repeated examination has also convinced me that the structure has no immediate connexion with the hexagonal form of the ice crystals; the angles of the prisms are too irregular and variable to admit of this explanation. Their sides, however, so far as I have seen, are always at right angles to the surface of freezing, and are best developed when the temperature of the neighbouring air for a considerable time does not differ much from 32° Fahr. I therefore consider the structure to be produced by contraction in the ice as it approaches the melting point, and so to be analogous to the columnar structure in basalt, though due to a rise instead of to a fall in temperature.

St. John's College, Cambridge T. G. BONNEY

A Probable Cause of Malaria

SINCE men of science, such as Dr. Carpenter, Jeffreys, and Wyville Thomson, have proved by repeated and well-conducted experiments that there is life in the ocean,* that there are moving, sensible, living creatures, of nearly every description, in its deepest recesses, it seems rather an idle question, "de lanâ caprinâ," which has been raised lately about their manner of living there; how they get their food where no plant of any description has ever grown; whether they take in their food by *intussusception* with a mouth, or by that kind of oozing-in-and-out styled endosmose and exosmose,† or by any other kind of absorption, suiting the glair-like sarcodic stuff which the eozoon of old was made up of, and which is still at work in building, roll upon roll, the myriads and myriads of microscopic *Globigerinæ*.‡ Yet these seemingly idle questions when treated by men of science and of experience may become the source of discoveries far greater and more important perhaps than they anticipate.

Thus it is that the indefatigable Italian diatomist, Count Castracane, after having proved the very abundant growth of his puny *protégés* in the brackish waters of the *Maremme* and *Paludi pontine*, did not esteem it a bootless task to search for what they live upon, and also why they suddenly die away nearly all at once.

Such is the subject of a recent memoir which he has lately presented to the Roman Academy *Dei Lincei*, of which he is one of the most active members. After insisting upon the necessity of mastering the subject more thoroughly before attempting any new revision or classification of the diatoms, showing the system he had followed himself, and the results he had obtained, especially during the last year in making the round of the Istrian peninsula, taking his headquarters at Trieste and Pirano most particularly, where he gathered a rich harvest of very important materials for future study, he goes on to state that nothing is so fatal to the life of marine or even brackish water diatoms as a sprinkling of pure fresh water. This he proved by repeated and carefully performed experiments. From this fact he comes to the very probable conclusion that the sudden dying away of myriads of diatoms, besides, perhaps, myriads of other living creatures, during the rainy season might be, if not the only, at least one of the most efficient causes of *malaria*.

Before concluding this letter I wish to call the attention of the British scientific public to another Italian naturalist, M. A. Acorti, Professor of Natural History at the R. Gymnasium of Trieste, who has made the Adriatic a special subject of his studies, and is now engaged in the publication of the diatoms of that sea. "The sketching of his figures," says Count Castracane, "is of such beauty that I never saw anything better of the kind, and I hope they will be soon published that I may purchase them."

J. GAGLIARDI

* We have now plenty of living Protozoa, Radiata, Annulosa, Mollusca, and even of Vertebrata *abyssicolæ*.

† On account of the porous substance, which is a speciality of those wonderful beings, Johnstone has classed them under the significant name of *Amorphozoa porifera*.

‡ After the late remarks on this subject by Prof. Wyville Thomson in NATURE, it is curious to see the manner in which a Fellow of the Royal Society of the last century (John Ray) treated "the various ways of extracting the nutritious juice out of the aliment in several kinds of creatures. For oviparous quadrupeds," he says, "as chameleons, lizards, frogs, as also in all sorts of serpents" (there were, of course, no protozoa known in his time), "there is no mastication or comminution of the meat either in mouth or stomach; but as they swallow insects or other animals whole, so they void their skins unbroken, having a heat or spirits, powerful enough to extract the juice they have need of, without breaking that which contains it: as the Parisian Academists tell us. I" (subjoins Ray candidly) "cannot myself warrant the truth of the observation in all. I have taken two entire adult mice out of the stomach of an adder, whose neck was not bigger than my little finger. These creatures, I say, draw out the juice of what they swallow without any comminution, or so much as breaking the skin; even as it is seen that the juice of grapes is drawn as well from the rape (cluster), where they remain whole, as from the vat, where they are bruised, to borrow the Parisian philosopher's similitude."

The Motion of a Free Rotating Body

I SHALL feel obliged if, through the medium of your widely-circulated journal, you will allow me to point out an extraordinary mistake into which Mr. Radau has fallen, in a memoir inserted in the *Annales Scientifiques de l'Ecole Normale Supérieure* tom. vi. 1869, in which he criticises certain of my conclusions about the representation of the motion of a free rotating body contained in a paper published by me in the "Philosophical Transactions" for 1866. In his preamble, M. Radau says, speaking of the theory of rotation in connection with the names of Poinsot, Rueb, Jacobi, and Richelot:—"Tout récemment M. Sylvester a essayé d'appliquer au même sujet des considérations nouvelles qui l'ont conduite à des résultats intéressants, à côté d'autres dont l'exactitude peut être contesteé."

Later on in his memoir M. Radau points out, and accompanies with very biting (albeit toothless) criticism, the nature of his objection, which is, in short, that I suppose Poinsot's ellipsoid, under the influence of an original impulse, to roll without slipping by virtue of its friction against the plane with which it is in contact. My answer is, that of course I do. And why not? when I suppose the plane "indefinitely rough" (see p. 761 of "Philosophical Transactions," 1866), and have actually determined the friction and pressure at each point of the motion, so that by solving a maximum and minimum problem of one variable, the extreme value of the ratio of one of these forces to the other, or if we please to say so, the limiting angle of friction, or, in other words, the necessary degree of roughness of the plane may be analytically determined for every given case. M. Radau falls into the schoolboy blunder of making the *ratio between the friction and pressure constant throughout the motion*, confounding the actual friction with its limiting maximum value! It is, indeed, surprising that such a perversion of the facts of the case should have found insertion in a serious journal, such as that published by the Ecole Normale Supérieure, and I might fairly have expected from M. Radau the courtesy habitual with his adopted countrymen, of applying to me for information on anything in my paper which might have appeared to him obscure or erroneous, before rushing into print with such a *mare's nest*.

But out of evil cometh good. M. Radau says:—"Mais M. Sylvester va plus loin; il pense que le problème pourrait se résoudre par l'observation directe du mouvement d'un ellipsoide matériel tournant sur un plan fixe en même temps qu'il tournerait autour de son centre également fixe. On ne se figure pas facilement par quel artifice on fixerait le centre d'un ellipsoide matériel."

In a future number of your esteemed journal (as time at present fails me) I propose to show how, by the simplest contrivance in the world, a downright material top of ellipsoidal form may be actually made to roll, with its centre fixed, on a fixed plane and so exhibit to the eye the surprising spectacle of a motion precisely identical *in time*, as well as in its successive displacements of *position*, with that of a body, turning round a fixed centre, but otherwise absolutely unconstrained.

This mode of representation, which flashed upon my mind almost instantaneously when my eye first lighted upon M. Radau's objections, is the compensating good to the evil of being made the victim (to the temporary disturbance of my beloved tranquillity) of so hasty and futile a criticism as has been allowed insertion in the "Scientific Annals" of so great an institution as the Ecole Normale of Paris.

The *bureau de rédaction* must surely have been nodding when they allowed such observations, so easily refuted by turning to the original memoir, to pass unchallenged. It was only within the last few days that I received M. Radau's paper.

Athenæum Club, March 8 J. J. SYLVESTER

"Engrais Complet"

IN England many people have no faith in simple remedies with simple names, such, for instance, as brimstone and treacle; but make the same materials into a jam, disguise its flavour, and call it, say, the "Universal Purgative Extract," and then believers in its efficacy will soon be reckoned by the thousand. It seems from a review in a recent number of NATURE, that farmers in France are similarly incredulous on the subject of manures with intelligible names, that they require what is really useful to be mixed with something useless, and called "Engrais Complet," before they will apply it to their land. The English idiosyncracy benefits a large number of patent medicine vendors, and I presume this French variety of it benefits the manure merchants. Let us hope, however, that English farmers will continue to mix their own "Engrais Complet," obtaining, as heretofore, their nitrogen from farmyard manure, guano, and nitrogenous salts; their phosphorus from guano and superphosphate; their potash from organic excreta and potash salts. Under ordinary circumstances, with the Norfolk four-course system, the "Engrais Complet" for barley is left on the land by sheep feeding off roots and oil-cake; that for roots is farmyard manure and super-phosphate; that for wheat is clover roots, with a top-dressing of guano and salt. Clover requires little from the land but potash and good cultivation; but every crop should be fed well enough to leave something handsome for its successor.

Pray excuse my homely comparisons, for although a reader and I hope a student of NATURE, I am still

ONLY A CLOD

The Preservation of Mollusca

THE notice in a recent number of the use of creosote by M. Holbein for the preservation of mollusca, &c., leads me to remark that I have found it of great value for the preservation of coleoptera and other insects. The solution of creosote and water appears to be quite as effectual a preservative as alcohol, and does not harden the tissues or cause discoloration. After an immersion of about a week the solution should be drained off, and the insects placed in tins and covered with sawdust. Probably small reptiles, &c., could equally well be preserved in this way, which would save the danger of leakage and breakage which now ruins so many consignments.

Cambridge. J. R. CROTCH

Frankland and Duppa on the Action of Sodium on Acetic Ether

IN their recent communication to the Royal Society, reported in the last number of NATURE, Messrs. Frankland and Duppa ascribe my not getting hydrogen by the action of sodium on the acetic ethers to the high pressure existing in my sealed tubes.

How could there be a high pressure in my tubes unless I had first developed a large quantity of hydrogen? How then could it possibly be high pressure which prevented my getting any hydrogen? The pressure could not be due to the tension of the vapours of the acetic ethers, for in one experiment I employed acetate of amyl, which boils at 140° C., whilst I heated only to 100° C., and in this case, instead of getting 250 c.c. of gas, I got not a trace of gas. Moreover, the experiment with potassium was made in an open vessel.

On the other hand nothing is plainer than that Frankland and Duppa were operating upon alcohol as well as upon acetic ether, and hence their hydrogen.

London, March 3 J. ALFRED WANKLYN

Sir W. Thomson and Geological Time

I AM curious to know in which of his writings Sir W. Thomson makes the assertion "that there was a time when the earth rotated too swiftly for the existence of life." I cannot see how the assertion, even if it were true, could be of the least use in determining questions as to the length of time during which the earth has been habitable. Certainly it has not the slightest connection with Thomson's argument as to the date of consolidation of the earth, founded on its figure and on the retardation of its rotation by tidal friction. Yet the assertion is distinctly ascribed to Thomson—*first* in the *Pall Mall Gazette*, May 3, 1869, and *secondly* in the *Edinburgh Review* for January last.

If the passage quoted, or at least something resembling it, cannot be found in Thomson's writings, I am anxious to know whether the charge is due to simple stupidity on the part of the critics (or critic?), or whether it proves more?

G. H.

Little Gull (*Larus minutus*)

IN the proceedings of the Royal Physical Society of Edinburgh, as reported in NATURE, July 17, Dr. Smith notices the capture of a specimen of the Little Gull (*Larus minutus*) in Scotland, and remarks that it is a rare straggler to Scotland, only some two or three specimens having been previously recorded. Although rare in Scotland, it is by no means uncommon on the Yorkshire coast during the autumn and winter, and specimens are frequently shot during these seasons near Flamborough Head and along the Bridlington coast. This winter they have been more than usually plentiful. Mr. Richardson, of Beverley, in a letter dated February 18, informs me "I have received thirteen Little Gulls, shot on the Bridlington coast during the last fortnight, seven adults and six immature." And, in a recent communication, "There have been twenty-nine Little Gulls shot in all, nineteen old and ten young birds."

I have a photograph of an adult bird in breeding plumage, with the black head, shot at Flamborough on July 13, 1868.

Great Cotes, Ulceby, Feb. 25 JOHN CORDEAUX

THE MICROSCOPIC FAUNA OF THE ENGLISH FEN DISTRICT

THE results of some recent researches amongst the Entomostraca of the rivers and "broads" of Norfolk and the adjacent counties have proved so interesting that a brief *résumé* of the subject will probably not be unacceptable to the readers of NATURE.

My attention was first directed to the district in the following manner:—My friend, Mr. E. C. Davison, a gentleman attached to the staff of H.M.S. *Porcupine*, has for several years interested himself very kindly, during the annual cruises of the vessel, in collecting for me such Entomostraca and other Microzoa as came in his way. Amongst the gatherings which thus came into my hands were two samples of sand from the Dutch rivers Maas and Scheldt, some similar dredgings from the English river Ouse (Norfolk), and one from Oulton Broad in Suffolk. The Dutch gatherings had been in my hands for several years, and their ostracoda described in the "Annals and Magazine of Natural History," before I received those from the English localities. An examination of these at once revealed a remarkable similarity between the inhabitants of all the localities—several species, up to that time unknown in Britain, being recognised as identical with some of those taken in Holland. This interesting observation induced me, in company with Mr. D. Robertson, of Glasgow, to visit the Fen district with a view of more thoroughly investigating its microscopic fauna—an inquiry which has resulted in very much strengthening our original view as to its close relationship with that of Holland, and seeming, moreover, to indicate that we have in the English fens a very remarkable group of Ostracoda and Foraminifera marked out by a hard and fast line, and forming a district fauna quite unparalleled in its isolation, as regards the surrounding British species.

The fact of a partial relationship between the fauna of the Fen counties, or East Anglian district, as we may conveniently call it, and that of North-Western Europe is not new; and the best account of the matter that I know of may be found in an interesting article on "The Fens," by the Rev. Canon Kingsley, in *Good Words* for 1867. The facts which most prominently indicate this relationship are the presence of various fishes of the family Cyprinidæ—roach, dace, &c., which attain their highest development in the rivers and lakes of Sweden,—of the "bearded tit," now however probably nearly extinct, and of the remains of the fresh-water tortoise, *Emys lutaria*, now an inhabitant only of Central and Eastern Europe, and whose presence in England can scarcely be accounted for except on the supposition of a free river communication between our island and the Continent during a bygone geological epoch. That the Straits of Dover were, indeed, not very long ago (geologically speaking) bridged over by dry land, and that at that time the rivers of North-Western Europe emptied themselves into one great estuary situated between us and the Scandinavian peninsula are well-established facts; and it is as giving additional confirmation to this belief by exhibiting perhaps more fully than has previously been done the close relationship of the fluvial faunas of East Anglia and Holland, that our present observations claim their chief interest. For it is evident that two faunas, possessing in common, even according to our present imperfect knowledge, a considerable number of species at once very peculiar in character, apparently very restricted in their distribution, and separated at the present time by a wide expanse of sea, must have sprung originally from one common centre, and can scarcely have been finally separated for any great length of time. The fishes to which we have referred have indeed spread, either through natural or artificial agencies, from the eastern rivers to other parts of England and even to Ireland. But this crustacean fauna seems to be rigidly confined to the Fen district of Norfolk and Suffolk on the western side of the German Ocean, and to the rivers of Holland on the eastern side. We make this assertion with some reserve, because much yet remains to be done in the examination of aquatic microzoa everywhere, and it is just possible that some of those species which we take to be peculiar to the Fen fauna may turn up elsewhere. But we have ourselves examined dredgings from many English rivers, especially on the east coast, and have explored in the search for Entomostraca (though without dredging), the lake districts of England and Southern Scotland, without ever meeting with any of them. In no part of the continent of Europe have the Entomostraca received so much attention as in Scandinavia, where, if anywhere, we should expect a similar fauna to be found. But neither Müller, Lilljeborg, nor Sars appears to have met with such. Nor does M. Felix Plateau's recent memoir on the "Fresh-water Crustacea of Belgium" mention any similar species, though we cannot help thinking that had the dredge been used there, the result would have been different.

Out of about 180 known species of British Ostracoda, eighty may be frequently met with in river estuaries or in marine situations where much fresh water habitually mingles with the salt. Of these, thirteen may be considered as coming down to the debatable ground from the fresh-water side and fifty-six from the sea; the remaining eleven haunt brackish water almost exclusively, so much so, indeed, that were they found to any large extent in a fossiliferous deposit, we should have no hesitation in saying that it was produced under brackish conditions.

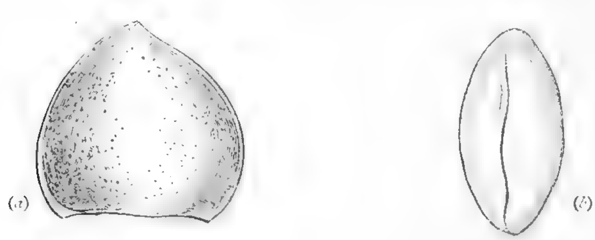
Of about 100 species and varieties found in the Fen district and its outlets, sixty-eight may be looked upon as usual inhabitants of either marine or estuarine situations. These are met with chiefly in the river outlets, and being, doubtless, derived from the sea may be left out of sight in any consideration of the fauna of the Fens. Again, nineteen are widely-distributed fresh-water species, of which little need be said except that those of the genus *Candona*, especially *C. compressa*, *albicans*, and *lactea*, seem here to attain a finer development and to exist in much greater abundance than in any other district. In connection with this it is curious to observe that the genus occupies an intermediate position between the crawling, non-natatory marine Cytheridæ and the freely swimming fresh-water Cyprides. Twelve (?) species, mostly undescribed, seem to be entirely or almost entirely confined to the fens of England and the corresponding districts of Holland, for we regard their appearance in dredgings from the estuaries of the Scheldt and Meuse as evidence, not of their *living* in those situations, but of their probable abundant existence nearer the water-head. Dead shells of the same species are met with in a similar manner in the river outlets of Norfolk, such as the Ouse and Breydon water, their real habitat being the fresh-water "broads" and the dykes and rivers as high up as, and very probably higher than, Peterborough and Ely.

The peculiar species of the district are the following:—*Goniocypris mitra*, Brady and Robertson; *Metacypris cordata*, B. and R.; *Cypris fretensis*, B. and R.; *Cypridopsis Newtoni*, B. and R.; *Candona Kingsleii*, B. and R.; *C. hyalina*, B. and R.; *Cythere fuscata*, Brady; *Limnicythere monstrifica*, Norman; *L. Sancti Patricii*, B. and R.; *Polycheles Stevensoni*, B. and R.; with some few other species of which few examples only have been found, and those are not yet fully worked out. Of the ten enumerated above, four of the most remarkable (*M. cordota, C. fuscata, P. Stevensoni, C. fretensis*) have occurred in the gatherings from the Meuse and Scheldt. The new species are not yet published, but will shortly be fully figured and described by the present writer, in conjunction with Mr. D. Robertson, in the *Annals and Magazine of Natural History.*

The Foraminifera of the broads and fen rivers are scarcely less interesting than the Entomostraca, and embrace some new species and varieties; we are not yet, however, in a position to institute any comparison between them and those of the Dutch rivers. One point of interest may

Polycheles Stevensoni, magnified 40 diameters: (*a*) seen from side; (*b*) seen from below. The young fry are seen through the translucent shell at its posterior end. The species is probably viviparous.

Metacypris cordata, magnified 84 diameters: (*a*) seen from side; (*b*) seen from below.



Goniocypris mitra, magnified 84 diameters: (*a*) seen rom side; (*b*) seen from below.

be noticed, that although, on the site of Whittlesea mere, Foraminifera are very abundant, scarcely any are to be met with in the river Nene, which is closely adjacent. This would seem to indicate that the faunas of the two places are independent of each other, or, at any rate, that the Foraminifera of the Fens are not recruited indirectly from the sea through the medium of river communication.

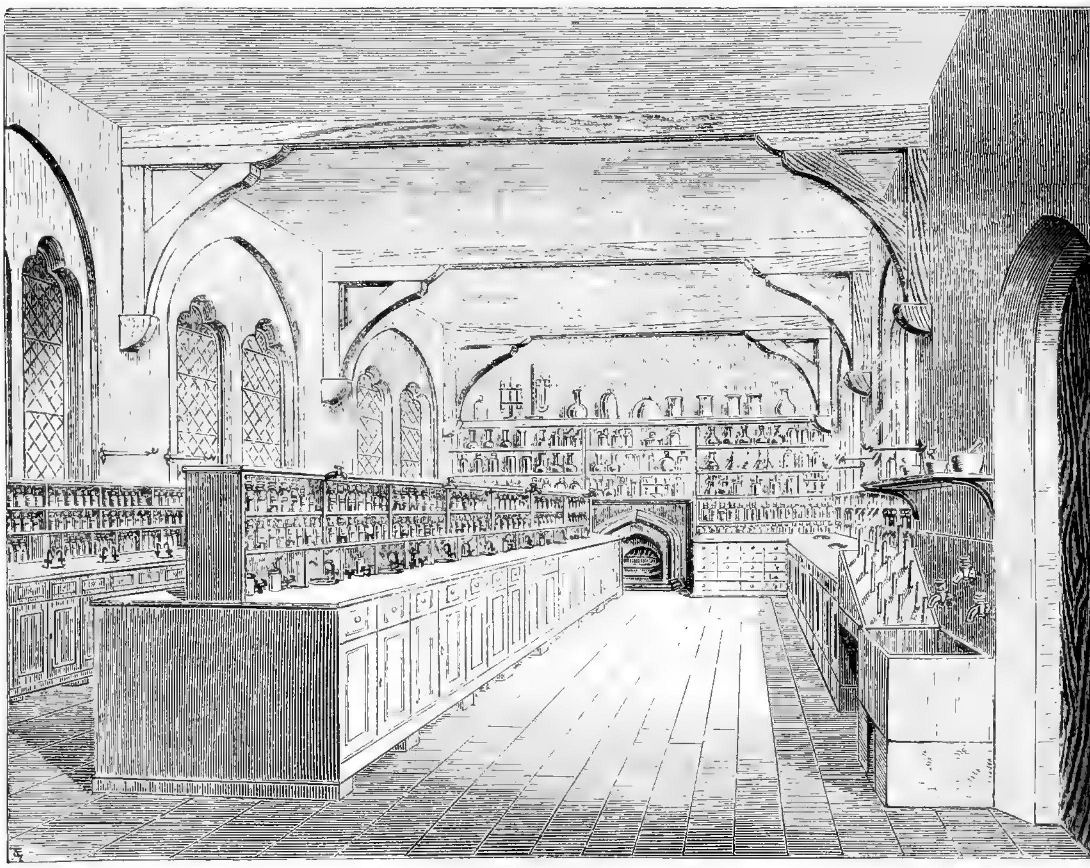
In conclusion it must be said that the free-swimming Entomostraca of the whole fen district present, so far as we have found, nothing calling for remark; many of the common fresh-water Lyncei and Copepoda are very abundant in the broads, rivers, and dykes, throughout the district; but had it not been for the use of the dredge we should have found nothing of great interest. *Not one* of the new species would have been found (though one of these is everywhere abundant, and some of the rest by no means rare), except *Goniocypris mitra*, of which one or two detached valves were observed in a gathering from Somerton Broad.

The explanation of the origin of this peculiar fauna is perhaps not very easy. If we might be allowed to speculate, we should say that it is probably the last surviving representative of a group of species which may have inhabited in remote times a large, lagoon-covered district possibly continuous between this country and Holland, the water of which we should suppose to have been ordinarily but slightly brackish. Possibly if this condition lasted during any great period of time, the species in question may have been developed by a process of modification from those inhabiting the estuaries on one side and the fresh water on the other. But two or three of them are so far removed in character from any others with which we are at present acquainted that it is impossible to speak more positively on the subject. Enough has been said to show that the subject is one of no little interest, and that the waters of the districts referred to would very probably well repay the labours of investigators in other departments of natural history.

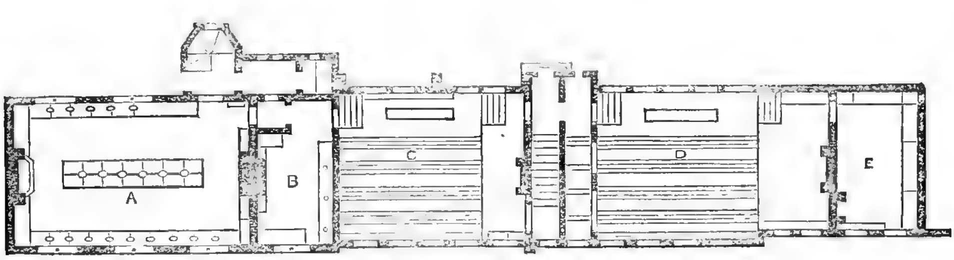
G. S. BRADY

THE NEW NATURAL SCIENCE SCHOOLS AT RUGBY

ALTHOUGH a brief notice of the new schools at Rugby has already appeared in the pages of this journal, a more detailed account of them may not be unacceptable to the readers of NATURE, especially at a time when so much attention is being paid to the subject of science teaching in schools.



GENERAL VIEW OF LABORATORY



GROUND PLAN

SCALE OF FEET

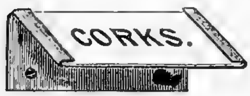
The accompanying ground-plan will show the general arrangement of the rooms.

The laboratory is 35 ft. by 22, and is intended to accommodate thirty boys. It is not, properly speaking, one of the new schools, as it was formerly the only Natural Science lecture-room; but it has been much altered and entirely refitted, in order to convert it into a laboratory. The working tables are divided into compartments, seven on each side of the centre table, and ten and six in those along the sides of the room. Each compartment comprises a cupboard and two drawers, two shelves for bottles, two gas taps, waste basin with water supply, and a working space of 3 ft. 6 in. by 1 ft. 9 in. The water taps and basins in the central table are placed so as to serve for boys working on either side, and thus much space is gained. The water taps have a small orifice, and are specially adapted for filling test tubes. A water pipe is also carried along the highest shelf and there are taps at intervals for filling tall vessels, for working with Liebig's condenser, &c.

The sink, with arrangements for washing and drying bottles, is seen near the door in the drawing.

At one end of the room is an open fireplace, with shelves and nests of drawers on either side. The drawers contain the various articles that are in general use in the laboratory, such as corks, cork-borers, elastic tubing, holders of different kinds, glass tubes and rods, &c. Every drawer is labelled on a simple plan that I find very convenient.

A bit of zinc is bent at an angle of 45°. The two edges of the one half are then just turned over, and the whole is screwed to the front of the drawer. A card slipped under the turned-down edges is held perfectly tight, and can be removed at any time. Labels so arranged are much more easily seen than if they were simply fastened to the face of the drawers. (One is shown in the figure.)



The lower shelves above the drawers contain all the dry chemicals required in Harcourt and Madan's "Practical Chemistry" (the book we chiefly use in the laboratory), together with the more costly re-agents, and others that are in less frequent use. Each boy has a complete set of all the ordinary acids and test solutions on the shelves of his compartment.

The contents of the drawers and shelves on either side of the fire-place are arranged in duplicate—a complete set on each side. In this way all chance of confusion and crowding is avoided, as no boy can have occasion to cross over from the side of the room on which he is working to the opposite side, everything being ready to his hand.

A common balance with sets of gramme weights is placed on the table above each nest of drawers. Here also are kept the various measuring flasks and cylinders. At the other end of the room is an ordinary six-feet kitchen range, which has been slightly modified so as to serve for a furnace. It has sand-bath, boiler, and drying-oven. On one side of the furnace is a cupboard to contain a stock of glass and porcelain apparatus. On the other side are two spacious evaporating closets with sliding glass doors. These are supplied with hoods and jets for creating a powerful draught. The draught can be still further increased, when necessary, by lighting a large ring of jets in the flue communicating with the closets.

A small cupboard for tools and a glass-blower's table complete the furniture of the laboratory.

The room marked B, in the ground plan, was formerly the only laboratory for the use of the school. It was built some years ago, at the same time as the Natural Science lecture-room, and, though small, was exceedingly well arranged. It is now converted into a private laboratory for the use of the chemical lecturer. It contains a large evaporating closet, also a sand-bath and distilling apparatus, both of which are worked by the fire in the school laboratory by means of appropriate dampers. Here also is the flue for obtaining a down-draught at the lecture-table in the adjoining chemical lecture theatre. As several pipes open into this flue it was found necessary to place the large ring of gas-jets for creating the draught at a considerable elevation above the floor. To light this ring an artifice was employed that it may be worth while to mention. A supplementary gas-pipe was carried alongside of the supply-pipe from a few feet above the floor to the ring of jets. This was pierced with small jets at short intervals all the way to the top. A separate tap turns on the gas in this pipe, and upon applying a light to the lowest jet the flame runs rapidly up the pipe and lights the ring at the top. The gas is then turned off from the supplementary pipe and the ring alone left burning.

From the private laboratory a door opens into the chemical lecture-room. This is provided with seats for fifty boys, the forms and desks rising tier above tier so that experiments at the lecture table are well seen by all. The down draught at the lecture table, already alluded to, is most useful. Experiments with chlorine may be performed with hardly any smell escaping.

The theatre is well supplied with shelves, cupboards, apparatus cases, diagram-screens, and black-board. There is also a capital cellar for stock chemicals, batteries and empty cases.

The Physical Science lecture theatre, D, is of still larger dimensions, and will hold sixty boys. A space at one end is fitted up with work-tables, &c., where experiments may be prepared, and also where boys may themselves learn how to use physical apparatus under the eye of a master.

The walls of the room, E, are entirely lined with glass cases for the reception of the school apparatus. Here, also, is a lathe with table-vice and bench, where an assistant, accustomed to mechanical work, can make various lecture illustrations, and repair instruments that are out of order.

I ought to add that the Natural Science Schools are only part of an extensive block of new buildings containing several classical and other schools, and that the whole has been erected from the designs of Mr. W. Butterfield. T. N. HUTCHINSON

NOTES

M. DELAUNAY is the new director of the Paris Observatory. We must congratulate the French Government upon their appointment. M. Delaunay, who has just received the Medal of our Royal Astronomical Society for his researches on the moon's motion, is an astronomer second to none, and is in every way admirably qualified for such an important post.

AT the Royal Society's Soirée on Saturday last, a number of interesting objects were exhibited, among which we may mention Mr. Roberts's specimens of electro-deposited iron; Mr. Siemens specimens of cast steel from the Landore-Siemens Works; a chronoscope of elaborate construction, exhibited by Capt. Noble, for recording at one observation the velocity with which a projectile passes different parts of the bore of a gun. The principle of this instrument is that of registering, by means of electric currents, upon a recording surface, travelling at a uniform and very high speed, the precise instant at which a shot passes certain defined points in the bore. It is capable of indicating intervals of time as minute as one-millionth part of a second. We shall again refer to some of the objects exhibited.

AT the meeting of the Royal Society last week, the names of the candidates for election, fifty-three in number, were read. From these, in accordance with the usual practice, fifteen will be chosen to be elected by the Fellows of the Society in June next. Last year the number of candidates was forty-five.

AT the same meeting two short papers were read from Mr. Le Sueur, who has charge of the great telescope at Melbourne, giving an account of his observations of some of the nebulæ included in Sir John Herschel's Cape Catalogue. The details are interesting, and full of promise for the future; as are also the particulars of spectroscopic observations of Jupiter which accompany the observations of nebulæ.

THE *Athenæum*, in reporting that Mr. Hind has issued a circular showing the path of the moon's shadow in the eclipse of the sun which will take place on the 22nd December, remarks that it is to be hoped that our Government will send out an expedition thoroughly equipped with spectroscopes to settle the nature of the corona; one of the last remaining questions of solar physics.

IT is satisfactory to know that the Municipal authorities of Glasgow are alive to the prospective benefits which their city is likely to gain, in a sanitary point of view, from the investigations which are to be instituted by the Sewage Committee of the British Association. If any city more than another needs the sanitarian besom it must surely be Glasgow, when it is remembered that it enjoys the unenviable notoriety of having the highest death-rate of all the great towns of the kingdom. Its desire to get this stigma removed is indicated by the fact that the Police Commissioners, at their last meeting, on the motion of a genuine sanitarian, the chairman of the Health Committee, voted the sum of 100*l.* towards defraying the expenses of the British Association Committee referred to above. We understand that the fund already amounts to upwards of 1,000*l.*

THE Swiney Lectures on Geology are to be delivered at the London Institution, by Dr. Cobbold, F.R.S., commencing on March 10th. During the course it is proposed to discuss, among other subjects, "The scope and tendency of the physical and biological sciences," "The best modes of acquiring adequate conceptions of geologic time," "Evidences of the incompleteness of the geological record," and "The claims of geology as an aid to the acquirement of high mental culture."

ON the 13th of January died F. T. Otto, Professor at the Polytechnic School of Brunswick, known chiefly as the translator of Graham's "Elements of Chemistry." Two editions of this translation having been rapidly sold, a third edition was commenced in 1852, in which the plan of the original was entirely changed. Otto treated mineral chemistry in three volumes; theoretical chemistry being reserved to Buff, Kopp and Zamminer, and organic chemistry to Kolbe and Fehling. Otto's chemical researches were not considerable. His books, however on the manufacture of vinegar and on agricultural industry are held in great esteem. Otto was born in Saxony in 1809.

THE paper to be read on Thursday at the Royal Society, by Mr. Warren de la Rue, Dr. Balfour Stewart, and Mr. Loewy, is expected to be of great interest.

PROFESSOR UNGER, of Vienna, a well-known botanist, whose death we reported last week, was, it is now stated, found murdered in his bed at Graz; and no trace of the murderer has as yet been discovered. A priest has taken this opportunity to assert from the pulpit at Cilly, Styria, that the body of the late philosopher had probably been destroyed by the devil himself, who had just claims upon his soul!

WE learn from the *Society of Arts Journal* that a Hygienic Council, attached to the Turkish Ministry of the Interior, has been created, with the function of improving the drainage, enforcing proper street scavengering and public cleanliness, both in the capital and throughout the provinces. Its further duty will be to improve existing civilian hospitals, and establish new ones where needed.

THE examination of candidates for the Royal Agricultural Society's prizes will take place in the week commencing 26th April.

THE Royal Asiatic Society offer to treat with any learned Society for the use of rooms in their new premises in Albemarle Street, which are more than they require.

THE *Photographic News* announces the death of Mr. Bingham, an English photographer long resident in Paris, and at one time assistant to Faraday.

THERE is a talk of an International Congress of Geographers at Antwerp. Many eminent French *savants* have promised to take part.

MR. ALGLAVE reports in the *Revue des Cours Scientifiques* that the Sars Fund now amounts to about 260*l.*

WE acknowledge the receipt of the ninth number of the *Free Sunday Advocate*, with a supplement, containing Professor Huxley's lecture "On the forefathers and forerunners of the English people"—a paper by Wm. Duthie, Esq, "On the social economy of Sunday, stating reasons for the opening of picture galleries, museums, and gardens, and running railway trains and steamboats on Sunday"—also the first of Dr. Carpenter's lectures "On the physical conditions and animal life of the deep sea."

Cosmos complains that the approaching réunion at the Sorbonne instead of being an assemblage of philosophers is to be merely a gathering of students, to compete for and receive prizes.

WE acknowledge the receipt of the Meteorological Tables for the Quarter ending 31st December last by Mr. Glaisher.

THE *Revue des Cours Scientifiques* states that the botanical collection formed by Baron Delessest, and since maintained by his son, who died lately, has been left to the town of Geneva. The library has been deposited in the Academy of Sciences.

WITH reference to Prof. Stanley Jevons's paper, read last month at the Royal Society, on the representation of logical processes by mechanism, it seems right to mention that Mr. Alfred Smee, F.R.S., published a book twenty years ago on the "Progress of Thought," in which engravings were given of a machine for the representation of mental operations. At present it is difficult to see what would be the utility of such machines; but if they are to be regarded as a step towards one that will some day be really useful, then the invention may be accepted as something more than an ingenious curiosity.

IN the report of the Royal Commission on Pollution of Rivers, the presence of arsenic in the water and mud of rivers near alkali works is pointed out, and it is also stated that the London sewage at Barking contains as much as ·004 of arsenic in 100,000 parts.

THE *Levant Herald* states that the Turkish Government is about to adopt the French Metric System. It is to be gradually brought into use. The oke very nearly corresponds to the kilogramme.

THE second of a course of weekly lectures on subjects connected with Economic Science, especially as concerned with labour and capital, under the auspices of the Social Science Association, was delivered inthe house of the Society of Arts, John Street, Adelphi, on Tuesday evening, by Frederick Hill, Esq., on "The Identity of the Interests of Employers and Workpeople." The chair taken by George Godwin, Esq.

THE Council of the Society of Arts will consider the award of the Albert medal early in May next.

AN injunction has been granted to restrain the Corporation of Leeds from discharging sewage into the river Aire.

THE first Exhibition of Spring Flowers at the Gardens of the Royal Botanic Society, is to take place on the 30th and 31st of this month.

AT a Session of the Council of University College, London, on Saturday last, Mr. George Grote, president, in the chair, Mr. Henry Maudsley, M.D. Lond., Fellow of the College, was appointed Professor of Medical Jurisprudence. A Whitworth Exhibition of 25*l.* was awarded to Mr. Robert Forsyth Scott, a student of the college.

THE new chemical laboratory erected for the use of the scholars at Eton College has just been opened for school purposes, under the superintendence of Mr. Madan. There are two large rooms, one of which will be used for lectures and the other for school purposes.

FROM a circular lately issued to the Government science teachers, we learn that the Lord President and the Vice-President of the Committee of Council on Education have found it advisable to modify the provisions of the Council's minute of the 30th November, 1869, in reference to the mode of paying those teachers for their arduous work of instructing the industrial classes in elementary science. Since the teachers held their meeting at Manchester, the complaint which they brought against the Science and Art Department of breach of faith, and repudiation of engagements made with them, has been pressed upon the Government by a strong force of Lancashire and Yorkshire members of Parliament.

THE *British Medical Journal* states that Prof. Agassiz is ill from nervous prostration and over-work, not being able even to write letters.

THE Gulstonian Lectures for this year will be delivered at the Royal College of Physicians, by Dr. Maudsley, on the 11th, 16th, and 18th of this month, the subject being "The Relations between Body and Mind, and between Mental and other Nervous Disorders." The Croonian Lectures will be on "Aneurism of the Heart," and will be delivered by Dr. Gibson on the 23rd, 25th, and 30th of March. The subject of the Lumleian Lectures on the 1st, 6th, and 8th of April, will be "The Natural History and Diagnosis of Intra-Thoracic Cancer," by Dr. J. R. Bennett. The lectures will commence in each case at 5 o'clock.

THE Acclimatation Society of Paris has awarded to Mr. P. L. Simmonds its silver medal, of the first class, for his paper on "Silk cultivation and supply," read before the Indian Conference of this Society last year. A similar medal has been awarded to Mr. G. W. Hart, of Hayling Island, for his labours in oyster culture.

THE Instituto Tecnico of Palermo has published another part of the *Giornale di Scienze Naturali ed Economiche*, which well sustains the character of the work. Among the papers therein contained we notice—"Avifauna del Modenese e della Sicilia," "Sui materiali per costruzione di mattoni refrattarii per le zolfare," "Nuove specie di funghi," "Determinazione del luogo chimico nelle sostanze aromatache," and "Studii palæontologici sulla fauna del calcario a telebratula janitor del nord di Sicilia." Besides all this, the part contains eight numbers of the *Bullettino* of the Royal Astronomical Observatory at Palermo, in which are records of observations astronomical and meteorological, notices of sun-spots and magnetic perturbations, and on shooting-stars and meteors, with lithographic illustrations. It is gratifying to find that even in Sicily science is making progress.

THE Government of India has lately sanctioned the commencement of the Damoodah Canal, at an estimated cost of about 540,000*l*. Its total length will be just 100 miles. One end of it will terminate in the heart of the Bengal coal-fields, and it will thus be the means of affording a cheap line of transport for carrying coals into Calcutta, relieving at the same time the railway of a portion of that traffic. A secondary but very important result of this canal is likely to be the drainage of the tract of land lying between the railway and the Damoodah, which for the last seven years has been desolated by malarious fever.

WE learn that the success of the Lectures for Women during the present term has equalled the most sanguine expectations of the originators of the scheme. Between seventy and eighty ladies are now attending eight courses of lectures, the number of attendances (counting each lecture separately) being in all 115. The committee proposes to issue in June a complete programme of the lectures for the next academical year. The present courses will be continued during the next (Easter) term at the present hours, unless special notice of a change be given.

WE have received from the Hydrographic Office of the Admiralty a copy of the notice to mariners stating that, on or about the 1st of April next, a telegraphic station vessel will be moored by the International Mid-Channel Telegraph Company off the entrance to the English Channel, in from fifty-five to fifty-nine fathoms water, in lat. 49° 20′ 30″ N., long. 6° 17′ W. of Greenwich. The vessel will be painted black, with the words "Telegraph Ship" in white letters on her sides; she will have three masts. At the top of the mainmast a large black cone will be hoisted during daytime, and a powerful globular light at night, elevated thirty feet above the sea, which in clear weather should be seen from a distance of six miles. A flare-up light will also be shown every fifteen minutes during the night, from an hour after sunset to an hour before sunrise. During foggy weather, day or night, a bell will be rung continuously for half a minute every quarter of an hour; and for the first six months, or until the 1st day of October 1870, a gun will be fired every quarter of an hour, and after that date every hour. The commercial code of signals for the use of all nations will be used on board, to the exclusion of all other codes, and none other can be noticed. In reference to this, M. Delehaye remarks in the *Bulletin* of the Association Scientifique of France that it will be of great service to navigation by saving time, and obviating risk and expense. For meteorological purposes also he believes this station will be very useful. He might have extended his list.

*ON THE TEMPERATURE AND ANIMAL LIFE OF THE DEEP SEA**

I.

THE present discourse embodies the most important general results obtained by the exploration of the deep sea in the neighbourhood of the British Isles, carried on during the summer of 1869 in H.M. surveying vessel *Porcupine*, with the view of completing and extending the inquiries commenced in the *Lightning* expedition of 1868, of which an account was given by the speaker at the Friday evening meeting of April 9, 1869.†

The expedition of the *Porcupine* was divided into three cruises. The first of these, which was placed under the scientific charge of Mr. J. Gwyn Jeffreys, F.R.S., accompanied by Mr. William L. Carpenter, as chemical assistant, commenced from Galway near the end of May, and concluded at Belfast at the beginning of July. It was directed in the first instance to the south-west, then to the west, and finally to the north-west as far as the Rockall Bank. The greatest depth at which temperature-sounding and dredging were carried on in this cruise was 1,476 fathoms; and these operations, through the excellent equipment of the *Porcupine* and the skill of her commander, Captain Calver, were so successfully performed, that it was confidently anticipated that still greater depths might be reached with an equally satisfactory result.

The second cruise, which was under the scientific charge of Prof. Wyville Thomson, F.R.S., with Mr. Hunter as chemical assistant, was consequently directed to the nearest point at which a depth of 2,500 fathoms was known to exist, viz., the northern extremity of the Bay of Biscay, about 250 miles to the west of Ushant. In this cruise temperature-sounding and dredging were carried down to the extraordinary depth of 2,345 fathoms, or nearly three miles—a depth nearly equal to the height of Mont Blanc, and exceeding by more than 500 fathoms that from which the Atlantic Cable was recovered. This sea-bed, on which the pressure of the superincumbent water is nearly three tons for every square inch, was found to support an abundance of animal life; about 1½ cwt. of "Atlantic mud," chiefly consisting of *Globigerinæ*, having been brought up in the dredge, together with various types of higher animals, Echinoderms, Annelids, Crustaceans, and Mollusks; among them a new Crinoid—referable, like the *Rhizocrinus*, whose discovery by M. Sars, jun., had been the starting-point of the present inquiry—to the *Apiocrinite* type which flourished during the Oolitic period.

The third cruise was under the scientific charge of the speaker, with Mr. P. H. Carpenter as chemical assistant; but he had the great advantage of being accompanied by his colleague Prof. Wyville Thomson, who, as in the *Lightning* expedition, took the entire superintendence of the dredging operations. The object of this cruise, which commenced in the middle of August and terminated in the middle of September, was a more thorough exploration of the area between the North of Scotland and the Faroe Islands, which had been found in the *Lightning* expedition to afford results of peculiar interest in regard alike to the inequality of temperature and to the distribution of animal life on the sea-bed, which here ranges between the comparatively shal-

* A Lecture delivered at the Royal Institution.
† Proceedings of the Royal Institution, vol. v. p. 503.

low depths of from 350 to 650 fathoms—the last-named being the greatest depth to which dredging had been carried in 1868.

The weather, during nearly the whole of the *Porcupine* expedition, was as favourable to its work, as during the greater part of the *Lightning* expedition it had been unfavourable; and the results obtained not only far exceeded the most sanguine expectations of those who had promoted it, but may be said, without exaggeration, to be such as no previous scientific exploration of so limited an extent and duration is known to have yielded.

The results of the temperature-soundings will be first stated, with their bearing on the doctrines advanced in the former discourse as probable inferences from the observations made during the *Lightning* expedition. These observations indicated that two very different submarine climates exist in the deep channel which lies E.N.E. and W.S.W. between the North of Scotland and the Faroe Banks; a minimum temperature of 32° having been registered in some parts of this channel, whilst in other parts of it, at the like depths, and with the same surface temperature (never varying much from 52°), the minimum temperature registered was never lower than 46°,—thus showing a difference of 14°. It could not be positively asserted that these minima are the bottom-temperatures of the Areas in which they respectively occur: but it was argued that they must almost necessarily be so:—first, because it is highly improbable that sea-water at 32° should overlie water at any higher temperature, which is specifically lighter than itself, unless the two strata have a motion in opposite directions sufficiently rapid to be recognisable; and secondly, because the nature of the animal life found on the bottom of the cold-area, which consists of quartzose sand including volcanic particles, exhibited a marked correspondence with its presumed reduction of temperature, whilst the sea-bed of the warm area is essentially composed of *Globigerina*-mud, and the animal life which it supports is characteristic of the warmer-temperate seas.

This conclusion, it is obvious, would not be invalidated by any error arising from the effect of pressure on the bulbs of the thermometers; since, although the actual minima might be, as was then surmised, from 2° to 4° below the recorded minima, the difference between temperatures taken at the same or nearly the same depths would remain unaffected.

The existence in the cold area, of a minimum temperature of 32°, with a Fauna essentially Boreal, could not, it was argued, be accounted for in any other way than by the supposition of an under-current of Polar water coming down from the north or north-east: whilst, conversely, the existence in the warm area, of a minimum temperature of 46°, extending to 500 or 600 fathoms' depth, in the latitude of 60° (being at least 8° above its isotherm), together with the warmer-temperate character of its Fauna, seemed equally indicative of a flow of equatorial waters from the south or south-west.

It was further urged that if the existence of two such different submarine climates in close proximity can only be accounted for on the hypothesis of an Arctic stream and an Equatorial stream running side by side (the latter also spreading over the former in consequence of its lower specific gravity), these streams are to be regarded (like the Gulf Stream) as particular cases of a great general Oceanic Circulation, which is continually bringing the water cooled-down in the Polar regions into the deepest parts of the Equatorial ocean-basins, whilst the water heated in the Equatorial regions moves towards the poles on or near the surface. Such a circulation was long since pointed out to be as much a physical necessity, as that interchange of *Air* between the Equatorial and Polar regions which has so large a share in the production of winds; but whilst physical geographers remained under the dominant idea that the temperature of the deep sea is everywhere 39°, they could not fully recognise its importance.

These doctrines have been fully tested by the very numerous and careful temperature-soundings taken in the *Porcupine* expedition; and the result has been not merely to confirm them in every particular—so that they may now take rank as established facts,—but also to show that a temperature 2½° below the freezing-point of fresh water may prevail over the sea-bed in a region far removed from the Polar, and that even this extreme reduction is by no means antagonistic to the existence of animal life in great variety and abundance.

All the temperature-soundings of the *Porcupine* expedition were taken with thermometers protected from the effects of pressure by the enclosure of the bulb of each instrument in an outer bulb, sealed round the neck of the tube; about three-fourths of the intervening space being filled with spirit, but a small vacuity being left, by which any reduction in the capacity of the outer bulb is prevented from communicating pressure to the inner. This plan of construction, which was suggested by Prof. W. A. Miller, has been so successfully carried into practice by Mr. Casella, that thermometers thus protected have been subjected to a pressure of three tons on the square inch, in a testing-machine devised for the purpose, without undergoing more than a very slight elevation, of which a part, at least, is attributable to the heat given out by the compression of the water in which they were immersed: whilst the very best thermometers of the ordinary construction were affected by the same pressure to the extent of 8° or 10°, the elevation in some instruments reaching as much as 50° or 60°.* Two of these protected Miller-Casella thermometers were used in each observation, and they always agreed within a fraction of a degree. The same pair was used throughout the expedition; and notwithstanding that they were used for 166 separate observations, in which they travelled up and down nearly 100 miles, they came back in perfectly good order; a result mainly due to the care with which they were handled by Captain Calver. It may be affirmed with great confidence that the temperatures which they indicated were correct within 1° (Fahr.); an approximation quite near enough for the scientific requirements of the case.

In order to connect the work of the *Porcupine* with that of the *Lightning* expedition, it will be desirable to commence with the third cruise of the former, in which a detailed survey was made of the area traversed in the preceding year by the latter. In this cruise bottom-soundings were taken at thirty-six different stations, at depths varying from 100 to 767 fathoms; of these, seventeen were in the cold area and fourteen in the warm, whilst five exhibited intermediate temperatures, in accordance with their border position between the two. In order to ascertain whether the minimum temperatures thus obtained were really the temperatures of the bottom, serial soundings were taken at three stations, of which one was in the warm area and two in the cold—the temperature at different depths between the surface and the bottom being ascertained by successive observations, at the same points, at intervals of 50 or 100 fathoms. All these results agreed extremely well with each other; and they closely accorded with the fifteen observations made in the *Lightning* expedition, when the requisite correction for pressure (from 2° to 3° according to the depth) was applied to the latter.

The following general summary of these results brings into marked contrast the conditions of the warm and cold areas, which occupy respectively the W.S.W. and E.N.E. portions of the Channel between the north of Scotland and the Faroe Islands, and lie side by side in its midst.

The surface-temperature may be said to be everywhere nearly the same, viz. 52°; the variations above and below this being attributable either to atmospheric differences (as wind, sunshine, &c.) or to difference of latitude. Alike in the warm and the cold areas there was a fall of from 3° to 4° in the first 50 fathoms, bringing down the temperature at that depth to 48°. A slow descent took place nearly at the same rate in both areas through the next 150 fathoms; the temperature in the warm area at the depth of 200 fathoms being 47°, whilst in the cold it was 45·7°. It is below this depth that the marked difference shows itself. For whilst in the warm area there is a slow and pretty uniform descent in the next 400 fathoms, amounting to less than four degrees in the whole, there is in the cold area, a descent of fifteen degrees in the next 100 fathoms, bringing down the temperature at 300 fathoms to 30·8°. Even this is not the lowest; for the serial soundings taken at depths intermediate between 300 and 640 fathoms (the latter being the greatest depth met with in the cold area, midway between the Faroe and the Shetland Islands) showed a further progressive descent; the lowest bottom-temperature met with being 29·6°. Thus, while the temperature of the superficial stratum of the water occupying the cold area clearly indicates its derivation from the same source as the general body of water occupying the warm area, the temperature of the deeper stratum, which may have a thickness of more than 2,000 feet,

* See Prof. W. A. Miller's "Note upon a Self-Registering Thermometer, adapted to Deep Sea Soundings," in "Proceedings of the Royal Society," June 17, 1869.—The same principle had been previously applied in thermometers constructed under the direction of Admiral Fitzroy; the space between the two bulbs, however, being occupied with mercury instead of spirit. Owing, however, to some imperfection in their construction, their performance was not satisfactory, and they were found very liable to fracture.

ranges from the freezing point of fresh water to 2½° below it. Between the two is a stratum of intermixture of about 100 fathoms thickness, which marks the transition between the warm superficial layer and the body of frigid water which occupies the deeper part of the channel.

The shortest distance within which these two contrasted submarine climates were observed at corresponding depths, was about 20 miles; but a much smaller distance was sufficient to produce it when the depth rapidly changed. Thus near the southern border of the deep channel, at a depth of 190 fathoms, the bottom-temperature was 48·7°; while only six miles off, where the depth had increased to 445 fathoms, the bottom-temperature was 30·1°. In the first case, the bottom evidently lay in the warm superficial stratum; whilst in the second it was overflowed by the deeper frigid stream.

It seems impossible to account for these phenomena on any other hypothesis than that of the direct derivation of this frigid water from the Arctic basin. And this agrees very well with other facts observed in the course of the exploration. Thus:—(1) The rapid descent of temperature marking the "stratum of intermixture" began about 50 fathoms nearer the surface in the most northerly portion of the cold area examined, than it did in the most southerly, as might be expected from the nearer proximity of the cold stream to its source. (2) The sand covering the bottom contains particles of volcanic minerals, probably brought down from Jan Mayen or Spitzbergen. (3) The Fauna of the cold area has a decidedly Boreal type; many of the animals which abound in it having been hitherto found only on the shores of Greenland, Iceland, or Spitzbergen.

Although the temperatures obtained in the warm areas do not afford the same striking evidence of the derivation of its whole body of water from a southern source, yet a careful examination of its condition seems fully to justify such an inference. For the water at 400 fathoms in lat. 59½° was only 2·4° colder than water at the same depth at the northern border of the Bay of Biscay, in a latitude more than 10° degrees to the south, where the surface-temperature was 62·7°; and the approximation of the two temperatures is yet nearer at still greater depths, the bottom-temperature at 767 fathoms at the former stations being 41·4°, whilst the temperature at 750 fathoms at the latter point was 42·5°. Now, as it may be certainly affirmed that the lowest temperature observed in the warm area is considerably above the isotherm of its latitude, and that this elevation could not be maintained against the cooling influence of the Arctic stream but for a continual supply of heat from a warmer region, the inference seems inevitable that the bulk of the water in the warm area must have come thither from the S.W. The influence of the Gulf Stream proper (meaning by this the body of superheated water which issues through the "Narrows" from the Gulf of Mexico), if it reaches this locality at all—which is very doubtful—could only affect the most superficial stratum; and the same may be said of the surface-drift caused by the prevalence of south-westerly winds, to which some have attributed the phenomena usually accounted for by the extension of the Gulf Stream to these regions. And the presence of the body of water which lies between 100 and 600 fathoms' depth, and the range of whose temperature is from 48° to 42°, can scarcely be accounted for on any other hypothesis than that of a great general movement of Equatorial water towards the Polar area; of which movement the Gulf Stream constitutes a peculiar case modified by local conditions. In like manner, the Arctic Stream which underlies the warm superficial stratum in our cold area, constitutes a peculiar case, modified by the local conditions to be presently explained, of a great general movement of Polar water towards the Equatorial area, which depresses the temperature of the deepest parts of the great Oceanic basins nearly to the freezing-point.

W. B. Carpenter

SOCIETIES AND ACADEMIES

London

Royal Society, March 3.—The following papers were read:—"Results of the Monthly Observations of Dip and Horizontal Force, made at the Kew Observatory, from April 1863 to March 1869 inclusive." By Dr. Balfour Stewart. "Spectroscopic observations on stars and nebulæ made with the Great Melbourne Telescope." By A. Le Sueur. "On the nebula of Argo, and on the spectrum of Jupiter." By A. Le Sueur. We shall return to these papers next week.

Geological Society, February 18.—Annual general meeting, Prof. T. H. Huxley, president, in the chair. The secretary read the Reports of the Council, of the Library and Museum Committee, and of the Auditors. The general position of the society, as evinced by the state of its finances, and by the continued increase in the number of its members, was stated to be very satisfactory. In presenting the Wollaston Gold Medal to John Evans, Esq., for transmission to M. G. P. Deshayes, the president requested him to transmit it to M. Deshayes as an expression on the part of the Geological Society of the high estimation in which his services to palæontology and geology, especially in regard to the classification of the tertiary formation, are held by the geologists of this country; adding, that six years ago the council of this society demonstrated the interest which it took in M. Deshayes's valuable investigations by awarding him the Donation-fund. Now that those researches, commenced just fifty years ago, are completed, and the labours of a life devoted to science are crowned by the publication of five great volumes containing descriptions and figures of all the mollusca of the Paris basin, it has seemed to the Council a fitting opportunity for bestowing the highest honour at its disposal upon the pupil, editor, and continuator of Lamarck, and the worthy successor of his great master in the Chair of Natural History in the Muséum d'Histoire Naturelle. Mr. Evans acknowledged on the part of M. Deshayes, the award of the Wollaston Medal, and read a letter from M. Deshayes expressing his sense of the honour conferred upon him. The president presented the balance of the proceeds of the Wollaston Donation-fund to Mr. Evans, for transmission to M. Rouault, Keeper of the Geological Museum at Rennes, in aid of his researches upon the Palæontology of the Devonian and Silurian Rocks of Brittany, and remarked that the cosmopolitanism of science was well illustrated by the fact that all the honours at the disposal of the society this year are gladly accorded to foreigners.—The President then read his anniversary address, prefaced by biographical notices of deceased Fellows, including Prof. Brayley, F.R.S.; Dr. Hermann von Meyer; Dr. B. Shumard; Dr. Roget, F.R.S.; Prof. Graham, F.R.S.; Prof. Jukes, F.R.S.; Dr. W. Clarke, F.R.S.; Mr. J. W. Salter; the Vicomte d'Archiac, &c. The ballot for the council and officers was taken, and the following were duly elected for the ensuing year:—President: Mr. Joseph Prestwich. Vice-Presidents: Sir P. de M. G. Egerton, R. A. C. Godwin-Austen, Sir Charles Lyell, Bart., Warrington W. Smyth. Secretaries: P. Martin Duncan, John Evans. Foreign Secretary: Professor D. T. Ansted. Treasurer: J. Gwyn Jeffreys. Council: Prof. D. T. Ansted, William Carruthers, W. Boyd Dawkins, P. Martin Duncan, Sir P. de M. G. Egerton, John Evans, David Forbes, J. Wickham Flower, Capt. Douglas Galton, R. A. C. Godwin-Austen, Harvey B. Holl, J. Whitaker Hulke, Prof. T. H. Huxley, J. Gwyn Jeffreys, Sir Charles Lyell, George Maw, John Carrick Moore, Prof. John Morris, Joseph Prestwich, Warrington W. Smyth, Rev. W. S. Symonds, Rev. Thomas Wiltshire, Henry Woodward.

Zoological Society, February 24.—Dr. E. Hamilton, V.P. in the chair. A communication was read from Mr. R. Swinhoe containing some information on the subject of the exact locality of the Amherst's pheasant (*Thaumalea amherstiæ*), which was stated to be the mountains between the Chinese province of Sechuen and Tibet.—A letter was read from Sir George Grey in reference to Professor Owen's communication of a letter from Dr. Haast read at the previous meeting. Sir G. Grey was of opinion that there were good grounds for believing that the *Dinornis* had been extirpated by the direct ancestors of the present race of Maories.—A second letter was read addressed to the Secretary by Mr. W. H. Hudson on the ornithology of Buenos Ayres.—Mr. Sclater exhibited a specimen of a new lemur, which had been lately discovered by Mr. Van Dam in North-eastern Madagascar, and had been named by Mr. Pollen *Propithecus damanus.*—Messrs. C. H. T. and G. F. L. Marshall read some notes on the classification of the birds of the family *Capitonidæ.*—Two communications were read from Mr. R. Swinhoe on the white wag-tails (*Motacillæ*) of China, and on a new species of *Accentor* from Northern China proposed to be called *A. erythropygius.*—Mr. P. L. Sclater read a paper on the deer living in the Society's menagerie, amongst which there were stated to be examples of several recently described and very little known species. Mr. Sclater concluded his paper with remarks on the arrangement and the geographical distribution of the *Cervidæ*, and in particular of the species of the genus *Cervus.* The total number of *Cervi* recognised as probably valid species were twenty-three in the Old World and seventeen in the New World.

Chemical Society, March 3.—Prof. Williamson, F.R.S, president, in the chair. Mr. Ch. P. Sandberg, of Stockholm, was elected a fellow of the society. The first paper was by Dr. Gladstone on "Refraction Equivalents," to which we shall return. The next paper was by Dr. Thudichum, on "Kryptophanic Acid," a normal ingredient of human urine. The substance is obtained from the primary material by first forming its lime salt, transforming this by neutral lead-acetate into lead-kryptophanate, and decomposing the latter by sulphuretted hydrogen. Kryptophanic acid is an amorphous, gummy mass, transparent and nearly colourless. It forms salts with the alkalis, the alkaline earths, and other metals. Mercuric nitrate produces in the aqueous solutions of its earthy salts a white precipitate; the ordinary analysis for urea is thus shown to be liable to error. The acid is dibasic, and has the formula $C_5H_9NO_5$, but in some instances it may be viewed as tetrabasic and in that case its formula must be written $C_{10}H_{18}N_2O_{10}$.

Linnean Society, March 3.—Mr. J. E. Howard read a paper by Mr. Broughton, chemist to the cinchona plantations in the Madras Presidency, "On hybridisation among cinchonas." He believes that the sub-varieties of *Cinchona officinalis* are permanent, but that hybrids can be artificially obtained, although they do not occur in nature. The cinchona has long been known to belong to the class of dimorphic plants. In the discussion which followed, Dr. Anderson, superintendent of the Botanic Gardens at Calcutta, gave some interesting particulars of the cultivation of cinchona at the Darjeeling plantations.—Dr. Hooker read a very interesting and important communication from Sir Henry Barkly, Governor of Mauritius, on the "Fauna and Flora of Round Island," a very little-known dependency of that colony. Although only about twenty-five miles from Port St. Louis, and the intervening sea not more than 400 feet deep, both plants and animals differ not only in species, but also in genera, from those of the Mauritius. The exploring party were only in the island one day, but during that time they captured four species of snakes and several lizards, no species of either family being found in the Mauritius. The insects and shells obtained were also peculiar, one of the latter being a *Cyclostoma.* Of flowering plants only twenty-four species were collected, but of these more than half were not natives of the Mauritius, including three species of palm, a *Pandanus*, or screw-pine, and two species of ebony. One of the palms is between thirty and forty feet high; another is similar to the Mauritian *Areca alba*, but different; and a third has a most remarkable bottle-shaped stem. Round Island is only about three miles in circumference and one and a quarter across. It consists of a mound of tufa about 1,000 feet in height, very little vegetation being found in the lower part. Sir H. Barkly believes the area to be one of elevation rather than subsidence.

Royal Archæological Institute, March 4.—The following papers were read:—"Remarks on a piece of Roman sculpture, found at Sens, and representing fresco painting." By Mr. J. G. Waller.—"On the Emerald Vernicle of the Vatican, with notices of other ancient portraitures of Our Saviour." By Mr. C. W. King, M.A.—"On an ancient Alms-box, found at Browne's Hospital, Stamford." By the Rev. C. Nevinson, warden of the hospital. Among the objects exhibited were a drawing of a leaden vessel containing Roman coins, found in Cornwall, by the Hon. W. O. Stanley, M.P.—Fragment of Anglo-Saxon M.S., found at Stamford Court, Worcester, by Sir T. E. Winnington, Bart.—Silver plate engraved with historical and allegorical subject, three portraits in Dresden porcelain, by Mr. Octavius Morgan, M.P.—Stone and bronze implements, found in Lincolnshire, by the Rev. E. Jarvis.

Anthropological Society, March 1.—Dr. Beigel, V.P., in the chair. Mr. Robert Wright and Dr. Hilliard, were elected Fellows. "On the Circassian slaves and the Sultan's harem." By Major Millingen. The author showed by what means the Turks insured to themselves in former days a supply of white slaves, so as to recruit their armies and their harems. The facts stated by the author with regard to the slave-trade seemed to prove that, from the highest to the lowest, all the ladies of Constantinople, those at least who have capital to invest, are regular slave-dealers. The author subsequently showed that the use of white slaves is a necessity for Mussulman nations on religious, social, and state-policy reasons, as slavery serves to keep women under subjection and in a state of seclusion; while politically it is indispensable for the maintenance of the reigning dynasty, whose matrimonial alliance with any other but slaves is against the statutes of the empire. A description of the seraglio then followed, its organisation being accurately exposed, while ample details were given concerning the wives and odalisks of the Sultan. In the seraglio the lot of the Circassian slaves was said to be better than that which befalls the generality of slaves; there they are provided with everything, and can attain high honours and power. The system was condemned by the author on account of its being a source of ruin and depravity for both slave and master. The author maintained that it is impossible that the Turks should seriously think of doing away with slavery for the reason that it is so much a part of the social and political edifice, that an attempt to alter the existing state of things would inevitably hasten its downfall. In conclusion, he said that if the Turks, instead of importing women and good-for-nothing slaves, had given their minds to peopling their half-deserted country with an emigration of hardy and industrious men, Turkey might be now at the head of the civilised countries of the earth.—Mr. E. Charlesworth exhibited some remarkable flint implements from Honduras.

Royal Geographical Society, February 14.—Sir R. Murchison, president, in the chair. "On the Runn of Cutch and neighbouring regions." By Sir Bartle Frere. The author defined the region as a broad belt of country between the Indus on the west and the Arivalli Mountains on the east, extending from the Himalaya to the Peninsula of Cutch on the Indian Ocean; the length was about 600 miles, and its breadth varied from 100 to 150 miles. The southern portion, called the Runn of Cutch, forms a level plain 150 miles in length, distinguished by the total absence of vegetation. It forms, during the greater part of the year, a plain of firm sand, saturated with salt, on which the hoofs of horses and camels in passing make scarcely any impression. It is so level that a heavy rainfall remains like a vast slop on the surface, and is blown about by the wind until it evaporates. During the south-west monsoon, however, the high tides flow into it and cover it with water to the depth of one or two feet. Travellers and caravans pass over it, but are sometimes lost, for there are absolutely no landmarks; the danger is somewhat lessened on the side of the hills of Cutch by a beacon-fire which is regularly lighted by a Mahommedan family there settled, to whom has descended the religious duty of thus guiding the wandering traveller over this desolate waste. The surface remains damp even in the driest season, and the soil never pulverises. Mirage and other surprising atmospheric phenomena are common in this singular district. North of the Runn the desert waterless tract is called the Thurr. The whole region slopes very gradually from the sub-Himalayan ranges, between the Jumna and the Sutlej, towards the south-west. The rivers descending from these lower ranges disappear as they advance into the desert, and none of them reach the Indus. The Thurr is covered with a constant succession of sandy ridges, rising as high as 200 feet above the valleys, and the aspect of the country is that of a billowy ocean converted into sand. In districts where rain falls and where the inhabitants have dug wells, some of which are 300 feet deep, there are cultivation and settlements; but the soil is throughout sandy, and over the whole region not a stone can be found that is not imported. That part where there is a hard level plain with abrupt sandhills, is called the "Put." Sir Bartle believed that the native terms of "Runn," "Thurr," and "Put," might be adopted in physical geography as denoting varieties of plain which are totally unlike savannah, prairie, steppe, pampa, or any other known description of land-surface. Travellers in attempting to cross the Thurr are subject to sudden death, not, as might be supposed, from the effects of sunstroke, but from some peculiar condition of the atmosphere connected with the intense heat and the nature of the soil, most of the fatal attacks occurring after sunset. The Runn of Cutch and the region north of it are much subject to volcanic disturbance. The great earthquake of 1819 is still remembered by the inhabitants; it was described by Lieutenant Burns, in an admirable paper on the Indus, read before the Royal Geographical Society in 1833. Sir Bartle was inclined to attribute the singular levelness of the salt-plain of Cutch to the great frequency of slight shocks or tremors. During earthquakes, mounds are thrown up some ten or twelve miles in length, and of considerable height, formed, Sir Bartle believed, by a crack or fissure of the surface at right angles to the direction of the earthquake wave, one lip of the fissure being tilted up and overlapping the other, so as to form a ridge. Small craters and hillocks of ejected sand are sometimes formed on the surface of the Runn, and afterwards subside again to the level of the plain. Dry beds of rivers are traceable throughout the desert tract to the north. From the difficulties of access to the Thurr, it had been for centuries the place of refuge to remnants of various races and nations who had invaded Hindoostan, or succumbed to the fortunes of war. Here are still found specimens of the wild Bheels who claim to be the autochthones and whose blood is essential to ratify every solemn ceremony of the Rajpoot dynasties; Coolies, who are anterior to the earliest Hindoo immigrants; Jutts, who are said to be of Scythian origin and are hardly ever known to forsake their ancestral occupation as breeders of cattle. Hindoos of every tribe and caste are here found, and many representatives are seen of later immigrations—Belooches, Afghans, Kurds, Arabs, and even Turcomans. One tribe of Rajpoots in the Desert, the Sodas, retain their primitive custom of bringing up all their female children, and, in consequence, all the chiefs in Rajpootana, where female infanticide had become established, have had for ages to take their wives from the humble Soda settlements. The poor Soda chiefs have therefore powerful connections among their wealthy sons-in-law; but, though they often pay a round of visits among them, they are said never to exchange their lives of freedom and simplicity, in the desert, for the palaces of Rajpootana. In the discussion which followed, Lord Napier of Magdala stated his belief that if the improvements Sir Bartle Frere suggested, when Commissioner of Scinde, had been put in execution at the time, a great alteration for the better would by this time have taken place in the desert tract which he had described. — The following new fellows were elected: — Rev. T. H. Braim, John E. Dawson, E. Hutchins, J. Irvine, M. H. Lackersteen, Joseph Moore, Commander Noel Osborn, J. N. Robertson, Joseph Starling, Henry Stilwell, Charles Stenning, John Wilton.

February 28.—Sir R. I. Murchison, president, in the chair. The following Fellows were elected:—Donald Butler, Commander George M. Balfour, W. A. M. Browne, W. L. Barclay, F. W. Buxton, Lieutenant E. F. Chapman, Colonel D. Carleton, Dr. R. H. Hilliard, R. A. Hankey, W. M. James, Colonel Charles E. Law, the Hon. Henry Lyttelton, John Markham, W. C. Midwinter, Major-General W. C. McLeod, Lieutenant-Colonel George W. Raikes, Right Hon. Sir John Rose, W. A. Whyte.

"A Visit to Yarkand and Kaskgar." By R. B. Shaw. The author commenced by saying that the common idea of Tartary was that of a succession of vast plains, over which hordes of barbarians wandered at will with their cattle and tents. He had found the reality widely different. It was a well-cultivated country, containing flourishing cities of more than 100,000 inhabitants, where many of the arts of civilisation are carried on. Security of life and property exists, commerce is protected, the roads are full of life and movement, and markets are held on a fixed day of the week, even in the smallest villages. In the towns extensive bazaars, covered in against the rays of the sun, contain rows of shops, where goods of every kind and from every country are exhibited. In Yarkand alone there are sixty colleges, with endowments in land, for the education of students of Mussulman law and divinity, while every street contains a primary school attached to a mosque. There are special streets for the various trades. In one street will be found the silks of China, in another the cotton goods and prints of Russia, while a third will contain robes made of both materials, three or four of which make up the ordinary dress of the Turki inhabitants. In some streets all kinds of groceries are sold: others are set apart for the butchers, who offer a choice of horse-flesh, camel, beef, or mutton. The first is rather a luxury, but the two last are most abundant, selling at about one penny a pound. The bakers make most excellent light loaves by a process of steaming the bread. The greengrocers present abundant supplies of vegetables in great variety, besides cream nearly as thick as that of Devonshire, and delicious cream-cheeses. Everywhere sherbet made of fruit is sold, which you can get cooled at any street corner, where there are stalls for the sale of ice. There are tea-shops where the great urns are ever steaming, and eating-houses in abundance. Such is the manifold life of this little-known nation; living a life of its own, making history very fast, and looking upon European politics with the same indifference with which its own have been regarded by us. The author, who made his journey with the view of opening the way for trade, especially in tea, between India and Eastern Turkistan, described the manner of his reception by the Governor of Yarkand, and by the Atalìgh Ghazee, the ruler of the country, then resident in Kashgar, who now seems firmly established as king over a productive region containing a population variously estimated at from 20 to 60 millions. The Andijanis occupy the chief places in the administration, and form the strength of the army; but their attitude towards the native Yarkandis is very conciliatory, and they are looked upon, not as conquerors, but as brothers in faith and blood, who have delivered them from the yoke of unbelievers and idolaters. The Yarkandis are naturally addicted to commerce and the arts of peace, while the Usbeks of Andijan find their most congenial occupation in administration and arms. Both peoples speak the same language, which is essentially that of the Turks of Constantinople. The Atalìgh, Yakoob Beg, impressed Mr. Shaw as a man of remarkable intelligence and energy. Merchants from India are beginning to frequent Yarkand, and it only required the removal of a few obstacles in the hill countries subject to our own influence to open out a field for trade, of which it would be difficult to over-estimate the importance. The whole region forms a vast elevated basin, in Central Asia, about 4,000 feet above the sea-level, surrounded on three sides by a wall of snow-covered mountains, reaching in many places an altitude of more than 20,000 feet. On the east it passes into the sandy desert of Gobi, which separates it from China. All the rivers which descend from the snows of the mountain, flowing eastward, are lost in the sands, and, as there is little or no rain, the soil has to be fertilised by canals and irrigation. The beautiful cultivation and luxuriance of the thickly-peopled parts are entirely due to these irrigating canals, which are exceedingly numerous and carefully kept. Mr. Shaw stated that the King himself superintended the works at a new canal whilst he was there, and even laboured at it himself. The country is separated from the plains of India by the mountain-system of the Himalaya, forming an elevated belt 500 miles broad, with eleven more or less elevated parallel ridges of mountains lying along it. The most northerly of these ridges was styled Kuen-lun by the Chinese, but was not a distinct chain from the rest of the mountains. Mr. Shaw concluded by describing his return journey over the Karakorum Pass. Sir Henry Rawlinson said that the Government of India had considered Mr. Shaw's discoveries of so much importance that they had entered into negotiations with the Maharajah of Cashmere for the purpose of encouraging trade with Eastern Turkistan, and arrangements had been entered into by which all transit duties through Ladak would be abolished. The difficulties of the route northward from Ladak over the Karakorum would probably be obviated by the adoption of the much easier road to the east *viâ* Changchenmo, or, still better, by the elevated level plains of Rudok still farther east. The difficult Sanju Pass over the Kuen-lun would also be avoided in future by the adoption of the Yenghi Pass, all that was necessary being the establishment of a fort at its foot to protect caravans from the depredations of hordes of robbers who frequent that district.—The President reminded the meeting that Mr. Shaw was the first European since the days of Marco Polo who had penetrated to Yarkand, and been allowed to return from that wonderful country. The Society's envoy, Mr. Hayward, had reached the place a few days after him; but the two were not allowed to see each other until they were on the way back again.—A second paper was read, "On a Journey through Shantung and a visit to the Tomb of Confucius," by Mr. J. Markham, Consul at Chefoo. The paper contained a most interesting account of the author's reception at Kio-foo, the city of Confucius, and his examination of the monuments and temples connected with the fame of the Chinese sage. The great majority of the inhabitants of the city are descendants of Confucius and bear his surname, and the magistrate's office is hereditary in the family. The result of the author's experience acquired in journeys throughout the length and breadth of this important province was that the middle and lower classes of China were, as a rule, inclined to be friendly to strangers, and that all acts of offence are instigated by the governing class of mandarins.

Royal Institution of Great Britain, March 7. — Colonel P. J. Yorke in the chair. His Royal Highness the Prince Christian of Schleswig-Holstein was elected an honorary member, and W. H. Barlow, A. J. Booth, F. W. Buxton, J. T. Clover, Rev. J. Congreve, G. H. Darwin, F. Galton, Lord R. Gower, R. Grubb, J. Gurney, H. Hoare, J. Houldsworth, Lieut.-Colonel G. Ives, T. Jacomb, E. C. Johnson, Sir J. J. T. Lawrence, F. M'Clean, J. O'Halloran, H. Pechell, F. Pennington, G. Phillips, M. R. Pryor, Dr. J. Rae, Rev. D. M. Salter, A. G.

Sandeman, G. Stone, A. A. de Lille Strickland, C. B. Thurston, the Hon. J. G. P. Vereker, Mrs. Michael Wills, and H. Woods, were elected members of the Royal Institution.

CAMBRIDGE

Philosophical Society, March 7.—The following communications were made to the society:—"On the Centro-surface of an Ellipsoid," by Prof. Cayley. "On the correct expressions for the resistance which bodies experience whilst moving in gases and liquids: with a description of the verifying experiments," by Mr. Potter.

DUBLIN

Royal Irish Academy, February 14.—Rev. J. H. Jellett, president, in the chair. The president read a paper entitled "Researches in the application of Optics to Chemistry," No. 1, "Combinations of Nitric Acid with Quinia."—A letter from M. De Vismes Kane, was read, describing the circumstances under which the large stone implement and the curious wooden vessel, which he had presented to the Academy's museum, through Dr. Stokes, were found.—The secretary read a description by Mr. R. R. Brath, of an Ogham inscribed stone at Kiltena, county Waterford.

PARIS

Academy of Sciences, February 28.—M. A. Trécul presented the third part of his memoir on the position of the tracheæ in the ferns. His object in this important paper is to show that there is "no unity of constitution, circulation, and symmetry" in the vascular Acrogens, and in illustration of this view he describes the arrangements of the tracheæ in the following forms:—*Athyrium filix-femina*, several species of *Aspidium* and *Asplenium*, *Struthiopteris germanica*, *Adiantum tenerum*, *Scolopendrium officinale*, *Ceterach officinarum*, and *Gymnogramme chrysophylla* and *calomelanos*.—A letter by Father Secchi on the modifications produced by magnetism in the light emitted by rarefied gases, was read. In this the author described some experiments made by him with a powerful electro-magnet upon Geissler's tubes. He stated that when a tube is placed between or close to the poles of the electro-magnet the light is condensed towards the part of the tube most distant from the magnet, so that instead of a diffused light a bright streak is visible. The effect was said to be very curious, appearing as if the gas itself was displaced, and resembling the great movements of the streamers in the Aurora Borealis. The more brilliant light gives a more brilliant and distinct spectrum, and the author stated that when the gas has a double spectrum, the two spectra are produced separately—one from the brilliant part of the tube, the other from the parts nearer the magnet. The author remarked that the effect of magnetism was as if it narrowed the tubes. He ascribed it to a repulsion of the rarefied gases, due to diamagnetism. M. Dumas remarked that M. de la Rive had been carrying on some experiments of a like nature, the results of which are not yet published, but he believed that in some points they coincided with Father Secchi's.—In a memoir on the spectra of various kinds of simple bodies, M. Dubrunfaut ascribed the double spectra obtained from some vacuum tubes to impurity in the gases employed, and indicated some other sources of error. He referred especially to hydrogen. He also noticed that variations of temperatures may cause anomalies in spectrum analysis, and remarked that the line K *a* of potassium may be made to appear and dissappear by raising and lowering the temperature.—Notes of a further investigation of propylic, butylic, and amylic aldehydes were presented by MM. I. Pierre and E. Puchot. Their researches related chiefly to the temperatures of ebullition and densities of these bodies, as to which their results differ considerably from those of former writers.—In a memoir by M. Gustave Lambert on the experimental determination of the form of the earth, that gentleman proposed a simplification of the method of observation by means of the pendulum, and a ready means of measuring a base-line. He submitted his methods to the judgment of the Academy, intending to employ them, if approved, in the projected French Arctic expedition. — M. Delaunay communicated a report by MM. Wolf, André, and Capitaneano, on a bolide observed by them at the Paris Observatory on the 26th February.—This meteor started from between α and β *Canis minoris*, and passed as a yellow streak between Sirius and β *Canis majoris*, when it took the form of a very brilliant, bluish white ball about 5′ in diameter, followed by a broad yellow tail; near ν *Canis majoris*, it burst into several fragments and disappeared. The phenomena commenced at $9^h\ 35^m\ 20^s$ and lasted about 3 seconds. No sound was heard.—M. F. Lucas presented a note relating to the physical state of bodies; M. H. Montucci a memoir on Gauss's method for the reduction of trinominal equations; and M. H. Sainte-ClaireDeville a note by M. A. Martin on Léon Foncault's "method of autocollimation" and its application to the investigation of parabolic mirrors.—M. H. Caron communicated a note on the solution of reductive gases by iron and carburets of iron in fusion, in which he suggested a cause of the spirting of cast-steel and iron in cooling.—M. H. Sainte-Claire Deville made some remarks on this paper.—A memoir on the oxidation of iron by Mr. P. Crace Calvert, was read; from his experiments he concludes that it is the presence of carbonic acid in the air that causes the rusting of iron.—M. Chevreul made some remarks npon this paper.—A note on the dissociation of ammoniacal compounds, by M. F. Isambert, was presented by M. H. Sainte-Claire Deville.—The author noticed the compounds formed by the sulphates of zinc and cadmium with gaseous ammonia, and the tensions of the ammoniacal gas set free from these compounds by the action of heat, which are constant at given temperatures.—M. Campana communicated a note "On the texture and differential character of the Lungs in Birds," in which he described the mode of origin and distribution of the secondary bronchial tubes, which, he stated, terminate in a single tertiary tube, and this in its turn unites with the extremity of another secondary tube. This applies also, according to the author, to the lateral tertiary tubes.—M. Elie de Beaumont communicated an extract from a letter of M. Prost giving an account of earthquake shocks experienced at Nice, and containing a journal of shocks observed during the years 1866—1869.—M. H. Sainte-Claire Deville presented a note by Father Denza on an Aurora borealis and some other meteorological phenomena observed in Piedmont on the 3d of January, 1870.

BERLIN

German Chemical Society, February 29.—C. Liebermann communicated the result of his researches on chrysene, of which large quantities have lately been obtained from coal tar. He has specially devoted attention to the chinone of chrysene, obtained by oxydising this hydro-carbon. The colouring properties of this substance are very inferior to those of its analogous anthracene.—C. Scheibler reported on betain, a base he obtained from beetroot-juice, or molasses. The young roots contain considerable quantities of this substance, and certain molasses furnish as much as 3 per cent. of it. The base has been found identical with oxyneurin, lately discovered in the brain, in eggs, &c., by Leibriech. It is not poisonous, and yields well crystallised salts.—H. Wichelhaus has determined the vapordensity of chloronidtride of phosphorus, thus proving the correctness of the formula $P_3N_3Cl_6$ which had already been fully established by Gladstone and Holmes.—C. Rammelsberg delivered a lecture on meteorites, giving a succinct and interesting history of these remarkable bodies, the existence of which had been regarded as a superstition up to the end of the last century.—Mr. Gordon has prepared Reisets' and Magnus' salts containing ethylamine, aniline, and toluidine in the place of ammonia.—T. Thomsen of Copenhagen sent a paper on the heat of combination. The heat produced by adding an acid to a base attains the maximum when the latter is neutralised by the former. Based upon this observation, the author concludes that sulfhydric acid must be monbasic, a startling fact, which in order to be fully confirmed appears to need further examination.—Two papers were sent in after the last meeting of the society, and printed in the abstracts of that meeting. One is by Kekulé, on the substance described as chloraceten. The author proves the non-existence of this substance, a solution of oxychloride of carbon in para-aldehyde having been taken for a chemical individual. The other paper is by Ceck, describing the combustion of part of the Bohemian diamond, and removing any uncertainty concerning its nature.

German Geological Society.—At the February meeting Dr. Lossen reported on the composition of Karpholithe from the metamorphic slate of Biscaroda, in the Harz Mountains. Hauchecorne and Meyne reported on borings made at Stade for rocksalt. Its discovery was anticipated with certainty. Lindig reported on the borings made at Spurenberg (thirty miles from Berlin), where an immense saltlayer was discovered two years ago. The boring is now 2,630 feet deep, 2,347 of which go through one layer of pure rocksalt! The temperature was found to be 31° 5′ C. at the bottom.

VIENNA

Imperial Academy of Sciences, January 20.—The Ministry of Commerce called upon the Academy to appoint a member to arrange the reproduction of the French standard meter, and also forwarded a nautical instrument for the correction of the course of vessels, invented by Carl Zamara.—A note by Prof. G. Hinrichs of Iowa, on the structure of quartz, was communicated by Prof. von Haidinger.—Prof. E. Mach communicated the results of an investigation by M. C. Neumann upon the vibrations of a string under the bow. His results for the most part confirm Helmholtz's theoretical views.—Dr. Boué presented a geographico-geognostic map of the valley of Sutchesa, and remarked upon its peculiarities.—Dr. A. Friedlowsky communicated a memoir on three cases of augmentation of the carpal and tarsal bones in man.—Prof. F. Simony gave a comparative account of the conditions of temperature in the Lakes of Hallstatt, Gmund, and Langbath, at different depths, and Dr. J. Hann presented a memoir on the decrease of temperature with elevation on the surface of the earth.—The table of the meteorological and magnetic observations at the Central Observatory during the month of December last was also communicated.

February 3.—Memoirs were read by Prof. Rochleder "On some colouring matters from Madder," and by M. A. von Miller-Hauenfels on "The dualistic functions," and "On the electrical current which appears to stand in relation to endosmose." Dr. L. J. Fitzinger communicated the second and concluding portion of his "Critical revision of the family of the *Rhinophylli*," in which he treats of the genera *Ariteus*, *Rhinolophus*, *Rhinonycteris* and *Aquias*. — "Investigation of the white mustard seed." By Professor H. Will. In place of the myronate of potash found in black mustard seed there is in white mustard seed an analogous body sinalbin which splits up into sugar or sulphocyanogen compound and acid sulphate. The sulphocyanogen compound is not volatile, it contains an oxygenated radicle akrinyl C_7H_7O. The acid sulphate contains in place of potassium sinapisin. The sulphocyanide of akrinyl freed from sulphur and treated with alkali when in the state of nitryl yields ammonia and a salt of the acid $C_8H_8O_3$, which melts at 136° C, and is not identical with any known acid of the same formula.

Geological Institution, February 15.—Herr von Hauer in the chair. Prof. von Ettingshausen communicated the results of his study of the fossil flora from the environs of Berlin, Bohemia. Nearly five hundred species have been determined from six beds of different age. The oldest of them—the freshwater-chalk of Kostenblatt and the strata of Kutschlin—correspond with the Aquitanian series; the plastic clay of Priesen, as well as the clay and spherosiderit of Languageyd, belong to the middle part of the Miocene formation. The menilites and opales of the Sichrow valley, as well as the shists of Sobrusan, contain the plants of the Oemingen series. Herr Flanenschild pointed out that the existence of large layers of the so-called Alpine chalk (Alpenkreide), the mud of glaciers, which eroded the dolomitic rocks, indicates the existence of old glaciers in the Alm- and Steierling valleys, Upper Austria. This mud consists, therefore, of carbonate of lime and carbonate of magnesia, and, when burnt at a low temperature, gives a good hydraulic cement.—Herr. Ch. Paul exhibited detailed sections of the small mountain range near Homonna, North-eastern Hungary, consisting of different layers of the triassic, rhætic, liassic, jurassic, and cretaceous formations. Of high interest is the discovery of marls with fossils of the *Gault* series, which are so very rare in the eastern Alps and Carpathians.—Herr Stache exhibited geological maps of the environs of Unghvar and Mandak, North-eastern Hungary, which he had surveyed last summer. Trachytes with their tufts, and Carpathian sandstones of Eocenic age, are the prevailing formations.

DIARY

THURSDAY, MARCH 10.

ROYAL SOCIETY, at 8.30.—On some Elementary Principles in Animal Mechanics (No. III.): Rev. S. Haughton.—On the Contact of Conics with Surfaces: W. Spottiswoode.—On the Spotted Area of the Sun's Visible Disc from the Commencement of 1832 up to May 1868: W. De la Rue, B. Stewart and B. Loewy.—Tables of the Numerical Values of the Sine-Integral, Cosine-Integral, and Exponential-Integral: J. W. L. Glaisher.

SOCIETY OF ANTIQUARIES, at 8.30.—Roman Inscription in the Disney Collection: Mr. H. C. Coote.

ZOOLOGICAL SOCIETY, at 8.30.—Dinornis (Part XV.): Professor Owen.—New species of *Ampullaria*: Dr. J. C. Cox.—Birds of Veragua: Mr. O. Salvin.—New birds from the Yantze-kiang: Mr. R. Swinhoe.

MATHEMATICAL SOCIETY, at 8.

ROYAL INSTITUTION, at 3.—Chemistry: Prof. Odling.

LONDON INSTITUTION, at 7.30.—Swiney Lecture: Dr. Cobbold.

FRIDAY, MARCH 11.

ROYAL INSTITUTION, at 8.—On Art: Mr. Westmacott.

QUEKETT MICROSCOPICAL CLUB, at 8.

ASTRONOMICAL SOCIETY, at 8.

SATURDAY, MARCH 12.

ROYAL INSTITUTION, at 3.—Science of Religion: Prof. Max Müller.

ROYAL BOTANIC SOCIETY, at 3.30.

MONDAY, MARCH 14.

MEDICAL SOCIETY, at 8.—Anniversary.

SOCIETY OF ARTS, at 8.—Cantor Lecture: Dr. Paul.

TUESDAY, MARCH 15.

ROYAL INSTITUTION, at 3.—Nervous System: Dr. Rolleston.

ANTHROPOLOGICAL SOCIETY, at 8.—On Strange Peculiarities observed by a Religious Sect of Moscovites, called Scoptsis: Dr. Kopernicky and Dr. Barnard Davis.—Phallic Worship: Mr. Hodder Westropp.—Consanguineous Marriages; Mr. George C. Thompson.

STATISTICAL SOCIETY, at 8.—The Financial System of the Free Church of Scotland: Rev. D. Buchanan.

PATHOLOGICAL SOCIETY, at 8.

INSTITUTION OF CIVIL ENGINEERS, at 8.—1. Discussion upon Mr. Fox's paper "On the San Paulo Railway;" 2. and if time permits, the following paper will be read, "On the Conditions and the Limits which govern the Proportions of Rotary Fans:" Mr. Robert Briggs.

WEDNESDAY, MARCH 16.

SOCIETY OF ARTS, at 8.—Surface Decoration: Mr. Pitman.

ROYAL HORTICULTURAL SOCIETY, at 1.30

METEOROLOGICAL SOCIETY, at 7.

THURSDAY, MARCH 17.

ROYAL INSTITUTION, at 3.—Chemistry: Prof. Odling.

ROYAL SOCIETY, at 8.30.

LINNEAN SOCIETY, at 8.—The Flora and Fauna of Round Island: Sir Henry Barkly.—Algæ found in the North Atlantic Ocean: Dr. Dickie.

CHEMICAL SOCIETY, at 8.

ZOOLOGICAL SOCIETY, at 4.

NUMISMATIC SOCIETY, at 7.

ANTIQUARIES' SOCIETY, at 8·30.

BOOKS RECEIVED

ENGLISH.—The Bottom of the Sea: B. Z. Sonrel; illustrated. Translated and edited by Elihu Rich (Sampson Low and Marston).—Weapons of War: A history of arms and armour from the earliest periods to the present time: A. Demmin; illustrated. Translated by C. C. Black (Bell and Daldy).—Sketches of Life and Sport in South Eastern Africa: C. ON FLOATING MATTER AND BEAMS OF LIGHT

BEAMS of light may be employed to reveal the existence of floating matter in the air; or the floating matter may be employed to reveal the track of the beams.

When the beam is intense it becomes an extremely powerful searcher and revealer of the state of the air. Thus examined, the air of a room which in diffuse daylight appears absolutely pure is seen to be loaded with suspended matter. Many of the fine clouds developed in my experiments on the action of light upon vapours disappear utterly in diffuse daylight; while when the room is darkened and the light of an intense beam confined to the clouds themselves, they appear highly luminous. The eye is the real re-agent here. Rendered sensitive by darkness, and receiving light from the floating matter alone, the amount of light competent to produce a sensible effect is incalculably small. The power of the light to make an impression is moreover increased by the extension given to the body which emits it.

The mobility of these actinic clouds is in some cases quite extraordinary. The differences of temperature introduced by the act of decomposition often cause the clouds to assume forms of astonishing complexity and beauty. The clouds which thus shape themselves by internal action are also exceedingly sensitive to external action. Supposing a thin actinic cloud to fill the experimental tube, the whole of it being flooded with the light of a beam passing longitudinally through the tube, an instant's contact of the tip of a spirit lamp flame with the under surface of the tube causes the cloud to break upwards in a violent current, and to whirl itself into the most beautiful vortices right and left of the vertical line. The rapidity with which the heat passes through the thick glass and sets the cloud in motion is surprising. The warmth of the finger suffices to produce an effect feebler than, but substantially the same, as that produced by the spirit lamp flame.

In fact, the floating matter of the air, properly illuminated, might be converted into a thermoscope of surpassing delicacy. A little brown paper smoke was diffused in an ordinary glass shade; the track of the beam through it was much whiter than through the air. Hence the invasion of the smokeless air could be instantly seen by the darkness it produced. On introducing the hand at the open base of the shade, a violent uprush of air immediately occurred. The smoke was violently whirled about, and the course of the whirlwinds distinctly marked by the relative action on the light of the smoky and the unsmoky air. I was not prepared to see so small a difference of temperature produce so large and prompt an effect.

Nor is it necessary to introduce dark extraneous air to render the currents through nebulous matter visible. The current produced in the actinic cloud by the spirit flame forms a dark vertical septum between the two adjacent parts of the cloud. When the current curls to form a cyclone, the septum curls also, producing dark spirals through the illuminated nebulæ.

The late Principal Forbes often referred to the floating scum on water slowly flowing through a channel, the lateral parts of which are retarded by friction. Such scum, or froth, arranges itself in distinct striæ, separated from each other by comparatively free intervals. It is practically impossible to establish differential motions, either in solids or liquids, without producing some effect of this kind. Fibrous iron shows it; while in the atmosphere differential currents produce cirrus clouds. I have often watched the way in which the suspended matter of the turbid Arve at Chamouni traced itself through the water. Notwithstanding the tossing endured from the source of the Arveyron downwards, the mixture of mud and liquid was by no means perfect. In fact, every new obstacle which introduced differential motion introduced also the striæ, and destroyed all uniformity of mixture.

Five or six weeks ago I had a square chamber constructed, the upper half of which is glazed, its floor consisting of transverse rails, over which is placed a thick mat of cotton wool. The chamber has a brass chimney, in which a rose burner can be lighted. An upward current is thus established in the chimney, the air below entering through the cotton-wool to supply the place of that discharged by the flame. When the chamber is filled with the ordinary laboratory air, a beam sent through it tracks its course on the floating matter. When the flame is ignited, the air enters through the cotton-wool; but the consequence is not a uniform enfeeblement of the light of the beam. Perfectly dark striæ pass through the luminous track, and they sometimes bend and whirl so as to form gracefully curved streams of darkness. Even air urged from the nozzle of a bellows through the luminous track, shows a tendency to form those striæ, though it, like the water of the Arve at Chamouni, is filled with the same floating matter as that of the air through which it is urged.

On a recent occasion the following effects were described, and an attempt was then made to explain them:—

In a cylindrical beam, which powerfully illuminated the dust of the laboratory, was placed an ignited spirit-lamp. Mingling with the flame, and round its rim, were seen wreaths of darkness resembling an intensely black smoke. On lowering the flame below the beam the same dark masses stormed upwards. They were at times blacker than the blackest smoke that I have ever seen issuing from the funnel of a steamer, and their resemblance to smoke was so perfect as to lead the most practised observer to conclude that the apparently pure flame of the alcohol lamp required but a beam of sufficient intensity to reveal its clouds of liberated carbon.

But is the blackness smoke? This question presented itself in a moment. A red-hot poker was placed underneath the beam, and from it the black wreaths also ascended. A large hydrogen flame was next employed, and it produced those whirling masses of darkness far more copiously than either the spirit-flame or poker. Smoke was therefore out of the question.

What then was the blackness? It was simply that of stellar space; that is to say, blackness resulting from the absence from the track of the beam of all matter competent to scatter its light. When the flame was placed below the beam the floating matter was destroyed *in situ;* and the air, freed from this matter, rose into the beam, jostled aside the illuminated particles, and substituted for their light the darkness due to its own perfect transparency. Nothing could more forcibly illustrate the invisibility of the agent which renders all things visible. The beam crossed, unseen, the black chasm formed by the transparent air, while at both sides of the gap the thick-strewn particles shone out like a luminous solid under the powerful illumination.

But here a difficulty meets us. It is not necessary to burn the particles to produce a stream of darkness. Without actual combustion, currents may be generated which shall exclude the floating matter, and therefore appear dark amid the surrounding brightness. I noticed this effect first on placing a red-hot copper ball below the beam, and permitting it to remain there until its temperature had fallen below that of boiling water. The dark currents, though much enfeebled, were still produced. They may also be produced by a flask filled with hot water.

To study this effect a platinum wire was stretched across the beam, the two ends of the wire being connected with the two poles of a voltaic battery. To regulate the strength of the current a rheostat was placed in the circuit. Beginning with a feeble current the temperature of the wire was gradually augmented, but before it reached the heat of ignition a flat stream of air rose from it, which when looked at edgeways appeared darker and sharper than one of the blackest lines of Fraunhofer in the solar spectrum. Right and left of this dark vertical band the floating matter rose upwards, bounding definitely the non-luminous stream of air. What is the explanation? Simply this. The hot wire rarefied the air in contact with it, but it did not equally lighten the floating matter. The convection current of pure air therefore passed upwards *among the particles*, dragging them after it right and left, but forming between them an impassable black partition. In this way we render an account of the dark currents produced by bodies at a temperature below that of combustion.

This explanation has been found difficult. When the wire is white hot, it sends up a band of intense darkness. This, I say, is due to the *destruction* of the floating matter. But even when its temperature does not exceed that of boiling water the wire produces a dark ascending current. This, I say, is due to the *distribution* of the floating matter. The difficulty alluded to is probably to be referred to the brevity of the explanation. Imagine the wire clasped by the mote-filled air. My idea is that it heats the air and lightens it, without in the same degree lightening the floating matter. The tendency, therefore, is to start a current of clean air through the mote-filled air. Figure the motion of the air all round the wire. Looking at it transversely we should see the air at the bottom of the wire bending round it right and left in two branch currents, ascending its sides and turning to fil the partial vacuum created above the wire. Now as each new supply of air filled with its motes comes in contact with the hot wire, the clean air, as just stated, is first started through the inert motes. They are dragged after it, but there is a fringe of cleansed air in advance of the motes. The two purified fringes of the two branch currents unite above the wire, and, keeping the motes that once belonged to them right and left, they form by their union the dark band observed in the experiment. This process is incessant. Always the moment the mote-filled air touches the wire this distribution is effected, a permanent dark band being thus produced. Could the air and the particles under the wire pass *through* its mass we should have a vertical current of particles, but no dark band. For here, though the motes would be left behind at starting, they would hotly follow the ascending current and thus abolish the darkness.

It has been said that when the platinum wire is intensely heated, the floating matter is not only distributed, but destroyed. Let this be proved. I stretched a wire about four inches long through the air of an ordinary glass-shade resting on its stand. Its lower rim rested on cotton wool, which also surrounded the rim. The wire was raised to a white heat by an electric current. The air expanded, and some of it was forced through the cotton wool, while when the current was interrupted and the air within the shade cooled, the expelled air in its return did not carry motes along with it. At the beginning of this experiment the shade was charged with floating matter; at the end of half an hour it was optically empty.

On the wooden base of a cubical glass shade measuring eleven and a half inches a side, upright supports were fixed, and from one support to the other thirty-eight inches of platinum wire were stretched in four parallel lines. The ends of the platinum wire were soldered to two stout copper wires which passed through the base of the shade and could be connected with a battery. As in the last experiment the shade rested upon cotton wool. A beam sent through the shade revealed the suspended matter. The platinum wire was then raised to whiteness. In five minutes there was a sensible diminution of the matter, and in ten minutes it was totally consumed. This proves that when the platinum wire is sufficiently heated, the floating matter, instead of being distributed, is destroyed.

But is not the matter really of a character which permits of its destruction by the moderately heated platinum wire also? Here is the reply:—

1. A platinum tube with its plug of platinum gauze was connected with an experimental tube, through which a powerful beam could be sent from an electric lamp placed at its end. The platinum tube was heated till it glowed feebly but distinctly in the dark. The experimental tube was exhausted and then filled with air which had passed through the red-hot tube. A considerable amount of floating matter which had escaped combustion was revealed by the electric beam.

2. The tube was raised to brighter redness and the air permitted to pass slowly through it. Though diminished in quantity, a certain amount of floating matter passed into the exhausted experimental tube.

3. The platinum tube was rendered still hotter; a barely perceptible trace of the floating matter now passed through it.

4 The experiment was repeated, with the difference that the air was sent more slowly through the red-hot tube. The floating matter was totally destroyed.

5. The platinum tube was now lowered until it bordered upon a visible red heat. The air sent through it still more slowly than in the last experiment carried with it a cloud of floating matter.

If then the suspended matter is destroyed by a bright red heat, much more is it destroyed by a flame whose temperature is vastly higher than any here employed. So that the blackness introduced into a luminous beam where a flame is placed beneath it is due, as stated, to the destruction of the suspended matter. At a dull red heat, however, and still more when only on the verge of redness, the platinum tube permitted the motes to pass freely. In the latter case the temperature was 800° or 900° Fahrenheit. This was unable to destroy the suspended matter; much less, therefore, would a platinum wire heated to 212° be competent to do so. Such a wire can only distribute the matter, not destroy it.

The floating dust is revealed by intense local illumination. It is seen by contrast with the adjacent unilluminated space; the brighter the illumination the more sensible is the difference. Now the beam employed in the foregoing experiments is not of the same brightness throughout its entire transverse section. Pass a white switch, or an ivory paper-cutter, rapidly across the beam, the impression of its section will linger on the retina. The section seems to float for a moment in the air as a luminous circle with a rim much brighter than its central portion. The core of the beam is thus seen to be enclosed by an intensely luminous sheath. An effect complementary to this is observed when the beam is intersected by the dark band from the platinum wire. The brighter the illumination, the greater must be the relative darkness consequent on the withdrawal of the light. Hence the cross section of the sheath surrounds the dark band as a darker ring.

The following four paragraphs, though printed nearly two months ago, have not been published hitherto. Might I say that whatever my opinion on the subject of "spontaneous generation" may be, I purposely abstain from expressing it here? That expression shall be given at the proper time. I desire now to show the practical value of the luminous beam as an investigator of the state of the air.

The question of "Spontaneous generation" is intimately connected with our present subject. On this point a kind of polar antagonism has long existed between different classes of investigators. Van Helmont gave a receipt for the manufacture of mice, and it was for ages firmly believed that the maggots in putrefying flesh were spontaneously produced. Redi, a member of the famous Academy del Cimento, destroyed this notion by proving that it was only necessary to protect the meat by a covering of gauze to prevent the reputed generation. In 1745 two very able men, Needham and Spallanzani, took opposite sides in the discussion, the forming affirming and the latter denying the fact of spontaneous generation. At the beginning of our own century, we find on the affirmative side Lamarck, Oken, and J. Müller; and on the negative Schwann, Schultze, and Ehrenberg. The chief representatives of the two opposing parties in our day are Pouchet and Pasteur.

The method of inquiry pursued in this discourse will, I think, help to clear the field of discussion. The experimenters do not seem to have been by any means fully aware of the character of the atmosphere in which they worked; for if this had been the case, some of the experiments recorded would never have been made. For example, to make the destruction of atmospheric germs doubly sure, M. Pouchet, the distinguished supporter of the doctrine of spontaneous generation, burnt hydrogen* in air and collected the water produced by the combustion. Even in this water he afterwards found organisms. But supposing he had seen, as you have, the manner in which the air is clouded with floating matter, would he have concluded that the deportment of water which had been permitted to trickle through such air could have the least influence in deciding this great question? I think not. Here is a quantity of water produced and collected exactly as M. Pouchet produced and collected his. This water is perfectly clear in the common light; but in the condensed electric beam it is seen to be laden with particles, so thick-strewn and minute, as to produce a continuous cone of light. In passing through the air the water loaded itself with this matter, and hence became charged with incipient life.*

Let me now draw your attention to an experiment of Pasteur, which I believe perplexes some of the readers and admirers of that excellent investigator. Pasteur prepared twenty-one flasks, each containing a decoction of yeast, filtered and clear. He boiled the decoction, so as to destroy whatever germs it might contain, and while the space above the liquid was filled with pure steam he sealed his flasks with a blow-pipe. He opened ten of them in the deep, damp caves of the Paris Observatory, and eleven of them in the courtyard of the establishment. Of the former, one only showed signs of life subsequently. In nine out of the ten flasks no organisms of any kind were developed. In all the others organisms speedily appeared.

Now here is an experiment conducted in Paris, which shows that the air of one locality can develop life when the air of another locality cannot. Let us see whether we cannot here in London justify and throw light upon this experiment. I place this large flask in the beam, and you see the luminous track crossing it from side to side. The flask is filled with the air of this room, charged with its germs and its dust, and hence capable of illumination. But here is another similar flask, which cuts a clear gap out of the beam. It is filled with unfiltered air, and still no trace of the beam is visible. Why? By pure accident I stumbled on this flask in our apparatus room, and on inquiry learnt that it had been a short time previously taken out of one of the cellars below stairs. Other flasks were in the same cellar. I had three of them brought up to me; they were optically empty. The still air had deposited its dust, germs and all, and was itself practically free from suspended matter. You can now understand the impotence of the air of the Paris caves. The observation illustrates at once the influence of the germs and the accuracy of Pasteur.

* In this case a polished silver basin was soldered to one end of a wide brass tube; the tube was filled with ice, the hydrogen flame was permitted to play upon the basin, and the water of condensation was then collected. Dr. Child also objects to Pouchet's experiment.

The air of the cellar was afterwards examined by the electric lamp. Though less heavily charged than the air outside, it was by no means free from particles. This was to be expected, because the door of the cellar was frequently opened. The flasks themselves were the true tranquil chambers; on their sides the dust had been deposited, and to them it firmly clung. To prove this several flasks about ten inches in diameter were filled with common air, corked, and laid upon a table in the laboratory. After two days' quiet they were optically empty.

Nor is it necessary even to cork the flasks; for with their mouths open the air within them is scarcely disturbed, certainly not displaced. Two days' rest on one of the laboratory tables suffices to deposit the organic dust and to render the open flasks optically empty.

I have had a chamber erected with a view to experiments on this subject. The lower half is of wood, its upper half being enclosed by four glazed window-frames. The chamber tapers to a truncated cone at the top. It measures in plan 3 ft. by 2 ft. 6 in., and its height is 5 ft. 10 in. On the 6th of February this chamber was closed, and every crevice that could admit dust or cause displacement of the air was carefully pasted over with paper. The electric beam at first revealed the floating dust within the chamber as it did in the air of the laboratory. The chamber was examined almost daily; a perceptible diminution of the floating matter being noticed on each occasion. At the end of a week the chamber was optically empty, exhibiting no trace of matter competent to scatter the light. But where the beam entered, and where it quitted the chamber, the white circles stamped upon the interior surfaces of the glass showed what had become of the dust. It clung to those surfaces, and from them instead of from the air, the light was scattered. If the electric beam were sent through the air of the Paris Caves, the cause of its impotence as a generator of life would, I venture to predict, be revealed.

It cannot, I think, be doubted that the method of observation here pursued is destined to furnish useful control and guidance in researches of this nature.

Royal Institution, March 14 J. TYNDALL.

HEREDITARY GENIUS

Hereditary Genius, an Inquiry into its Laws and Consequences. By Francis Galton, F.R.S., &c. (Macmillan & Co.)

IN this book Mr. Galton proposes to show that a man's natural abilities are derived by inheritance, under exactly the same limitations as are the form and physical features of the whole organic world. Many who read it without the care and attention it requires and deserves, will admit that it is ingenious, but declare that the question is incapable of proof. Such a verdict will, however, by no means do justice to Mr. Galton's argument, which we shall endeavour to set forth as succinctly as possible. He first discusses the classification of men by "reputation," and from a study of biographical dictionaries and obituaries for certain years taken at wide intervals, arrives at the conclusion that not more than 250 men in each million, or 1 in 4,000, can be termed "eminent"; and he shows what a small proportion that is, by the well-known fact that there are never so many as 4,000 stars visible to the naked eye at once, and that we feel it to be an extraordinary distinction in a star to be the brightest in the sky. These "eminent" men are the lowest class he deals with. The more illustrious names are as one in a million or one in many millions; but unless a man is so much above the average that there is only one like him in every 4,000, he is not admitted into the ranks of the eminent men on whom Mr. Galton founds his deductions.

He next discusses the classification of men according to their natural gifts. He shows first, that each man has a certain defined limit to his mental as well as to his physical powers, and that this limit is in most cases soon discovered and reached. He next shows the enormous difference that exists between mediocre and high class men, by the evidence of examination papers; the senior wrangler at Cambridge, for example, often getting thirty times as many marks as the lowest wrangler, who must himself be a man very far above the average. Statistics show, that the number of imbeciles and idiots are about the same per thousand as the eminent men. He then applies Quetelet's "law of deviation from an average" (which will be new to many of his readers), and deduces from it, that if men are divided into sixteen equal grades of ability, eight above and eight below the average, the six mediocre classes will comprise nineteen-twentieths of the whole; while it will be only the sixth, seventh, and eighth above the average who will rank as eminent and illustrious men, and form about one in four thousand of the adult male population.

The next chapter relates to the important question on which, indeed, the possibility of any solution of the problem depends, of whether "reputation" is a fair test of "ability." The subject is very ably discussed, and it is, I think, proved, that notwithstanding all the counteracting influences which may repress genius on one side, or give undue advantage to mediocrity on the other, the amount of ability requisite to make a man truly "eminent" will, in the great majority of cases, make itself felt, and obtain a just appreciation. But if this be the case, the question of whether "hereditary genius" exists is settled. For if it does not, then, the proportion of mediocre to eminent men being 4,000 to 1, we ought to find that only 1 in 4,000 of the relations of eminent men are themselves eminent. Every case of two brothers, or of father and son, being equally talented, becomes an extraordinary coincidence; and the mass of evidence adduced by Mr. Galton in the body of his work, proves that there are more than a hundred times as many relations of eminent men who are themselves eminent, than the average would require.

Turning now to the concluding chapters of the book, we meet with some of the most startling and suggestive ideas to be found in any modern work. The law of deviation from an average enables us to determine the general intellectual status of any nation, if we are able to estimate the ability of its most eminent men, and know approximately the amount of the population. We have these data in the case of ancient Attica; and Mr. Galton arrives at the conclusion, that the Athenians of the age of Pericles were, on the lowest possible estimate, nearly two whole grades of ability higher than we are. With all our boasted civilisation, and the vast social and scientific problems with which we have to grapple; with all our world-wide interests, our noble literature, and accumulated wealth; the intellectual status of the most civilised modern nation is actually lower than it was more than two thousand years ago! Well may Mr. Galton maintain that it is most essential to the well-being of future generations that the average standard of ability of the present time should be raised. Not less striking is his exposition of the effects of prudential restraints on marriage, on the general character of a nation. If one class of people, as a rule, marry early, and another class marry late in life, the former have a double advantage, both in having on the average larger families, and in producing more generations in each century. But, by the supposition, it is the imprudent who gain this advantage over the prudent; and Mr. Galton therefore denounces the doctrine of Malthus, that marriage should be delayed till a family can be supported, unless the rule could be imposed on all alike. I hardly think that this argument is sound, and I doubt if the imprudent who make early marriages do, in the long run, increase more rapidly than the prudent who marry late. Increase of population depends less upon the number of children born, than on those which reach manhood; and I believe that the prudent man who has acquired some wealth and wisdom before he marries, will give to the world more healthy men and women, than the ignorant and imprudent youth, who marries a girl as ignorant and imprudent as himself. It is also to be remembered that the men who marry late often marry young wives, and have as good a chance of large families as the imprudent.

Mr. Galton traces the long-continued darkness of the Middle Ages, and our present low intellectual and moral status, to the practice of celibacy and to religious persecution. Whenever men and women were possessed of gentle natures, that fitted them for deeds of charity, for literature, or for art, the social condition of the times was such that they had no refuge but in the bosom of the Church; and the Church exacted celibacy. Those gentle natures left no offspring; and thus was the race of our forefathers morally deteriorated. The Church acted as if she had aimed at selecting the rudest portion of the community for the parents of future generations; and the rules as to fellowships at our Universities are a relic of this barbarous custom, being bribes to men of exceptional ability not to marry. Religious persecution acted in the same way. The most fearless, truth-seeking, and intelligent were year by year incarcerated in dungeons or burned at the stake; so that, by this twofold selection, human nature was brutalised and demoralised, and we still feel its hateful effects in the long-continued antagonism to the essential requirements of an advancing civilisation. These concluding chapters stamp Mr. Galton as an original thinker, as well as a forcible and eloquent writer; and his book will take rank as an important and valuable addition to the science of human nature.

ALFRED R. WALLACE

SPECTRUM ANALYSIS

Die Spectral Analyse in ihrer Anwendung auf die Stoffe der Erde und die Natur der Himmelskörper. By Dr. H. Schellen, director der Realschule I.O., Cologne. (Brunswick, Westermann, 1870. London: Williams and Norgate.)

THIS book contains an accurate and luminous account of the recent discoveries in celestial chemistry and physics, and especially of the researches of our countrymen Huggins and Lockyer. As regards the completeness of that portion of the work bearing directly upon terrestrial chemistry, readers will, I fear, be disappointed. The first division of the book is devoted to a description of the means employed for the artificial evolution of light and heat of great intensity, beginning with combustions in oxygen, and ending with the electric-light. The second division is headed "The simple and compound spectra in their application to terrestrial matter;" whilst in the third and most important division Schellen considers the application of spectrum analysis to the heavenly bodies. The illustrations throughout the work are good, though many of them are not new, and are borrowed, without acknowledgment, from other books.

With respect to the physical constitution of the sun, it behoves us in this, the infancy of our knowledge, to be very careful in drawing positive conclusions. In the first place, there is no doubt that whilst Kirchhoff's original theory must undergo certain modifications, it will remain in its grand features as having first pointed out to us the true physical condition of the sun. The discovery of the chromosphere by Mr. Lockyer, in which, as a rule, only the bright hydrogen lines are seen, together with the yellow mysterious line of unknown origin, renders it difficult for us, especially if we accept Frankland and Lockyer's conclusions respecting the excessive tenuity of the upper chromospheric layers, to suppose that an atmosphere containing iron and the other 13 difficultly volatilisable metals can exist outside the chromosphere of sufficient density to effect such a powerful selective absorption as we see in the darkness of Fraunhofer's lines. Hence we should be inclined to agree with Lockyer that the absorption does not take place, as Kirchhoff suggested, in a far outlying layer of solar atmosphere, or in what we term the corona, but that the dark lines are produced within the chromosphere. But, on the other hand, upon what known physical basis are we entitled to assume that the higher lying portions of the solar atmosphere consist almost entirely of glowing hydrogen gas, whilst the lower lying layers contain the more easily condensible gases of the other 14 elements? The well-known laws of gaseous diffusion (to say nothing of the cyclones of vast magnitude and of enormous rapidity, which Lockyer has taught us are constantly mingling up the various layers of solar atmosphere), forbid us to suppose that the lighter hydrogen gas can ascend whilst the heavier metallic gases remain quietly below. If the components of the solar atmosphere are gaseous, they must be uniformly, or nearly uniformly, mixed. How then can we account for the constant presence in the chromosphere of the hydrogen lines, whereas the lines of the other constituents of the solar atmosphere are scarcely visible, except in special cases of the occasional projection of the vapours of magnesium and other metals, whilst the absorption is to occur in a lower gaseous layer, having a totally different composition?

Another point to be remembered is, that according to the law of exchanges the fact of the existence of absorption *necessitates* the existence of a lower temperature in the absorptive medium than in the *media* (either above or below) in which such absorption is not exhibited, and which may either give continuous or broken spectra, according to the physical and chemical nature of the incandescent bodies. How then can the iron and magnesium vapour exist nearer to the white-hot body of the sun than the hydrogen and yet possess a lower temperature? I am here forcibly reminded of the plausibility of a suggestion thrown out by Kirchhoff, in a conversation with me a few weeks ago, viz.: that the upper regions of the solar atmosphere may be constantly illumed by discharges of electricity; that the incandescent hydrogen may be heated not from below but from within its own mass, either by continuous flashes of lightning or constant auroral discharges; and, indeed, Zöllner has noticed the flashing out of certain bright points in the prominences, which may possibly be caused by solar lightning.

We must also bear in mind that the existence in the sun of a solid or liquid white-hot nucleus, as originally assumed, is not proved by the results of subsequent research; inasmuch as we learn from the recent researches of Frankland, Lockyer, and Wüllner (as indeed we may do from much older experiments), that incandescent gases under certain physical conditions emit white light and yield a continuous spectrum. So that spectrum analysis does not give us any *certain* information as to the physical state of that portion of the sun's body from which the main portion of light and heat proceeds.

H. E. ROSCOE

OUR BOOK SHELF

Essays on Physiological Subjects. By Gilbert W. Child, M.A., F.L.S., F.C.S. Second edition, with Additions; pp. 293. (London: Longmans, Green, and Co. 1869.)

THE present edition of Dr. Child's work is by no means a mere reprint of the last. It has undergone considerable modifications, chiefly in the form of additions, which will tend to make it more acceptable to a large class of readers. There is an almost entirely new essay on "Some Aspects of the Theory of Evolution," in which he endeavours to show how this theory is related to religious belief. He believes its proper meaning and tendency to have been much misunderstood; that far from being an "atheistical" conception, it is in reality only the scientific form of natural religion. The subject of "Physiological Experimentation on Animals" is also considered, whilst the last and longest essay, also new, is entitled "Physiological Psychology," in which he endeavours to make known to persons whose chief interest is in psychological rather than physiological science, all the chief points in the anatomy of the nervous system, necessary to be understood before he could explain, as he also attempts to do, the principal physiological conclusions which have been arrived at concerning brain action and mind.

Monographie der Molluskengattung Venus, Linné. I *Band. Sub-genus Cytherea, Lamarck.* Von Dr. Eduard Römer. 4to. (Cassel, 1869.)

NATURALISTS have been divided into those of the field and those of the closet. The author of this monograph may be classed in the latter category; and he certainly shares the indefatigable industry of his countrymen. Such labour, however, when applied to subjects of natural history, sometimes tends to an excessive multiplication of species; and its utility is in that respect questionable. Professor Römer, in a critical examination of the species of *Venus* which he published in 1857, enumerated 145 species arranged in eight sub-genera. In the present work one only of these sub-genera is treated, and includes no less than 209 species. We may well ask, with Cicero, "Quousque tandem abuteris patientiâ nostrâ?" A common European species (*Circe minima*) is described in two sections under different names; and some of the author's new species seem to be merely the young of well-known forms. The method in which he subordinates this host of species is unusual. Eight sections of the sub-genus *Cytherea* are named and described; and the specific names are applied, not to the genus or even to the sub-genus, but to each section. The sectional name is used in a generic sense; so that *Venus meretrix* becomes *Meretrix meretrix*, and *V. Dione* is converted into *Dione Dione*. The description of species is not in every case consistent with the sectional characters. In the first section, *Tivela*, the shape is stated to be "trigona;" but in *T. nitidula* we find it is "ovato-elliptica," and in *T. nucula* "cordato-ovata." It would also be more convenient to have the descriptive characters given in the same order throughout. In the description of the first species colour takes precedence of sculpture; in that of the second species the order of these characters is reversed. The same confusion occurs as to the teeth and pallial scar as well as to other characters. But the excellence of the illustrations compensates to a great extent for the small blemishes which it is the unpleasant duty of a critic to point out. The plates are fifty-nine in number and contain many hundred figures, all of which are evidently truthful, admirably engraved, and exquisitely coloured. The monograph must be indispensable to collectors, who are better pleased with a redundancy than with a paucity of species. Dealers have the same feeling.

J. GWYN JEFFREYS

Abstracts of Two Papers on the Geography of Disease. I. The Geographical Distribution of Heart Disease and Dropsy in England and Wales. II. The Geographical Distribution of Cancer in England and Wales. By Alfred Haviland, M.R.C.S. Pp. 18. (London, 1869.)

THIS pamphlet contains a reprint of two papers, in which the author has endeavoured to map out the districts in which the particular forms of disease above-mentioned are most frequently encountered. The subject of his geographical distribution of disease is a most important one in its bearings upon the great question of the causation of disease. It is a subject, however, in which the facts should be many and the conclusions few, if he who draws them wishes to make lasting contributions to the science of medicine.

Leçons sur la Physiologie Comparée de la Respiration. Par Paul Bert. (Paris: Baillière. London: Williams and Norgate.)

IN his preface, the author to some extent apologises for the imperfections of this volume, on account of the difficulties, including "the singular penury of the laboratory over which he presided," attending the delivery of the course of lectures of which it forms the report. No apology, however, is needed for an interesting and admirable series of discourses on a difficult and yet important topic. The book does not profess to be a complete Treatise on Respiration, but rather treats fully of certain selected points, such as the respiration of tissues, the gases of blood, the respiratory mechanism in various classes of animals, asphyxia, &c., &c. The "graphic method" is employed throughout, by far the larger number of the illustrations being representations of various respiratory movements. We would especially call attention to the chapters on the respiratory movements of fishes, amphibia, reptiles, and birds, in which the graphic method brings out many singular and interesting facts. Even in matters of science, national characteristics come to the surface; and quite apart from the language, it is generally an easy matter to distinguish the work of a Frenchman from that of German or an Englishman. Prof. Bert's work is no exception to the rule, though we must add, with singular pleasure, that it is far more cosmopolitan than many of the writings of his fellow countrymen. The author has evidently studied and appreciated the labours of countries other than his own.

Systematische Beschreibung der bekannten europäischen zweiflügeligen Insekten. Von J. W. Meigen, Achter Theil, von Hermann Loew, Erster Band. Schmidt, Halle, 1869. (London: Williams and Norgate.)

PROFESSOR LOEW, who is to be regarded as the highest authority on European Diptera, contents himself in this book with supplying a sort of supplement to Meigen's great work on the insects of that order inhabiting Europe. It is, perhaps, to be regretted that he does not rather direct his efforts to the production of a complete systematic work on the subject, but he probably thinks that the time is not yet ripe for such an undertaking, and in the meanwhile the full and detailed descriptions of species detected since the publication of Meigen's last volume will be most welcome to entomologists. The present volume contains descriptions of 182 species of two-winged insects, belonging to various families from the *Tipulidæ* to the *Dolichopodidæ*, and especially of numerous forms of *Asilidæ* and *Bombyliidæ*. No fewer than 138 of the species are described as new, and the greater part of the remainder are species described by Professor Loew himself in various scattered papers.

Nachrichten von der K. Gesellschaft der Wissenschaften und der Georg-Augusts Universität zu Göttingen, aus dem Jahre 1869.

THE volume of "Reports of the Royal Society of Sciences and University of Göttingen," for 1869, which has lately reached us, contains a great number of papers of considerable value, for the most part relating to mathematics, physics, and chemistry. There are also some memoirs relating to literary antiquities, but natural history receives little attention, the only papers being a notice of some marine animals and their metamorphoses by Dr. E. Mecznikow, and a revision of the *Butomaceæ*, *Juncaceæ*, &c., collected by the Brothers Schlagintweit in Upper Asia by M. F. Buchenau, to which we may specially call the attention of botanists, as a good many new species are described in it.

Via Medica. A Treatise on the Laws and Customs of the Medical Profession, in relation especially to Principals and Assistants; with Suggestions and Advice to Students on Preliminary Education. By J. Baxter Langley, M.R.C.S., F.L.S. Third edition. (London: R. Hardwicke. 1869.)

THIS little work is full of most useful information concerning the subjects indicated on its title-page. That it meets a demand for information of this description is sufficiently indicated by the rapid sale of the two previous editions.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Geological Calculus

MR. WALLACE'S essay, completed in NATURE, No. 18, brings to the front the question whether or no we can measure the Geological Past by the historical unit of years. Have we any basis for fixing with any certainty the date of any geological epoch? Mr. Wallace's answer in the affirmative to this is worthy of a careful analysis, because it represents fairly the ideas current in the minds of many geologists.

There are three ways by which the attempt to solve the problem has been made:—(1.) The slow geological changes which have been noted during the period of history, such as the modification of coast line, the silting up of estuaries, and the like. This method Mr. Wallace very justly discards as being "too minute, too limited, and too uncertain to afford the basis of even any approximate measurement" of the geological past. (2.) The change in organic life. This also is a unit of measurement "which we have not yet been able to get; for the whole length of the Historical Period has not produced the slightest perceptible change in any living thing in a state of nature." Professor Huxley, in 1869, gave expression to very much the same view, in his Presidential Address to the Geological Society. This method, therefore, of approaching the problem may also be given up as hopeless. (3.) The excentricity of the earth's orbit which Mr. Croll has used, in making his ingenious computation of the lapse of time since the glacial period, on the hypothesis that the severity of climate at that time was due solely to astronomical causes, and not, as had been previously supposed, to changes in the physical geography of the earth. But, as Sir Charles Lyell argues, since the distribution of land and water and the course of marine currents now modify climate, they cannot be fairly supposed to have had no share in causing the severity of the glacial period. And therefore, the fact that they are ignored in Mr. Croll's computation, destroys its value as fixing the glacial date, although there may be astronomical reasons for a depression of temperature at certain times in the northern hemisphere without the aid of any terrestrial agent. This, indeed, is practically admitted by Mr. Croll, when he reduces the date of the last glacial period from 750,000 to about 80,000 years ago, because of the amount of sub-aerial denudation that has taken place since that time. There are, moreover, two fatal objections to any estimate that can be formed of the amount of denudation since the glacial period. First of all, the denudation now going on, over any wide area, has not yet been ascertained with anything like accuracy, and it acts unequally, even in any one limited region. Secondly, as we do not know the original thickness of the glacial deposits, or the extent to which the existing valleys were excavated in preglacial times, it is impossible to estimate the amount of denudation since that period, even if we had trustworthy data from our own experience. This third method, therefore, of measuring geological time, is not more satisfactory than the former ones.

Mr. Wallace, however, assumes in the second part of his essay that the *vera causa* of the glacial epoch was the high excentricity of the earth; and then he proceeds to reduce Mr. Croll's lowest estimate by 20,000 years, by using precisely that argument of observed change in physical geography which in the first part was discarded as "too uncertain." From this untenable standpoint hangs the following chain of reasoning.

"Now it is most important to observe that, for the last 60,000 years, the excentricity has been very small—for three-fourths of the time less than it is now. During this time the opposite phases of precession, each lasting 10,500 years, will have produced scarcely any effect on climate, which in every part of the earth will have been *nearly uniform for that long period.* But this is quite an exceptional state of things; for the curve of excentricity shows us that, during almost the whole of the last three million years, the excentricity has been high—almost always twice, and sometimes three and four times as much as it is now. If, therefore, Mr. Croll's theory be correct, there will have been a change each 10,500 years during this vast period (in all the extra-tropical regions at least) from a very cold to a very mild climate. This will necessarily have caused much migration, both of plants and animals, which would inevitably result in much extinction and comparatively rapid modification. Allied races would be continually brought into competition, altered physical conditions would induce variation, and thus we should have all the elements for natural selection, and the struggle for life, to work upon and develop new races. High excentricity would therefore lead to a rapid change of species; low excentricity to a persistence of the same forms; and, as we are now and have been for 60,000 years, in a period of low excentricity, *the rate of change of species during that time may be no measure of the rate that has generally obtained in past geological epochs.* Thus we should have explained the extraordinary persistence of organic forms during the historical period, as well as during the preceding Neolithic age, although slight changes of climate and of physical geograghy have undoubtedly taken place; and it would prove to be not so much the *usually* slow rate of organic change, as the fact of our living in the midst of an *exceptionally uniform climatic epoch*, that has hitherto prevented us from obtaining a measure of the average duration of species."

The major premiss latent in this argument is, that all climatal change from the glacial epoch to the present day has depended solely on the excentricity of the earth's orbit, a proposition which Mr. Wallace himself would be the last to endorse. If it be admitted that the alteration of a marine current here, or the elevation of a sea-bed there, be factors in climatal change, the estimate of 60,000 years in which they are not reckoned is without value. The study of the mammalia, of historic, pre-historic, and post-glacial times does not warrant the conclusion that the persistence of organic forms was "extraordinary," nor the recognition of an "exceptionally uniform climatic epoch." The mammals have exhibited on the whole a steady diminution *in size* from the post-glacial to the present day, owing probably to the fact that they have been worried off their feeding and hunting grounds by man. The non-development of new species during that time may be ascribed to its short duration as compared with past geological epochs, rather than to exceptional conditions of life caused by exceptional excentricity. The deposits in Britain since the glacial epoch are a mere surface film compared with those of previous geological periods. The steady northern retreat of the reindeer during historic times, taken in conjunction with its pre-historic range, testifies to a gradual increase of temperature in central and northern Europe, to say nothing of the historical evidence of the former severity of winter in Gaul and Italy from Cæsar's time to the present.

There is another point which ought not to be omitted. Mr. Scott Moore is quoted as maintaining that the group of mammalia commonly called "Quaternary" is pre-glacial because of the "striking fact, that none of the supposed pre-glacial gravels ever rest on the boulder clay, but always on an older rock, which could hardly have been the case in every instance were they all post-glacial." So far from this being true, the famous Bedford section proves, as Mr. Wyatt showed in 1860, that the mammaliferous and flint-implement producing gravels are post-glacial without the possibility of a doubt. On the Norfolk coast mammaliferous gravel overlies the boulder clay in certain places. The mammalia found in making the Ipswich tunnel were derived from a river deposit, clearly of later date than the boulder clay of the district. Very many other cases might be quoted that would show that this sweeping generalisation is without any foundation in fact.

But can we measure geological time by the lapse of years? If so, we shall have solved a problem infinitely harder than that which has foiled the archæologists. Can they fix the date, say of the introduction of iron into Europe, or of the dawn of the age of bronze or of stone? No man would venture to answer yes. Modern historians are becoming more and more alive to the worthlessness of the so-called chronology of the Assyrian kings and of the Manethonian dynasties. If, then, we are ignorant of the date of any one of these events, which are, comparatively speaking, of yesterday, and we can simply tell that one succeeded another in a definite order, how can we reasonably expect to fix the date of any one period of the geological past? The attempt can only be made by forsaking those laws of rigid induction by which geology has become a science—by the assumption of a premiss which we have no right to assume. The strict interpretation of geological phenomena only warrants our saying that, one event, say the deposition of the chalk, took place in Europe after another,—the deposition of the Neocomian strata,—how much after none can tell. In other words, the geological "when" merely implies before and after, while in history the idea not only of sequence, but of the lapse of how long before and how long after, can be mastered. The attempt to fathom the geological past with our short historical sounding line has up to the present time resulted merely in estimates, varying according to the assumed basis in each by thousands of centuries, that have been about as valuable in geological theory as Archbishop Usher's chronology has been found in Biblical criticism. The problem is hedged in by innumerable difficulties, which cannot be overcome in the present state of science.

W. BOYD DAWKINS

On the Diffraction Spectrum and Wave Lengths

THE letter which I wrote about the diffraction spectrum has called forth several inquiries. I have been asked how it is that in that spectrum the position of a line depends only on its wave-length, and I may take the opportunity of answering these questions through your columns. First, however, let me state that the numbers given in the table in my letter of February 9 are copied, including the obvious errors, *verbatim* from the translation of Mossotti's memoir in vol. v. of Taylor's "Scientific Memoirs." I attach no importance to such analogies. Any analogy between these lines and interdependent notes of music must, I expect, be entirely accidental. The latest experiments made by Mr. Lockyer have shown that the lines given out by a gas vary according to temperature and pressure, and if these be caused by vibrations of the particles of the gas, whether atomic or molecular, the periods of these vibrations must be dependent on the temperature and pressure. A distinct numerical statement of this interdependence is a great desideratum in this part of science with a view of affording the materials for making and testing a mechanical theory of that interdependence. These are the great problems which demand our attention, as I take it, with respect to the fixed lines, and our ability to correlate light with other modes of force.

If a beam of homogeneous light be admitted through a small hole into a dark room, and fall on the opposite wall, it will illuminate only the portion of the wall directly opposite it. But if a series of fine parallel wires, or a fine grating be put across the hole, there will be seen ranged in a line perpendicular to the grating a series of nearly equal distant spots, or rather streaks of light. This is because the wires of the grating shut out those waves of light which at these points would destroy the other waves. To understand this more clearly, suppose A*a*, B*b*, &c., &c., to be a number of consecutive and equidistant points in the front of a wave coming through a small hole, A*a*, &c. These may, by the principle of Huyghens, be regarded each as the origin of a new wave, together having the same effect as the original

wave, all starting in the same phase. There is darkness at every point on an opposite wall, except directly opposite the hole, because of the interference of these elementary waves, which destroy one another everywhere except exactly in front. This is owing to the shortness of the waves and the number of sources. Let P be a point on the wall which we shall suppose sufficiently far from the hole in order that the lines PA, Pa, PB, Pb, &c., may be regarded as all sensibly parallel. On that account also each of these lines exceeds the one next it by the same amount. Now, generally, when the waves from A, *a*, &c. arrive at P, the wave from *a* will not entirely blot out that from A, but a residue will be left, which will be blotted out by other similar residues. But there will be certain points along the wall at which the waves will blot one another out in a peculiarly regular way. We shall suppose P to be one of these points, namely, that each of the distances A P, *a* P, &c., exceeds the one next it by exactly some odd multiple of the length of half a wave—say in this instance half a wave's length. Then in this case the disturbance originating at *a* will arrive at P exactly half a wave's length in advance of that from A, and the wave from A will be exactly blotted out, so to speak, by that from *a*; similarly that from B will be exactly blotted out by that from *b*; and so on. So that if I were to put wires at *a*, *b*, *c*, &c., so as to stop up the waves entering there, the waves from A, B, C, &c., would fall at P each undestroyed and assisting one another, each disturbance being an exact wave-length behind the other, and therefore all in the same phase. Thus light would be restored at P. And similarly at other points where the difference between A P, *a* P, &c., is three, five, &c., semi-wave-lengths. Light would be restored in the same way at no other places because the elementary waves do not at other points destroy one another in this peculiar alternative manner. Supposing *a*, *b*, *c*, &c., to be the centres of the wires, A, B, C, &c., to be the centres of the spaces between, a more refined consideration shows us that the position of P does not depend on the space A *a* being equal to the space *a* B, but only on the total length A B (or *a b*). Hence we have a very accurate method of determining the wave-length from the position of P. For if θ be the angle between the line drawn from the hole straight forward in the direction of the ray and the line drawn to P, then the difference between A P and B P, which is a wave-length, is also A B sin θ. So that to get the wave-length all that we have to do is to measure θ and A B. A B may be very accurately got by ruling the grating on glass with a machine, and counting the whole number of rules given and the total space which they occupy. Adaptations of this method may be made to suit circumstances, as for instance the grating may be attached to the object glass of a telescope used for measuring the angle θ. It is by such a method that the wave-lengths have been found for the principal fixed lines in the solar spectrum, and the wave-lengths of all other lines are determined from these by some formula or other which may best suit the views of the calculator; the constants of the formula being determined so as to constrain the formula to satisfy the truth at those fixed lines whose wave-lengths are got directly from the refraction spectrum. Uncertainty, therefore, prevails about all wave-lengths thus obtained, although, of course, the uncertainty must, from the method of calculation and the number of lines whose wave-lengths have been obtained from the diffraction spectrum, lie necessarily between narrow limits. These latter are the only wave-lengths, however, which have the recommendation of being due to direct observation; and the method of obtaining the wave-length by observation from the diffraction spectrum is one capable of such accuracy, that I have sometimes considered that the wave-length thus determined might be used as an absolute and recoverable standard of linear measure.

Of course, the preceding investigation must not be considered to be perfectly exhaustive in giving the whole character of the phenomena, which are explained by a more refined investigation, in which the space between each wire is regarded, not as the source of one, but of an infinity of waves, so that the application of Huyghens' principle becomes rigidly correct. By this means the difference of the spaces occupied by the wire and the opening is found to have no effect on the position of P, but a certain effect on the brightness there, which, under certain circumstances, causes one of the spectra entirely to disappear: an experimental result which, being thus deducible from the theory of undulations, gives a striking proof of the power of that theory to account for phenomena.

Trinity College, Cambridge, March 2

The Valuation of Liquid Town Sewage

IF there is one thing that is more to be deprecated than another, it is the unnecessary importation of personalities into a scientific discussion, or indeed into any serious matter of business, and fortunately this is not now a common proceeding in this country. It was therefore with a feeling of unqualified disappointment that I read Dr. Paul's personal attack on myself in your columns.

Whenever I hear or read an opinion or statement which I believe to be erroneous, I endeavour to point out its fallacy, and shall always continue to do so. It is the undoubted right, as it is in some degree the duty, of every man to do this. But opinions may be criticised and condemned without any reflection on the man who holds them. This is all I did in Dr. Paul's case, and I certainly endeavoured to do it good-naturedly; at all events I not only made no reflection whatever on Dr. Paul's character, but I did not even mention his name. He had, in his article, hazarded an opinion on a question of practical farming, of which, so far as I know, he does not profess to have any personal knowledge or experience whatever. This opinion I knew from experience to be utterly erroneous, although exceedingly plausible. I therefore did my best to point out its fallacy, partly with a view of convincing him. He replies, not by arguments, but by a personal attack on me, the acrimony of which I deplore but cannot explain, and by re-asserting his opinion as "a fact long accepted as beyond question . . . . by authorities too numerous to name." In short, it appears to be "a fact" which the proverbial schoolboy ought to know; but I am never more pleased than when the schoolboy with his universal knowledge is brought out against me. It is generally a sure sign that the assumed "fact" has no other foundation than that intelligent youth's imagination.

In the present case I say that if a man buys sewage he should buy it as he would any other manure, on the basis of a chemical analysis. I say that this is the *only* safe and reliable basis on which to found a calculation of its money value. And I say that if a farmer puts so much money's worth of manure into his land, he is simply a bungler if he does not get it out again with its proper increment of profit, whether he buries it in his land by means of a plough, or of a spade, or of water. Dr. Paul, on the other hand, says that if a man pays so much money for so much sewage because it contains a certain percentage of ammonia he will be ruined. Why? Because of the water.

Of course we all know that water applied to certain crops in certain stages would spoil them; so would manure. If, therefore, a farmer applies sewage under such conditions, he is a bungler. His skill, as a sewage farmer, is shown in so arranging his land and crops as never to injure but always to benefit them by the application of his sewage. This is simply a question of good *versus* bad management. It is one to be decided on the farm and not in the laboratory. Incredible as it may appear to Dr. Paul, on taking a lease of the sewage of the town of Romford, although bound, under penalty, to use it every day in the year, I stipulated for an additional dilution of the sewage to the extent of twenty gallons of water per head of the population *per diem*, and this although I have not got the proportion of "twenty-five acres for every 100 persons," as Dr. Paul says I recommend, but which I never recommended, and should be the first to condemn.

Having defended my opinion, I will now, with your permission, defend my character. Dr. Paul regrets that I should "declare myself a partisan of one particular solution of the town-refuse problem." It may be that he has so recently commenced the study of this large question that he has, as yet, formed no opinion upon it except that by irrigation the value of the manure cannot be recovered; but I have laboured at it for many years, and it is not possible that in those years I should not have formed some very distinct opinions. Will any one else regret that I should "declare" what those opinions are? I think not; and I think that such a declaration is straightforward and honest, though why Dr. Paul should affect to think that I have made it now for the first time I cannot say. My views on this subject have been publicly expressed for many years, and have been so expressed in his presence. Dr. Paul complains that I desire "the promotion of a project at any price." I do. I desire to see sewage utilised all over the country, and by irrigation, if possible, because I believe it is the right thing, and I am gratified to find that my views are in exact accord with those expressed in the unusually careful and able report just published by the Royal Commission on Pollution of Rivers. But when I joined the Committee of the British Association on Sewage, I at once suggested that the scope of their inquiry should be enlarged so as to include a full investigation into every proposal for the utilisation of sewage which presented any appearance of practicability. I also suggested a source from which the necessary funds might be obtained. My suggestions were approved both by the Committee and by the Council of the Association, the funds have been in great part obtained, and the inquiry is about to be prosecuted. Whether Dr. Paul is justified in the personal attack he makes upon me, I will therefore leave to the judgment of your readers.

I will merely add, as regards my opinions, that they were condemned in the most unqualified and unmeasured language by Baron Liebig five years ago; but I have lived to prove Liebig mistaken in this instance, and, on the practical farming part of the question, I think I may claim to be a very much better authority than Dr. Paul. At all events, as the German philosopher said of the author of the Epistle to the Corinthians, "I do not agree with your Dr. Paulus," and I have yet to learn that such a disagreement involves the breach of any law, human or divine, although Dr. Paul is evidently firmly convinced that while *he* has an undoubted right to express "a foregone conclusion," such an expression on *my* part is a sign of great moral depravity. This is a common form of superstition, but it is scarcely scientific, and seldom adds much weight to a man's opinions. W. HOPE

Parsloes, March 6

Transactions of Scientific Bodies

I WISH it were possible to induce our learned societies to be a little more liberal; it should be their aim to spread knowledge, not make it a luxury for the wealthy. I happen to wish to read a paper by Professor Tait on "Rotation," published in the Transactions of the Royal Society of Edinburgh. The only libraries I have access to are those of the British Museum and London Institution. At the Museum there is no volume of the "Transactions" later than 1864; at the London Institution no volume later than 1862; so that if I persevere in my intention of reading the paper, I must buy the volume containing it, for which I must pay 2*l.* 2*s.*—that is, I must buy thirteen papers I don't want in order to be able to read one which I do want: these include one on the temperature of newly-born children, and another on tetanus in cold-blooded animals.

All papers should be published separately; this would lead to a much wider diffusion of them, and the Societies would benefit by their increased sale.

London, March 7 G.

Sir. W. Thomson and Geological Time.

THE *North British Review*, for July last, thoroughly exposes the inaccuracy of the quotation from Prof. Thomson, referred to by your correspondent G.H., in its article devoted to the consideration of Geological Time. J. S.

YOUR correspondent G.H. will find in one of Thomson's papers something very like the assertion "that there was a time when the earth rotated too swiftly for the existence of life," but expressed in a manner at once more precise and less pleonastic. "The existence of life" reminds me of a phrase which I heard a few days ago from a female beggar; she lamented that her husband had "fallen into habits that are habitual." Well; the required reference is the paper "On Geological Time," in the Transactions of the Geological Society of Glasgow, vol. iii. Part I. pp. 15 and 16 (§§ 19 and 20). A thousand million years ago, says Thomson, "there must have been more centrifugal force at the equator due to rotation than now, in the proportion of 64 to 49. . . . If the earth rotated seventeen times faster, bodies would fly off at the equator. . . . If you go back ten thousand million years ago—which, I believe, will not satisfy some geologists—the earth must have been rotating more than twice as fast as at present—and if it had been solid then [which he thinks improbable], it must be now something totally different from what it was." Such a state of things he seems to consider inconsistent with any organic life such as we know of. Surely the connection of this question with the argument from retardation by tidal friction is too plain to need exposition.

Ilford, March 11 C. M. INGLEBY

How large seems the Moon?

READING Mr. R. A. Proctor's communication under the above heading in NATURE of March 3rd, reminds me of an experiment I tried some time ago. I imagined I should get all sorts of answers to the question, varying from "a fourpenny-piece" upwards, without any particular size being more frequently pitched on than any other. I did not collect more than about twenty or thirty replies, but they were sufficient to show that, contrary to my expectation, *one to two feet* was assigned more frequently than other sizes. Mr. Proctor says the estimate of a foot in diameter assigns a distance of 115 feet to the moon. If he were to try to convince the observer of the soundness of this deduction, the latter would probably meet him with vehement reiteration that he only means the moon *looks* a foot large. It seems to me fairer to say that such a man thinks a two-foot rule 115 feet off, a fit and proper measure for celestial objects. I think many, who are aware of the futility of attempting to convey their ideas to other minds by these comparisons, yet involuntarily make them in their own. I am conscious of a lurking idea that the moon is more like a fourpenny-piece in size than anything else. The question is, what is the cause of the "personal equation" which determines for each individual the distance of the imaginary two-foot rule—and why is about 115 feet more common than other distances?

I think it probable the sort of objects with which a man is familiar in his daily life may have some influence on his judgment in this respect. The men I questioned were for the most part engaged in warehouse or out-door work. I should like to know what answers watchmakers or jewellers would give. This theory, however, fails to account for the different estimate formed by the same individual when the moon is high above, or on the horizon; but I imagine, in the latter case, the imaginary rule is superseded, or more properly modified, by the terrestrial objects which are in the field of vision with the moon.

Cardiff, March 7 GEORGE C. THOMPSON

Cuckows' Eggs

MAY I be permitted to make a few observations upon Mr. Sterland's letter in your issue of the 27th of January, relative to the cuckows' eggs' controversy.

In answer to Prof. Newton's query, "If the eggs in question were not cuckows', what birds laid them?" Mr. Sterland says, "My reply is simply that they were laid by the birds in whose nests they were found."

Besides the well-known fact mentioned by Mr. Newton (NATURE, p. 266), "that when birds lay larger eggs than usual the colouring is commonly less deep," which tells so strongly against Mr. Sterland, I will only mention the following instances.

1st. The egg No. 9 in the series given by Herr Baldamus, (see *Zoologist* for April 1868), which the Royal Forester, Mr. Braune, found *in the ovary* of a just-killed cuckow, and which "was coloured exactly like the eggs of Hypolais."

2ndly. The egg No. 26 in the same series, belonging to the collection of Dr. Dehne, described as a "light-greenish blue egg without any markings," and "might have passed for the egg of either species of the redstarts," which specimen "was *laid in a cage* by a cuckoo that was caught in a hay loft." (The *italics* are mine.)

3rdly. The two instances given by Mr. H. E. Dresser, (NATURE, p. 218) of two eggs of the cuckow "closely resembling" those "of the common bunting (*Emberiza miliaria*)," one found in a blackbird's, the other in a robin's nest.

Can Mr. Sterland explain away the 1st and 2nd instances? and how does he reconcile the 3rd instance with his affirmation? Will he venture to say that the two apparent bunting's eggs were laid by a blackbird and a robin respectively, or, will he risk the remark that a common bunting had taken a cuckow-like freak into its head and been laying its eggs in other birds' nests? As either alternative is too absurd to be worth a moment's consideration, we can only conclude that they are cuckows' eggs, unless there has been some mistake as to the nests from which they were taken—scarcely likely, if Mr. Dresser's remarks are carefully read.

Therefore I think Mr. Sterland must admit, if he accepts these facts as authentic, that the cuckow's eggs *do* vary to a large extent, and doing so, he has little foundation for doubting the identity of the specimens mentioned by Herr Baldamus as taken from nests whose eggs they resembled.

For my own part I have every confidence in the discrimination of that ornithologist, and am not afraid that he had been carried away by a pet theory that led him to *imagine* this or that egg taken "out of the nest of the hedge-sparrow or tree-pipit" to be a cuckow's merely because it is "an egg rather larger than the rest, but marked and coloured in a similar manner." If Mr. Sterland will carefully examine Herr Baldamus's evidence he will find that it is not of such a superficial character.

I agree with Mr. Sterland that it is certainly singular that British and Continental observers should come to such opposite conclusions as to this variation of the cuckow's egg in their respective countries; but this is no reason for impeaching (merely because our experience differs) the testimony of the eminent Continental oologists who affirm this extreme variation, and to some of whom Herr Baldamus's theory is probably unknown; as instance, in the two quotations by Prof. Newton (NATURE, p. 266) from *Des Murs* and *Degland et Gerbe*.

Can it be that such extreme variation really does occur on the Continent, and is yet comparatively absent in Britain? I leave it to abler hands than mine to discuss; but if it should prove so, it will be another feature in the already remarkable habits of the cuckow.

Tadcaster, Feb. 7. FRANCIS G. BINNIE

MR. RUSKIN ON RIVER CONSERVATION

IN his recent Friday evening discourse on Verona and its Rivers, at the Royal Institution, Mr. Ruskin, speaking of the Adige and the Po, said: "I want to speak for a minute or two about these great rivers; because in the efforts that are now being made to restore some of its commerce to Venice precisely the same questions are in course of debate which again and again, ever since Venice was a city, have put her Senate at pause—namely, how to hold in check the continually advancing morass formed by the silt brought down by the Alpine rivers. Is it not strange that for at least six hundred years the Venetians have been contending with those rivers at their *mouths*—that is to say, where their strength has become wholly irresistible—and never once thought of contending with them at their sources, where their infinitely separated streamlets might be, and are meant by Heaven to be, ruled as easily as children? And observe how sternly, how constantly the place where they are to be governed is marked by the mischief done by their liberty. Consider what the advance of the delta of the Po in the Adriatic signifies among the Alps. The evil of the delta itself, however great, is as nothing in comparison of that which is in its origin. The gradual destruction of the harbourage of Venice, the endless cost of delaying it, the malaria of the whole coast down to Ravenna, nay, the raising of the bed of the Po, to the imperilling of all Lombardy, are but secondary evils. Every acre of that increasing delta means *the devastation of part of an Alpine valley, and the loss of so much fruitful soil and ministering rain.* Some of you now present must have passed this year through the valleys of the Torcia and Ticino. You know, therefore, the devastation that was caused there, as well as in the valley of the Rhone, by the great floods of 1868, and that ten years of labour, even if the peasantry had still the heart for labour, cannot redeem those districts into fertility. What you have there seen on a vast scale, takes place to a certain extent during every summer thunderstorm, and from the ruin of some portion of fruitful land the dust descends to increase the marshes of the Po. But observe further—whether fed by sudden melting of snow or by storm—every destructive rise of the Italian rivers signifies the loss of so much power of irrigation on the south side of the Alps. You must all well know the look of their chain—seen from Milan or Turin late in summer—how little snow is left, except on Monte Rosa, how vast a territory of brown mountain-side heated and barren, without rocks, yet without forest. There is in that brown-purple zone, and along the flanks of every valley that divides it, another Lombardy of cultivable land; and every drift of rain that swells the mountain torrents, if it were caught where it falls, is literally rain of gold. We seek gold beneath the rocks; and we will not so much as make a trench along the hillside to catch it where it falls from heaven, and where, if not so caught, it changes into a frantic monster, first ravaging hamlet, hill, and plain, then sinking along the shores of Venice into poisoned sleep. Think what that belt of the Alps might be—up to four thousand feet above the plain—if the system of terraced irrigation, which even half-savage nations discovered and practised long ago in China and in Borneo, and by which our own engineers have subdued vast districts of farthest India, were but in part also practised here—here, in the oldest and proudest centre of European arts, where Leonardo da Vinci—master amongst masters—first discerned the laws of the coiling clouds and wandering streams, so that to this day his engineering remains unbettered by modern science: and yet in this centre of all human achievements of genius no thought has been taken to receive with sacred art these great gifts of quiet snow and flying rain. Think, I repeat, what that south slope of the Alps might be; one paradise of lovely pasture and avenued forest of chestnut and blossomed trees, with cascades docile and innocent as infants, laughing all summer long from crag to crag and pool to pool, and the Adige and the Po, the Dora and the Ticino, no more defiled, no more alternating between fierce flood and venomous languor, but in calm clear currents bearing ships to every city and health to every field of all that azure plain of Lombard Italy. . . . . Without in the least urging my plans impatiently on any one else, I know thoroughly that this which I have said *should* be done, *can* be done, for the Italian rivers, and that no method of employment of our idle able-bodied labourers would be in the end more remunerative, or in the beginnings of it more healthful and every way more beneficial than, with the concurrence of the Italian and Swiss Governments, setting them to redeem the valleys of the Ticino and the Rhone. And I pray you to think of this; for I tell you truly—you who care for Italy, that both her passions and her mountain streams are noble; but that her happiness depends, not on the liberty, but the right government of both."

CAPTAIN FRED. BROME

WITH great regret we have to record the death of Captain Fred. Brome, formerly Governor of the Military Prison on Windmill Hill, Gibraltar, and well known to many of our geological and archæological readers as the able and indefatigable explorer of the ossiferous caves and fissures of the rock.

His explorations, an account of which, so far as they related to the human remains and relics, was published in the Transactions of the Congress of Prehistoric Archæology for 1868, were commenced in April, 1863, and unremittingly continued, often under considerable difficulties, to December, 1868, when he was most unaccountably removed from the post he had so long and so well occupied.

The amount of labour and responsibility thus voluntarily undertaken by Captain Brome, solely in the interest of science, and without any personal motive whatever, can scarcely be imagined, nor can the value of the results obtained by him be easily over-estimated.

A more striking instance of self-devotion to a purely scientific object can nowhere be found.

The results of Captain Brome's work may be said to have afforded all, or nearly all, the knowledge we possess of the priscan population of the Rock of Gibraltar, and have added enormously to our materials for determining the nature of its quaternary fauna, as disclosed in the ossiferous breccia and other contents of the rock fissures, from the examination of which Cuvier truly anticipated that the most important information would be derived.

Captain Brome's death occurred, we are sorry to say, under very melancholy circumstances. Having been removed from the post which he had so long and so usefully filled, and for which, from his great experience, extraordinary energy, and high sense of duty, he was so admirably qualified, he was appointed, on coming to England, Governor of the Military Prison at Weedon. Here he hoped to find an asylum for his family, and some compensation for the sacrifices he had been compelled to make in leaving Gibraltar.

But this was not to be. Amongst the numerous reductions of late effected in our military establishments, the disestablishment of the prison at Weedon was one. The notice that his services would be no longer required was received by Captain Brome a short time since, and it seems to have so affected him, from the apprehension that his family would thus be deprived of all support—and this after a public service of thirty years—that, although a strong and vigorous man, he gradually sank, from mental depression, as it would seem, and he may truly be said to have died of a broken heart on the 4th March, leaving a widow and eight children, we fear wholly unprovided for.

A more melancholy case, and one more deserving of the sympathy of the scientific world, and, as we should venture to hope, of the consideration of the authorities at the War Office, it is impossible to conceive. G. BUSK

THE GEOLOGY OF THE HOLY LAND

IN the year 1866 the Duc de Luynes organised an expedition for investigating the physical geography and geology of the Holy Land and part of the surrounding territories. Narratives of some features of the explorations have already been given to the world, but it is only now that the first part of the geological report appears. M. Lartet, the geologist of the expedition, has chosen as the vehicle of publication for his memoir, the opening number of a new magazine—the *Annales des Sciences Géologiques*. Instead of confining himself to a record of what he personally accomplished, he has with much labour given a brief summary of the publications of previous writers, and has incorporated their results with his own, so as to present in a clear and connected form the sum of all that is at present known regarding the geology of the country between Lebanon and the Red Sea. Until the whole of the memoir is published it would be premature to pass judgment upon the position which it will ultimately take in the geological bibliography of Palestine. The present instalment, after its introductory and historical sections, passes on to describe the igneous and crystalline rocks, leaving the great limestone and later formations for a subsequent paper.

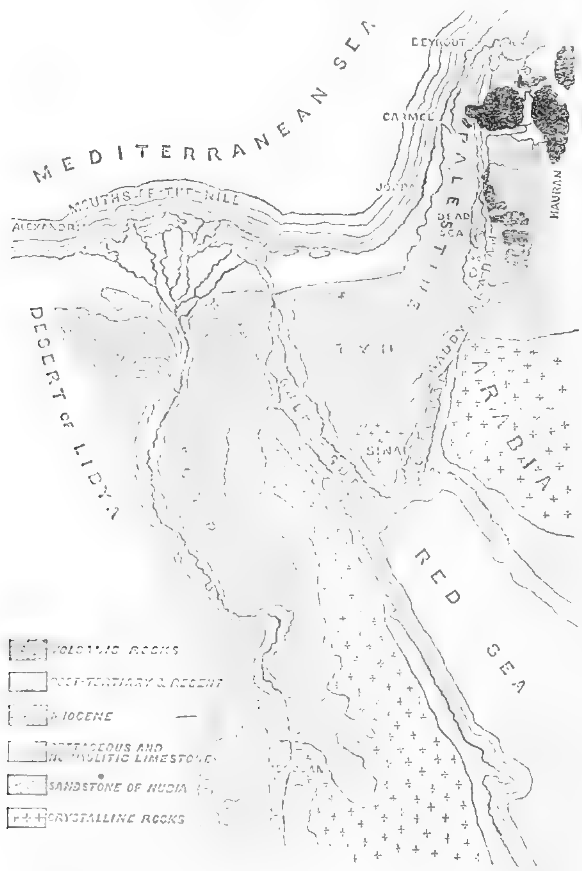
Viewed in the great scale, the geological structure of Palestine is remarkably simple. A long table-land or succession of table-lands, consisting for the most part of horizontal or gently inclined cretaceous and nummulitic limestones, is traversed by the valley of the Jordan, and cut through by transverse valleys, many of which are now quite dry. Stretching southwards into the peninsula of Sinai, these calcareous plateaux end against a mass of high rugged ground—the mountain-group of Sinai and Arabia—consisting of crystalline rocks. Here and there on the west side of the Jordan Valley, but much more markedly on the east side, the table-lands are roughened by rocks of volcanic origin. Everywhere there is evidence of vast denudation, whereby the plateaux have been cut into valleys and hills, and of a former climate when rain and river-water were much more developed than they are now.

M. Lartet describes at some length the crystalline rocks which enclose the upper end of the Red Sea, and enters into considerable detail regarding the mineral differences of these various rocks; but he touches with tantalising brevity upon their geological relations—a fault, however, which he shares with all other writers who have treated of the geology of these regions. We only learn from him that there is a central nucleus of granite round which are folded successive zones of gneiss and various schists and slates, and that all these rocks are pierced by intrusive masses of porphyry, diorite, melaphyre, serpentine, &c. From the granites and old intrusive rocks he passes, by what seems an abrupt and awkward transition, to the basalts and lavas, which are among the most recent of the geological formations of the country; and he then takes up the schistose rocks. This arrangement is much more a petrographical than a geological one. We cannot but think that it interrupts the chronological sequence of events which it is the business of a geologist to decipher and describe. The volcanic rocks were not erupted until the cretaceous table-lands had been long exposed to denudation. It would surely have been better, therefore, to have deferred the history of the eruptions until some account had been given of the rocks over which they took place.

There can be no doubt that Palestine and the surrounding countries have been the scene of powerful volcanic activity from a time which, though in a geological sense recent, is yet immensely remote when measured by human standards. In the Holy Land itself that action has now ceased, though abundant hot springs still testify to its recentness, while along the shores of the Red Sea there are even at this day some still active craters. On the west side of the Jordan Valley, the fertile plain of Esdraelon is strewed over with basaltic débris, while a little farther to the north and east, true *coulées* of basalt are found on the flanks of Little Hermon. Near Tiberias another *coulée* comes down from the west to the margin of the Lake; while still farther north stands the basaltic freshest traces of volcanic phenomena occur; some of the cinder cones still remaining with their enclosed craters like those of the Puys of Auvergne.

The long period during which volcanic action continued to manifest itself is well shown by the fact that the older basalts are found capping limestone plateaux which have since been cut through by valleys descending into the Jordan and the Dead Sea, while these valleys have served as moulds into which the later lava currents have, in numerous instances, been poured. Such a sequence of events is a repetition of the well-known structure of Auvergne. There is a further resemblance to the volcanic district of central France in the singular freshness of some of the cones.

But of all the geological features of Palestine, that which possesses, perhaps, the strongest interest is the



GEOLOGICAL MAP OF PALESTINE AND LOWER EGYPT

mass of Safed, which seems to have been the great volcanic centre of that district. But it is on the east side of the line of the Jordan and Dead Sea that the most remarkable display of volcanic rocks is to be found. The high grounds of Moab and Ammonitis are dotted with the sites of ancient volcanos, from which streams of lava have descended, sometimes even into the Dead Sea. The houses of Rabbath-Moab were built of these basalts. Farther north, from the heights of Ajlun, the eye travels over a vast basaltic plateau, which stretches north to the roots of Hermon and Anti-Lebanon, and eastward until it is crowned by the imposing volcanic mountain of Hauran. Some portions of these regions are dreary beyond expression—rough with dark rugged lava streams and scattered scoriæ, rendering the journey of a traveller slow and laborious. It is in this wild region that the valley or depression which stretches from Lebanon along the line of the Jordan, the Dead Sea, and the Waddi Akabah to the head of the eastern arm of the Red Sea. Notwithstanding the yearly increase of travellers in the Holy Land and the rapid multiplication of descriptions of the country, it must be owned that no very satisfactory account has yet been given of the geographical structure and probable origin of this, the most remarkable depression upon the globe. In the present part of his report M. Lartet does not discuss this subject, nor does he enter into the existing contour of Syria or the causes which may have led to the drying up of the Waddys and the general desiccation of the climate. These questions he will probably discuss in the next portion of his valuable memoir, to which we hope to call attention when it appears.

ARCH. GEIKIE

NOTES

WE are informed that it is probable that Dr. Sharpey, Prof. Huxley, and Sir John Lubbock will be among the members of the Royal Commission to inquire into the present state of Science in this country.

THE Society of Arts has resolved to hold a morning conference on the same subject, which will probably take place on Friday week. The council of the Society has requested Lieut.-Colonel A. Strange to open the discussion with a paper, the title of which will be "On the inquiry by a Royal Commission into the relations of the State to Science." We understand that the Society intends to invite the attendance at the conference of Her Majesty's present and late Ministers, of all members of the Legislature known to be interested in analogous questions, of the councils of all scientific societies, and of learned bodies generally.

IT is surely a sign of the times that we should be able to lay before our readers a scientific lecture delivered on a Sunday before a great audience, composed chiefly of the middle classes. The history—the all too short history—of English Sunday lectures is very curious and, withal, instructive. Some years ago the movement was commenced by lectures in St. Martin's Hall, which lectures, thanks to the activity displayed by "The Lord's Day Observance Society," were brought to a close somewhat suddenly. They were afterwards revived (such is the perfection of our English law) with impunity, by the simple process of enrolling the lecturers and their friends as a religious body! But many of those who had taken an active part in the origination of the lectures declined to shelter themselves under what they conceived to be an unworthy, as well as an unnecessary, subterfuge; and, believing that the law was really on their side, determined to take the earliest opportunity of obtaining experimental proof of the justice of their views. So we have had two movements—one, embodied in the Sunday Lecture Society, a lecture *pur et simple* being delivered each Sunday afternoon, and another, emphatically the working men's movement, in which the exact programme which was at first threatened with prosecution is reproduced. Both these movements have been in operation, and have been the means of doing much good, for some time past; and no attempt has been made to interfere with that "Free Sunday" which is of a good deal more importance to the working men of this country than even a "Free Breakfast-table." Surely one of those quiet victories by which each step in the march of real progress has been made good in English history, has been won.

A NEW mathematical journal, edited under the direction of MM. Chasles, Bertrand, Serret, Delaunay, Puiseux, Darboux, &c., is about to appear, under the name of *Bulletin des Sciences Mathématiques et Astronomiques.* Twelve parts will be issued yearly.

WE have received from Mr. Murray a pamphlet on Compulsory Education, by the Hon. Dudley Campbell, which is clear enough in treatment, and sound enough in argument to do great good at the present time, when the Government bill is before the country. It is very hard for a man of scientific training to bear with the shifts and compromises with which politicians are too often apt to cover their own shortcomings and lukewarmness, but in the matter of compulsory education there is less halting than usual. Mr. Campbell well points out that people are vaccinated and otherwise dealt with compulsorily for the public weal, and he asks why should this system stop just at the point where our lamentable backwardness points in the clearest way for the necessity of Government action. The country not only asks for compulsory education, but we are convinced in time that the system of local boards will be swept away. In connection with this subject we would call special attention to the fearful state to which the voluntary system has reduced education in Birmingham, Leeds, Liverpool and Manchester, as recorded in the reports of Messrs. Fitch and Fearon just presented to Parliament.

THE fund raised in this country for the benefit of the family of that great naturalist, the late Professor Sars, now amounts to 265*l*. 6*s*. 10*d*. Among the contributions from the provinces may be especially noticed those of Newcastle and Glasgow, showing the favour with which science is regarded in those places. Devonshire and Wales have hitherto given no sign, although it might have been expected that the last meeting of the British Association at Exeter would have left some impress of its visit. The French and Belgian subscriptions amount to 6283 fr. or 251*l*. 6*s*. 10*d*.

THE Lectures of the present year at the Royal College of Physicians will be delivered at the College, Pall Mall East, at five o'clock on each of the following Wednesdays and Fridays:—Goulstonian Lectures, by Dr. Maudsley, March 18. "On the relations between body and mind, and between mental and nervous disorders." Croonian Lectures, by Dr. Sibson, March 23, 25, 30, "On aneurisms of the aorta." Lumleian Lectures, by Dr. J. R. Bennett, April 1, 6, 8, "On the natural history and diagnosis of intra-thoracic cancer."

NOTICES of motion have been given by Mr. Strutt for a return relative to the expenditure of the Meteorological Committee, voted in Class 4 of the Civil Service Estimates, 1869-70; by Mr. Grant Duff for a copy of report on measures adopted for sanitary improvements in India; by Mr. Macfie for a select committee to consider and report on the law relating to letters patent for inventions; by Mr. Mundella of an amendment to Mr. Macfie's motion.

A NATURAL HISTORY SOCIETY has just been formed at Winchester College. The subjects it embraces at present are botany, ethnology, and geology, these being the most easy of access under the existing circumstances. One of the main objects of this society is the formation of a museum, which, it is hoped, will tend to keep up an interest in scientific subjects among the members of the school. The meetings have been largely attended, and there is every reason to expect that the society will prove a lasting benefit to the college.

WE must congratulate the Leamington Philosophical Society and its energetic president, Dr. O'Callaghan, upon the successful way in which they are doing the good work of fostering science in Warwickshire by means of lectures, and upon the fact that they can prevail upon such busy men as Mr. E. J. Reed and Sir Bartle Frere—to mention two of their recent lecturers—to help them. Mr. Reed's lecture on "Our Ironclad Navy" was given last week, and we hope to place some parts of it before our readers.

THE prospectus of the forthcoming course of instruction at the Working Men's College is a most gratifying one. Besides classes in Art, History and Law, Languages and Mathematics, we have the following in physical science:—The Use of the Microscope, Mr. J. Slade; Astronomy, Mr. R. B. Litchfield, B.A.; Muscular Anatomy of the Human Body, Mr. J. Beswick Perrin. Besides these classes, there are free general lectures at 8.30 on Saturdays, among which we note four on Crystals, by Prof. N. S. Maskelyne, of the British Museum. All should feel grateful to those connected with this institution who, without fee or reward, devote their small spare time to the arduous work of teaching.

WE regret to hear that Dr. Kirk, the indefatigable friend and former companion of Livingstone finds his efforts to send supplies to the latter paralysed by the presence of cholera on the East Coast of such severity that 10,000 have died in Zanzibar in the course of six weeks. He adds that "the scourge rages up and down the coast. At Quiloa, by the last accounts, there were 200 deaths a day among the slaves; when offered at one dollar a head they found no purchasers, so very worthless had slave property become from the disease. It is also going inland, which is strange, as it came to us from the interior, first showing on the coast at Pangani; now it goes in from Bogamoyo, and has reached Ugogo. Caravans on the route are stopped by death, ivory is left abandoned, and a party is being sent off to bring one large lot down, all the porters being dead in Ugogo. The expedition with valuable goods and a gang of men I sent off to assist Livingstone has been caught by it, and is at a standstill. Many of those I had engaged and paid considerable advances to are dead. There will be much loss this season, and Dr. Livingstone will come in for a share of it."

THE Working Men's Club and Institute Union have, with permission of the authorities, arranged for a series of visits to the national museums on Saturday afternoons, for the members of workmen's clubs. The important feature connected with these visits is, that in each case the party will be under the guidance of some gentleman specially qualified to afford instruction in some particular branch of science and art. A party of fifty workmen were thus enabled to pay a visit to the Egyptian Department of the British Museum on Saturday, under the guidance of Mr. Samuel Sharpe. We are informed that the "Club Union" will be very glad to have similar valuable services rendered by other gentlemen for visits to the national collections.

A LETTER has been received at Alexandria from Sir Samuel Baker, dated Khartoum, February 7, wherein he reports that 32 boats were collected together to convey him and his party to Gondokoro. With the last shipment of troops the total expeditionary force amounts to 700, including a battery of artillery. Mr. Higginbotham is reported to be within four days' march of Khartoum, having crossed the Nubian Desert. He has under his charge the steel steamers for the lake Albert Nyanza. Mr. Higginbotham has command of the rear expedition, and will follow Sir Samuel Baker immediately. All the members of the expedition are in good health and spirits.

THE *Pall Mall Gazette* states that the Arctic explorer, Mr. C. F. Hall, has, in a lecture given at Washington, developed his plans for a third voyage.

THE establishment of the first sewage farm in India has taken place in the vicinity of Madras. It is an experiment, but the results as given in the official report are most hopeful, both as regards the drainage of Indian towns and the profit likely to accrue from the operation. The site is an old swamp four feet only above the sea level; the soil is a stiff clay, mixed with much salt and a little sand—one of the worst possible soils for the purpose. The surface was levelled and protected from floods, and the sewage from Perambore barracks and a small portion of the adjacent village, after being raised 22 feet, is conducted in an open earthenware conduit, and floated over the surface of the ground. The total area is 37 acres, but about 2 acres only have been put under cultivation. The sewage is as thick as pea-soup, and sometimes more diluted. Its smell is overpowering close to the channel, but as it flows over the ground "it loses its offensiveness very soon." Various crops have been tried on the sewaged area. Guinea grass succeeds so well that its yield is at the rate of 88 tons of fresh grass, or 29 tons of hay per acre. The value is 58*l.* per acre. It is stated that grass will take any quantity of sewage, but that other useful crops, chiefly native vegetables, also succeed. Different plants require different treatment. Some of the best crops are native greens, which grow most luxuriantly and take a large quantity of sewage. The report states that the results to health have been satisfactory, and that one great source of disease has been removed. The application of the sewage of two other districts of the city was nearly completed at the date of the report.

CANDIDATES for the first chair of Algebra at the Paris Faculty of Sciences are requested to send in certificates.

MESSRS. MOXON AND CO. are preparing for publication a Dictionary of Science, edited by Mr. G. Farrer Rodwell. It will be uniform with Haydn's "Dictionary of Dates" and "Dictionary of Biography," and will comprise acoustics, astronomy, chemistry, dynamics, electricity, heat, hydrodynamics, hydrostatics, light, magnetism, meteorology, pneumatics, and statics. These subjects will be treated of by Mr. J. T. Bottomley, Lecturer on Natural Science in King's College School; Mr. William Crookes, Mr. Frederick Guthrie, Professor of Natural Philosophy in the Royal School of Mines; Mr. R. A. Proctor, Mr. Richard Wormell; and the Editor.

THE Paris Zoological Acclimatisation Society celebrated their seventeenth anniversary last week in the Hôtel de Ville. Dr. Hooker was unanimously elected an honorary fellow, and the following prizes were awarded:—The gold medal offered to the society by the Minister of Agriculture and Commerce to M. Carbonnier, for the introduction of Chinese fish; another gold medal to M. Vekemans, the director of the Zoological Gardens at Antwerp; grand gold medal to M. Alfred Grandidier for his travels in Africa and America; a prize of 500fr. for the theoretical researches of M. Verreaux on acclimatisation subjects; a similar prize for works of pure zoology to the late Professor Sars for his publication on the littoral fauna of Norway and the development of sea-fish; a prize of 200fr. was also awarded to M. E. Gayot for his essay on *Leporides*.

THE Liverpool Naturalists' Field Club held a soirée at the Royal Institution on the 11th instant, the Mayor and about two hundred members and friends attending. The principal objects exhibited, interesting in a natural history point of view, were a very large collection of British plants beautifully mounted by Mr. Gibson, sen., a member of the club; an interesting case of spiders found in the neighbourhood, preserved in spirits in flat glass bottles, and very effectively displayed by Mr. H. Higgins, son of the president; a selection of valuable shells lately presented to the Free Museum by Mr. Samuel Smith; young salmon; case illustrating anatomical structure of the elephant, &c.; the largest known Nudibranch and the largest known Foraminifer, both taken alive by Dr. Collingwood in the China seas—from the Free Museum; a case of sections of Brazilian creepers, showing curious abnormal structure, specific names unknown—by Mr. Robert Holland. Members of the Microscopical Society illustrated various subjects. A spectroscope and micro-spectroscope were worked by the secretary, Mr. Stearn; and the evening concluded with some chemical experiments bearing on Prof. Tyndall's "Dust and Disease" article in *Fraser*, by Mr. Davis, F.C.S.; the exhibition of Geissler tubes, a number of insects, &c.

AT a recent meeting, the Natural History Society of Montreal presented its medal to Sir William Logan, the distinguished geologist. The following resolution was passed:—"That this Society, in presenting its medal to Sir W. E. Logan, LL.D., F.R.S., although it cannot add appreciably to the many honours which he has received, desires to place on record, not merely on its own behalf, but on that of all the students of Natural Science in Canada, its high estimation of the value of his services in creating as well as directing the Geological Survey of this country, in promoting the development of its mineral resources, in stimulating and aiding the efforts of scientific institutions, and in extending throughout the world the name of Canadian science. We desire also to express our high appreciation of Sir William's admirable qualities, and our hope that he may be spared for many years to Canada and to science, and that the relief from official cares may give him the opportunity to pursue to completion the researches in scientific geology in which he is now engaged."

WE are glad to see that meetings are being held in support of Mr. W. S. Allen's motion in the House of Commons to open museums on week-day evenings. We know of no argument against the experiment, and we believe the experiment would be an entirely successful one.

THE infallibility of photographic reproductions, says the *Photographic Journal*, cannot be prized too highly. In the copying of elaborate tabular forms, containing numerous figures and intricate calculations, the aid of the camera is sometimes of the greatest importance. To obtain an exact and reliable copy of a complex document of this description by clerical means involves much time and labour, beyond the chance and risk of error; but with the camera a reproduction may be secured in a couple of hours, in which all the figures are exact, the totals correct, the calculations checked, the words spelt right, and to which the observation "certified a true copy" may be appended without hesitation.

THE Vicar of Cushendun, county Antrim, communicates the following to *Science Gossip*:—"The following incident was told me the other day by a resident, who vouches for the truth of it, and which happened close to his residence in Cushendun, county Antrim. A rat, nearly white with age, and blind, was frequently seen led to the water by a young rat, by means of a straw, of which the old rat held one end and the young rat the other. This incident corroborates a similar statement given by Jesse in his 'Gleanings of Natural History.'"

SCIENTIFIC SERIALS

THE new number of the *Zeitschrift für Biologie* (VI. i.) contains an interesting paper by Subbotin "On the Physiology of Fats." Towards an answer to the question—Is there in the animal organism any direct passage of fat from the alimentary canal to the cells of adipose tissue? a lean dog was fed for a month on meat, spermaceti, and common fat. Of the 1,000 grms. of spermaceti swallowed, 800, at least, were absorbed; but the merest trace only of spermaceti could be found in the fatty tissue of the body at the close of the experiment. Spermaceti, therefore, though absorbed and consumed in the economy, is not stored up unchanged. Hence there is a presumption that the same is the case with other fats (though it is obvious that many possible events might negative the presumption). Towards solving the further question—Are fats formed in the body out of proteids? a dog reduced to the utmost leanness was fed on leanest meat and palm oil (palmitin and olein) for twenty-five days, during which he gained three kilos in weight. The fat of the body was, at the close, found to contain 13·9 per cent. of stearin, though none had been taken. A very considerable quantity of stearin had therefore been formed in the body. A very lean dog was fed for six weeks on leanest meat, and a soda soap made with palmitic and stearic acids only. At the end of the experiment, the dog having gained over three kilos in weight, the fat of the body was found to consist of 53·6 per cent. palmitin, 13·4 per cent. stearin, and 33 per cent. olein. A large quantity of olein had therefore been formed in this case. But if olein was thus formed, possibly the palmitin and stearin were likewise formed from proteids, and not by synthesis of the fatty acids with the glycerin of the economy. Subbotin further points out that olein is more abundant in the sub-cutaneous than in the deep-seated fat, possibly on account of a less energetic transformation of proteids in the cooler surface regions. So also in cold-blooded animals the fat is proportionally richer in olein.—The same number contains a long paper by Vierordt, in which that distinguished physiologist continues his researches on the connection between the delicacy of touch and mobility of any part of the body. In this memoir he confines his attention to the arm from the shoulder downwards, working upon data provided by his pupils Kottenkamp and Ullrich, who have made a study of the sense of touch in all parts of the arm, to a much greater extent and with much fuller detail than did Weber, and whose elaborate results are given in a paper immediately preceding Vierordt's. In the arm Vierordt finds striking illustrations of his hypothesis that the delicacy of touch in any point in a region of the body which is moved as a whole, is proportional to the distance of the point from the centre of movement of the region. There are also hygienic papers by Pettenkofer and others on the cholera epidemic of 1865 at Gibraltar, and typhus and drinking water at the barracks at Neustift.

The *Journal of Botany*, New Series, No. 1 (double number for January and February, 1870), contains the following articles:—"Suggestions on the 'Species' question as regards *Rubus*," by the Hon. J. B. Leicester Warren; "Notes on *Quercus Wallichiana* Lindl," by Dr. Hance; "Descriptions of four new Chinese *Crassulaceæ*," by Dr. Hance; an interesting and important "Review of the contributions to Fossil Botany, published in Britain in 1869," by Mr. Carruthers, containing references to all papers on vegetable palæontology published in Britain during that period, with observations and a synopsis of the genera and species described in them. "Cinchona cultivation in Bengal," being an official report from Mr. C. B. Clarke, officiating superintendent of the Botanic Garden at Calcutta, and in charge of the Cinchona cultivation in Bengal, for the year ending March 31, 1869. It appears from this report that during the year the number of plants of Cinchona at the Darjeeling Government plantations was increased by 673,654, making a total (including those in private plantations) of upwards of three million plants, covering 965 acres. By far the larger number of plants are of the species *C. officinalis* and *succirubra*, with a few of *C. Calisaya* and *micrantha*, *C. Pahudiana* being considered worthless. The tallest plant of *C. succirubra* is 19 feet high, and of *C. officinalis* 11¼ feet. There is besides a small plantation of *C. succirubra* at Nunklow, in the Khasia Hills. "Review of the genus *Narcissus*," by Mr. J. G. Baker. An abridgment and translation by Mr. A. W. Bennett of Van Horen's paper in the *Bulletin de la Soc. Roy. de Bot. de Belgique*, "On the hibernation of Lemnaceæ," showing the production in several species of duck-weed of submerged leaves adapted to live through the winter. "The genus *Ascobolus*," by M. Boudier, from the *Annales des Sciences Naturelles*. Reviews of books, proceedings of societies, and shorter articles.

The *Geological Magazine* for the present month (No. 69) opens with an article by the editor on the Liassic Pterodactyle (*Dimorphodon*) as described by Professor Owen in the volume of memoirs just published by the Palæontographical Society. The most important paper in the number is one by Mr. Poulett Scrope, "On the character and composition of lavas," and next to this, in general interest, two articles on "Faults in Strata," by Mr. W. T. Blandford and Mr. G. H. Kinahan.—Two of the remaining papers are by lady geologists, namely, a description of the Pleistocene deposits of North Shropshire, by Miss Charlotte Eyton, and a notice of vegetable fossils in the Water Blain iron mines in South Cumberland.—A paper on "The Water-bearing Strata in the neighbourhood of Norwich," by Messrs. Taylor and Morant, contains some remarks upon sand-pipes in the chalk; and the final article is the conclusion of Mr. Davies' paper "On the Millstone Grit of the North Wales Border."—The usual notices of memoirs, reports of proceedings, letters, and miscellaneous intelligence make up the rest of the contents.

Revue des Cours Scientifiques, March 8.—This number contains a report of the congress of German naturalists and medical men at Innspruck; a paper on "Alsace during the Tertiary period," read by M. Delbos at the Mulhouse Conferences; a review of M. Gréhant's researches on the excretion of urea and on the respiration of fish, also a fifth list of subscribers to the Sars fund.

The *Revue des Cours Scientifiques* for the 12th inst., contains an admirable lecture by M. Wolf, of the Paris Observatory, on the Figure of the Earth, and a translation of Dr. Tyndall's lecture on Dust and Disease.

Moniteur Scientifique, February 15.—This number contains several abstracts of papers on dyeing materials, by Messrs. Hofmann, Martius, and Weidel.—A paper descriptive of the peat at Avigliana, near Turin, by MM. Kopp and Fino, shows that, in the air-dried state, its efficacy as fuel is little more than one-fourth that of coke.—In a paper by M. Fremy on nitrous acid, he points out the production of nitrous oxide by the reaction of nitrous acid with sulphurous acid, regarding this as one of the causes of loss in the manufacture of sulphuric acid, when there is an excess of sulphurous acid in the chambers. In the reaction of nitric acid with nascent hydrogen, he has ascertained the production of another substance besides nitrous acid and ammonia. By means of sodium amalgam he obtained it in large quantity but not sufficient for complete examination. Arsenious acid and arsenites give, with sodium amalgam, a similar product. Both the nitrogen and arsenic compounds are characterised by a remarkable reducing power. M. Fremy is continuing his examination of the subject.

THE FOREFATHERS OF THE ENGLISH PEOPLE *

THE English people of the present day present two types of physical structure, which are extremely different in their most marked forms, though they pass into one another by every shade of gradation. The one type is tall, fair-complexioned, yellow or red haired, and blue-eyed; the other, short, dark-complexioned, black-haired, and black-eyed. The two types and their intermediate gradations are, at present, to be found side by side in most parts of the British Islands; but there is a marked predominance of the fair type in the eastern half of Britain. The languages spoken by the English people have, at the present time, no relation to these two physical types; English speakers and Celtic speakers belonging no less to the one type than to the other. Nor are the two Celtic dialects, Cymric and Gaelic, confined to people of the one or the other physical type, as both the types described are exhibited in their extreme forms among Welshmen, Highlanders, and Irishmen.

The earliest historical records of the nature of the population of Britain, furnished by Cæsar, Strabo, and Tacitus, take us back nineteen hundred years, and show that, at that time, the physical characters of the population might be described in the same language as at present. The people of South-eastern England and of Caledonia were certainly tall, fair, and blue-eyed, with hair varying from yellow to red in hue; while, in South Wales, they had dark hair and complexions, resembling the Spaniards of that day. But there was a wonderful difference in language between the ancient and the modern inhabitants of these islands, inasmuch as all these people of Britain, so far as we know, spoke the Cymric dialect of the Celtic tongue; while it is probable, though we have no absolute knowledge on this point, that in Ireland they spoke Gaelic. Thus, at the time of the Roman invasion, the outward physical characters of the population of these islands were much what they are now, though the language spoken was, probably, altogether Celtic. And there was no parity between the distribution of the Cymric and Gaelic dialects of the Celtic and that of the two physical types, any more than there is now between English and Celtic and the fair and dark stocks by which those languages are spoken. If we confine our attention to the British Islands, therefore, we have absolutely no means of ascribing any special physical characters to the Celtic-speaking people. A British, or Irish, "Celt" might be tall or short, dark or fair, rounded-headed or long-headed; and the remark of Professor Max Müller that it is as rational to speak of a dolichocephalic language as of a Celtic skull is, for the "Celts" of Britain, perfectly justified.

Whence was this Celtic-speaking people, with its two contrasted dark and fair forms, which inhabited Britain nineteen hundred years ago, derived? The position of the British Islands is sufficient to suggest the extreme probability that it migrated from Europe, the eastern and the southern faces of these islands being within easy reach of the shores of those countries which are now Norway, Denmark, North Germany, Holland, Belgium, and France. And the probability suggested by the facts of geography becomes converted into a certainty by those of ethnology and of history.

In the first place, if we turn to the existing population of the continent of Europe and Asia, we shall at once recognise our two physical types—the fair and the dark. From Norway to North-eastern France the predominant constituents of the riverain population of the North Sea and of the British Channel are tall, fair-haired, and blue-eyed. In North-western France the proportion of short and dark people increases, until, in Southern and South-western France, they are the chief constituents of the population. A traveller who should set out from the Orkney Islands and call at every port in the North Sea, and who then should make a land journey from the mouth of the Elbe to that of the Don, would find the people with whom he met to be generally, and in many regions exclusively, of the fair type. On the other hand, if he set out from Galway and cruised along the western coasts of these islands, and of France and of Spain and the north shore of the Mediterranean, he would find as marked a predominance of the dark type. In fact, the population of the southern and western parts of France, of Spain, of the Ligurian shore, and of Western and Southern Italy, is as generally dark as that of North Germany is fair.

There is no reason to think that climatal conditions have had anything whatever to do with this singular distribution of the fair and the dark types. Not only do the dark Celtic-speakers of the Scotch Highlands lie five or six degrees farther north than the fair Black-foresters of Germany; but, to the north of all the fair inhabitants of Europe, in Lapland, there lives a race of people very different in their characters from the dark stock of Britain, but still having black hair, black eyes, and swarthy yellowish complexions.

Thus, having regard only to physical characters, the population of Europe falls into three broad bands, which run in a rough way from west to east. In the north is the zone of the black-haired, black-eyed Mongoloid Lapps. In the south is the zone of the people who resemble the dark type of the British Islands, and who have been called *Melonochroi;* between them lies the broad belt of fair people, who have been termed *Xanthochroi.* And if this were a mere natural history question, the facts I have mentioned would allow us to draw but one conclusion as to the origin of the population of these islands—namely, that the dark type has been furnished by immigrants from the Continental *Melanochroi;* the fair type by immigrants from the Continental *Xanthochroi.* But history and philology have every right to be heard in such a matter as this; and I must now try as well as I can (for I am neither historian nor philologer) to put before you what they have to say.

What history tells us, so far as it goes, is quite in accordance with the suggestions of biology. It is certain that, from the fifth century to the tenth a vast number of people from North Germany and Scandinavia poured into the British Islands on all sides, but, as might be expected, most persistently and numerously into the eastern moiety of Britain. They brought with them languages which may properly and conveniently be termed dialects of Teutonic, in contradistinction to the indigenous dialects of Celtic. Out of the North German dialects the language usually known as Anglo-Saxon was developed, and from it, by subsequent modification and absorption of, for the most part, Scandinavian, Celtic, and French elements, has grown English. The invasion which thus changed the language of Britain introduced no new element into the physical conformation of the people, so far as stature and complexion are concerned, though it may have done so in the matter of cranial conformation. It is unquestioned that Saxons, Danes, and Norsemen were alike a tall, fair-haired people; and their immigration strengthened the Xanthochroic element of our population, but added nothing new, unless it were a longer form of head. It is a very remarkable circumstance that the skulls of the existing Scandinavians—and of the Allemanni and Saxons, if not of the whole of the ancient Germans—are long, while those of the South Germans and Swiss of the present day, and those which very probably belonged to the ancient Belgæ, are round. Thus, to put the matter in another way, tall stature, fair hair, and blue eyes, in a native of Britain, are no evidence of his descent rather from the primitive Celtic-speaking, than from the immigrant Teutonic-speaking, element of our population, or the reverse. He is as likely to be a "Celt" as a "Teuton;" a "Teuton" as a "Celt."

But history teaches us more than this. There is the clearest evidence that the Gauls—the Celtic-speaking people who burnt Rome nearly four centuries before our era—belonged to the fair type, and neither by their stature, their complexions, the colour of their eyes or their hair, were distinguishable from such Teutonic-speaking people as the Goths, who sacked Rome four centuries after it: and that, for these eight centuries at any rate, North-western, Central, Eastern Europe, and the western part of Central Asia were occupied by a tall, fair, blue-eyed people* who were known by the names of Celtæ, Belgæ, Germani, Venedi or Wends, and Alani, according to the districts which they occupied and the languages which they spoke.†

Thus, when history first makes known the Celtic language to us, it is in the mouths of a people extremely similar in their outward appearance to the Germans and the Slavonians; and when the affinities of the Celtic, the Teutonic, and Slavonic languages are worked out by the philologer, they are all found to belong to the same great group of Aryan languages. The argument to be drawn from the physical affinity of the Celtic-speaking with the

* A Lecture delivered by Prof. Huxley, in St. George's Hall, on Sunday, March 13, and revised by the author.

* The story told by Suetonius, that Caligula tried to pass off some tall Gauls for Germans, by making them redden their hair, is often quoted to prove that the hair of the Gauls differed from that of the Germans. But as the Germans themselves were in the habit of reddening their hair artificially, the force of the argument does not appear.

† Those who have any doubts upon this subject had better consult the great work of Kaspar Zeuss, "Die Deutschen ünd die Nachbarstämme," published thirty years ago; or the excellent discussion, mainly based upon Zeuss, in Pritchard; or the instructive essays of Brandes and De Belloguet.

Teutonic-speaking people is therefore supported and intensified by the linguistic affinities between the Celtic and the Teutonic tongues; and philology concurs with history in testifying to the ethnic unity of the Celtic-speaking people on the left bank of the Rhine, with the Teutonic-speaking * people to the eastward. In their clothing, in their arms, in their houses, in their employment of horses and wheeled carriages, no differences of moment obtain between the Celtic-speaking and the Teutonic-speaking people of old Europe; nor in their fashion of government, their social organisation, their morality,† or their theology, do there seem to be any greater differences than are readily accounted for by the fact that the Teutonic-speaking nations were more remote from the corrupting influences of wealth and civilisation. The Tonga islanders of Mariner's time offered the same contrast to the Tahitians that the Germans of Tacitus do to the Gauls, but no one would dream, on that ground, of declaring them to be of different races.

Hence, there can be no reasonable doubt, that the fair element of the Celtic-speaking population of these islands 1,900 years ago was simply the western fringe of that vast stock which can be traced to Central Asia, and the existence of which on the confines of China in ancient times is testified by Chinese annalists. Throughout the central parts of the immense area which it covers, the people of this stock speak Aryan languages—belonging, that is, to the same family as the old Persian or Zend, and the Sanskrit. And they remain still largely represented among the Affghans and the Siahposh on the frontiers of Persia on the one hand, and of Hindostan on the other. But the old Sanskrit literature proves that the Aryan population of India came in from the north-west, at least 3,000 years ago. And in the Vedas these people portray themselves in characters which might have fitted the Gauls, the Germans, or the Goths. Unfortunately there is no evidence whether they were fair-haired or not.

India was already peopled by a dark-complexioned people more like the Australians than anyone else, and speaking a group of languages called Drawidian. They were fenced in on the north by the barrier of the Himalayas; but the Aryans poured from the plains of Central Asia over the Himalayas, into the great river basins of the Indus and the Ganges, where they have been, in the main, absorbed into the pre-existing population, leaving as evidence of their immigration an extensive modification of the physical characters of the population, a language, and a literature.

Italy is to the Alps what Hindostan is to the Himalayas. The Po is its Ganges. Four centuries B.C. it was peopled mainly by the dark and short stock represented by Ligurians, Etruscans, and old Italians. The Gauls poured into it over the north-western passes, and settled in Cis-Alpine Gaul, modifying the physical characters and the language of the population, but becoming lost eventually in the great Roman nationality. And, doubtless, in more ancient times, the Aryan-speaking ancestors of these Celtæ and Belgæ had similarly made their way through the Hercynian forest or along the shores of the North Sea, into Gaul, and thence into Britain. The correspondence of the names of places in Gaul and ancient Britain fully confirms Cæsar's statement that the Belgic Gauls had, at some comparatively recent time, colonised south-eastern Britain in great numbers. But the primitive colonisation of Britain from the mainland by the fair people is doubtless of extreme antiquity.

I have now, I believe, accounted for the fair Celtic-speaking population of ancient Britain. There remains the problem, Why did Britain contain another Celtic-speaking population, of a totally different type?

The key to this riddle is, I believe with Dr. Thurnam, De Belloguet, and others, afforded by history and philology. History, which tells by the mouths of Cæsar, Strabo, and Tacitus, that the Aquitani, who lived beyond the Garonne, were a small and dark people like the Iberians, who spoke a language different from that of Gaul. Philology, which tells us that this language was the Euskarian, represented by the modern Basque, which is unlike every other European language, and which once covered a vastly greater area than it now occupies—the great majority of the people who once spoke it having acquired other languages.

* I use this phrase without prejudice to the much-debated question, Did the Germans of Cæsar and Tacitus speak "Deutsch" (not 'Dutch,' *pace* Mr. Freeman) or Celtic? and with the greatest respect for the champions of both "Keltenthum" and "Deutschthum." It is enough for me if nobody doubts the "Deutschheit" of the Goths and Alemanni.

† The grossest immorality with which the Gauls are charged may well enough have been imported by the Greeks of Massilia along with other products of Greek civilisation.

Thus, once more, physical and philological ethnology properly viewed, concur. The physically distinct stock turns out to be linguistically distinct—to have, in fact, all the ethnological characters of a distinct race.

In Spain, and within the boundaries of the old Aquitania, the Euskarian language lingers only among a fragment of the population, though the Spaniards and southern Frenchmen retain, to a great extent, the dark complexion and short stature of the Melanochroic stock. In Britain the same process of extinction seems to have been consummated as far back as the time of Tacitus. For from what has been said, it can hardly be doubted that the Silures and the dark type in general were the outliers of the continental Euskarian-speaking dark type, just as the British Belgæ, and the fair type in general, were the offshoots of the continental Celtic-speaking fair type. And just as in Western and Middle Gaul, and in Spain, the Celtic-speaking fair people had, even in the time of Cæsar, largely supplanted and absorbed the dark stock; so, in Britain, it is to be supposed that it had altogether absorbed it, and that the dark stock had given up their Euskarian for the Celtic language.

All these reasonings may be put into the form of a probable hypothesis, as follows:—The chain of the Alps, the densely wooded highlands of Central Europe known in old times as the Hercynian forest, and the broad Rhine in its lower course, form a natural rampart between the vast central plains of Eurasia and Western and Southern Europe. Before England was peopled by the ancestors of its present population, the latter region, including the north shore of the Mediterranean, Spain, and Gaul (and perhaps the shores of the Baltic) were occupied by people of the dark type, who may, by possibility, have been the chief people of the so-called bronze age in those parts. These people occupied the British islands wholly or in part, and were, very probably, at first their sole occupants. And in Spain, France, and Britain they spoke Euskarian dialects.

During this time the fair stock, with its Aryan languages, wandered over the great Eurasiatic plain to the east of the rampart, from Poland to the frontiers of China, and from Siberia to those of Persia and India. But at length the fair people found their vast plains too narrow, or the luxuries beyond its natural barriers too tempting, and they began to overflow—as Celtic-speakers into Western Europe; as Zendic and Sanskritic speakers into Persia and Hindostan. The Celtic-speaking fair people, passing into Gaul, partly extirpated and partly mixed with the pre-existing dark Euskarian-speaking population, imposing their language and habits on all the northern, middle, and eastern parts of Gaul, and extending widely into Spain. From Gaul they passed into Britain, and Celticised it still more completely; so that, though much of the old blood of the dark stock remained, its language vanished.

The Teutonic-speaking people were simply another wave of the same great Aryan ocean of Central Eurasia. They treated the Celtic-speakers exactly as the latter had treated the dark stock, and before another century has passed the Celtic language will probably be as much a thing of the past in these islands as the Euskarian is.

If this is a fair picture of the general course of events, it furnishes the explanation of the fact from which we started, namely, the presence in the British Islands of two distinct ethnical elements—a fair and a dark.

T. H. HUXLEY

BOTANY

Floating Leaves of Marsilea

PROF. HILDEBRAND has noticed that if a plant of *Marsilea quadrifolia* (a species of the genus which furnishes *Nardoo*), is sunk beneath the surface of the water, so that all the leaves are more or less deeply covered, those leaves which are fully developed at the time of immersion, remain unchanged, while those which are not so far advanced, undergo a remarkable change; the petioles gradually lengthening in succession according to their position on the stem, and soon over-topping those which were already formed. At first the four leaflets do not increase, but they soon begin to enlarge, and by the time the surface of the water is reached, they exceed in size the ordinary leaves, forming a four-rayed star on the surface. While the petioles of the ordinary leaves are stiff, so that they stand erect out of the water, these floating leaves are weak and flexible, like those of water-lilies, allowing the leaf to maintain its position on the surface with the rise and fall of the water. Their upper surface is shining and coated with wax, so that the water flows off them. If immersed in deeper water, the petioles will lengthen still further, even to the extent of three feet. In these cases the formation of the organs of fructification appears to be suppressed. In the ordinary aërial leaves, stomata are found on both sides of the leaf in about equal numbers; in the floating leaves, on the other hand, the under side is entirely destitute of stomata, while on the upper surface they are about three times as numerous as in the aërial leaves; thus resembling *Nymphæa, Hydrocharis,* and other plants. (Botanische Zeitung.)

Alternation of Generation in Fungi

M. GAURIEL RIVET records in the *Bulletin de la Société Botanique de France* a remarkable illustration of this phenomenon in some very interesting observations on the "rust" of cereals. He finds that the Fungus which causes one of the common forms of this disease, *Puccinia graminis,* will not reproduce itself, but that if the spores are sown on the leaves of the common berberry, they give rise to the well-known orange spots of *Œcidium Berberidis,* generally considered as a fungus belonging to an entirely different group. The spores of the *Œcidium,* on the other hand, do not reproduce itself, but the *Puccinia,* thus furnishing a striking instance of alternation of generation. The connection of the berberry with the prevalence of rust in wheat was noticed by Sir Joseph Banks as long ago as 1806. In the commune of Genlis (Department of Côte d'Or) a railway company not long since planted a berberry hedge on one of its embankments; immediately the crops of wheat, rye, and barley in the neighbourhood became infested with rust. The remonstrances of the farmers caused the appointment of a commissioner to inquire into the subject, who, after a full inquiry, reported that wherever the berberry is planted the cereals are more or less attacked by rust; where they are absent the crops are free from disease, and that the planting of a single berberry bush is sufficient to produce the rust where it has never appeared before.

PHYSICS

Products of Respiration

PETTENKOFER and VOIT have been making some observations, by the help of their famous dog, on the products of respiration during starvation and during a diet entirely composed of fat. They find the most notable effect of the fatty food to be *a diminution of the oxygen consumed.* Thus in one series, on the 6th and 10th days of a period during which nothing but water was taken, the oxygen consumed amounted to 358 and 302, the carbonic acid given off to 366, 289 grammes respectively. On the 2nd, 3rd, and 8th days of a similar series the quantities were of oxygen consumed 371, 358, 335; of carbonic acid given off 380, 358, 334 grammes. When, on the other hand, 100 grammes of fat were taken daily, the 8th and 10th days of the series gave respectively 262, 226 grammes of oxygen consumed, 302, 312 grammes of carbonic acid exhaled. (Zeitschrift für Biologie, bd. iii., p. 369.)

In these observations Voit finds support of his views on the nutritive influence of fat, and bases on them an explanation of Bantingism. To bring down a fatty body, he says, we must get it to take in a larger supply of oxygen. This can best be done by cutting off all the fat and carbo-hydrates and increasing the quantity of proteids. The effect of increasing the proteids is to augment the metamorphosis taking place in the blood and diminish the storing up of material in the tissues in the shape either of flesh or fat. The store of fat existing in the body is consequently more and more encroached upon, and in spite of the great metamorphosis taking place in the circulation, the body continues to get lean. A very long discussion on the *modus operandi* of fat as food (of which the above forms a small part only) will be found at p. 329.

The same observers have also examined the respiratory products in the case of a man suffering from Leukaemia, a disease in which there is an undue abundance of white corpuscles and scantiness of the oxygen-bearing red ones. They find, however, no marked difference in the respiratory products; in amount these closely approximate the standard of health. (Ibid. p. 319.)

G. Quincke on Specific Cohesion and Capillarity Constants

VARIOUS bodies were formed into drops, which were allowed to fall on a platinum or porcelain plane; after they had acquired the temperature of the surrounding air, certain measurements were made of their dimensions. The square of the vertical distance in millimeters of the upper surface of the drop from the vertical element of its meridian curve is the constant of specific cohesion, from which, by a method of calculation stated by the author, the capillarity constant can be inferred.

Fused substances of similar chemical composition, and at a temperature very near to their melting point, have the same specific cohesion.

Water, carbonates, and sulphates in the liquid state have double the specific cohesion of mercury; the same is true for the nitrates, metallic chlorides, sugars, and fats; metallic iodides and bromides have only half the mercurial value.

Lead, bismuth, and antimony have the same specific cohesion as mercury; platinum, gold, silver, cadmium, tin, and copper twice that amount; zinc, iron, and palladium thrice, and sodium six times the specific cohesion of mercury.

PHYSIOLOGY

Microcephalous Children

DR. BUCHNER has measured lately the *crania* of two *microcephalous* children, and by way of comparison adds the cranial measure of his own healthy infant son.

	Helena Becker.	Sophia S.	W. Büchner.
Age	6½ years.	3 years.	3 years.
Circumference of head.	13½ inches, Rh.	16¾ inches.	20½ inches.
From ear to ear .	6½ ,,	10 ,,	12½ ,,
From root of nose to occipital protuberance	8¾ ,,	10½ ,,	14 ,,

In both cases the size of head has apparently remained stationary from birth, and both children were born with closed *fontanelles.* One of the children is now exhibited at Darmstadt. Her height is 3½ feet; she cannot speak, walk, or stand, or seize hold of anything; in fact she is in a state of complete helplessness, with involuntary action of bladder and rectum. The upper portion of her skull, not larger than a man's fist, roof-like, flattened at the sides; the absence of forehead, a long aquiline nose terminating in a sharp point, an exceedingly diminutive receding chin, and a mouth with irregularly set teeth, with the orbital regions very prominent, give her quite an animal aspect. The mental phenomena are below zero; and the senses, though seemingly active, produce no ideas; her look is staring, vacant, devoid of expression; only bright shining objects and music attract her attention; she does not laugh but utters inarticulate animal sounds. Another characteristic feature is, that her limbs and head are subject to an involuntary unceasing agitation, like the reflex movements of a decapitated frog; she suffers also from a great want of sleep.

DR. OMANZA describes a method of registering photographically the beats of the pulse. The apparatus essentially consists of a small inverted funnel, having a long narrow stem and a caoutchouc base. This instrument is filled with mercury to a certain distance up the stem, and its base is applied to the heart or an artery; the oscillations of the mercurial column are then photographed by well-known processes. It is said that with this apparatus the apparently single stroke of the pulse is shown to consist of three, or even four, in succession.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 3.—The following papers were read: "Results of the monthly observations of dip and horizontal force made at the Kew Observatory from April 1863 to March 1866, inclusive," by Dr. B. Stewart. The author exhibited tabular statements of dip observations during six years, from which was deduced the existence of a semi-annual inequality, in virtue of which the dip is on an average 0′·27 lower in the six months from April to September, and 0′·27 higher in the six months from October to March than is due to its mean value. This result is in the same direction as that found by Sir E. Sabine for the six years ending March 1863, but is less in amount than the latter, that determined from the first six years exhibiting a range of 1′·31, while that determined from last six years only exhibits a range of 0′·54. From the first six years we deduce a mean dip equal to 68° 20′·07, corresponding to middle epoch April 1, 1860, and from the latter six, a mean dip equal to 68° 6′·62, corresponding to middle epoch April 1, 1866, while the secular change deduced from the first series is 2′·00, and that deduced from the last series is 1′·92, the mean of these two values being 1′·96. If we apply this mean value of the secular change to the mean result corresponding to the epoch April 1, 1860, in order to bring it to the epoch April 1, 1866, we obtain—

$$68° \ 20'·07 - 11'·76 = 68° \ 8'·31,$$

whereas that deduced from the second series corresponding to this epoch is 68° 6′·82. The former of these is 1′·69 higher than the latter. As regards the reason of this difference the author does not think it due to any personal equation in the observer. It would appear that the Kew observations present a peculiarity similar to those at Toronto, so that the difference of 1′·69 between the two sets of observations may probably be accounted for by this cause. The probable error of a single monthly determination of the dip, derived from the seventy-two monthly determinations, and after the application of the correction for secular change and annual variation, as derived from the results of these observations, has been made, is ±0′·96. There is, however, reason to believe that this probable error is increased to some extent by periods of disturbance, some of these of considerable duration. In the observations of horizontal force during the first six years, mean value of the horizontal force is equal to 3·8034, corresponding to the middle epoch April 1, 1860, and from the latter six years' observations we have a mean value of horizontal force equal to 3·8360, corresponding to epoch April 1, 1866; also the secular change deduced from the first six years is + ·0053, while that deduced for the second six is + ·0055, the mean of the two being + ·0054. If we apply this mean value of the secular change to the mean result corresponding to epoch April 1, 1860, in order to bring it to epoch April 1, 1866, we obtain 3·8034 + 0·0324 = 3·8358, a value which agrees as nearly as possible with that deduced from the second series, and corresponding to the same epoch which was 3·8360. The coincidence of these two values naturally leads us to imagine that the secular change of the horizontal force does not present the same peculiarity as that observed in the dip. In the observations of total force the mean of the April to September values of the horizontal component of the force in the last six years is 3·8346, corresponding in epoch to January 1, 1866; and the mean of the April to September values of the dip in the same six years is 68° 6′·83. The mean of the October to March values are for the horizontal force 3·8372, and for the dip 68° 6′·41, corresponding to epoch July 1, 1866. We may reduce these to a common epoch by applying to the former dip the correction —0′·96, this being the proportional secular change (as shown by these six years) necessary to reduce the former epoch to the latter. The former dip will therefore become 68°6′·83—0′·96 = 68° 5′·87. Reducing in the same way the horizontal force, we have

$$3·8346 + 0·00275 = 3·83735.$$

The values thus become as follows:—

	Hor. orce.	Dip.
From the April to September observations (reduced to epoch July 1, 1866)	3·83735	68° 5′·87
And from the October to March observations (corresponding to the same epoch)	3·83720	68° 6′·41

The total force derived from the first series will therefore be 10·28717, and that derived from the second series 10·29080, showing thus a difference of 0·00363 in British units as the measure of the greater intensity of the terrestrial magnetic force in the October to March period, than in the April to September period. This is in the same direction, and very nearly of the same amount, as that determined by Sir E. Sabine from the first six years, which exhibited a similar difference of 0·00317 in British units. Thus we find that the two series agree in showing nearly the same semi-annual variation for the total force, while the first period exhibits the greatest semi-annual variation of the dip. It ought, however, to be borne in mind that the two series bear a different relation to the disturbance period, the maximum of disturbances occurring about the middle of the first series, and the minimum near the middle of the second.

"Spectroscopic observations with the great Melbourne Telescope." By A. Le Sueur. The author stated that the spectroscopic observations of the nebulæ of Orion show distinctly that considerable nebulosity exists within and about the trapezium. The author's *telescopic* observations reveal a positive though comparatively faint nebulosity within and about the trapezium; the *spectroscope*, however, shows with much force that this nebulosity not only exists, but is comparable in brightness to that surrounding the trapezium at some distance,—the brightest part of the nebulæ in fact; that, in ordinary observations, therefore, the faintness or apparent complete absence ot nebula is mainly due to the disturbing brightness of the four stars, not to any intrinsic extreme faintness or absolute vacuity.

In the examination of Jupiter, the large size of image is brought into prominent play; with the original Cassegrain image the light is barely sufficient, but with the image condensed (at pleasure within certain limits) fair work becomes possible, the spectrum being considerably bright. The lines G, F, *b*, C, D are seen without the slightest difficulty, and many other lines with attention. A marked feature is a nebulous band between C, D; from measures this turns out to be one of the bands examined by Mr. Huggins, 882 of his scale (C_6 of Brewster ?). With the slit perpendicular to Jupiter's equator and the advantage of a large image, an admirable opportunity is afforded of noting the behaviour ot the lines as they cross the different parts of the surface, a spectroscopic picture of the planet, as it were, being presented beautifully to the eye. The nebulous line C_6 was specially and narrowly watched, but without any satisfactory evidence being elicited;

It is found that the spectrum of η Argo is crossed by bright lines. The mere fact of a bright line spectrum is not very difficult to ascertain on a good night; for although from faintness of the light the phenomenon is necessarily delicate, yet the bright lines occasionally flash out so sharply that the character of the spectrum cannot be mistaken. The most marked lines were made out to be, if not coincident with, very near to C, D, *b*, F, and the principal green nitrogen line. It cannot be determined whether the coincidence is with the magnesium group or the air-band; nothing more definite can be said than that the star line lies within the limits of the group. The comparison spectrum employed does not show F, but the position of the previously adjusted pointer, with reference to air lines in the neighbourhood, leaves little doubt as to the identity of the blue star line with F, due regard being had to the collateral evidence (when such close limits are reached) that C coincides with a red star line. The yellow (or orange?) line in the star has not yet received sufficient attention, it is, however, very near D. With the dispersion employed, D and the bright air line on the less refrangible side of D are well separated; so that, notwithstanding the delicacy of the star line, the author hopes if not to get satisfactory evidence of coincidence with a particular line, at least to eliminate one of the competitors; at present it cannot even be said whether the line may not be slightly more refrangible than D; the limits are, however, very small, placing the bright air group about 1,180 of Mr. Huggins's scale completely outside the possible range. The very faint nebulosity (if any) in the immediate neighbourhood of the star η is incompetent to give a trace of spectral lines with even a wide slit; for a considerable space S and *f* of η no lines at all are visible; the nearest nebula bright enough to show a line (the three usual lines are now easily seen on a good night over the brighter parts) is reached in the direction about 45° N p from η, and even then the distances from η, as judged by the appearance in the spectroscope with η threaded on the thus directed slit, is little less than one minute. This remark is of some importance in connection with the ordinary telescopic observations of the nebula, but is mentioned at this point to relieve any impression which might arise that the nitrogen line seen on the star spectrum is merely the chief nebula line crossing it. In the present state of the inquiry there is little doubt left as to the presence of hydrogen in the star; the other lines may perhaps be accounted for by nitrogen alone, or by nitrogen, magnesium, and sodium. On the whole the weight of collateral evidence will probably be considered to be in favour of the latter combination, with the possibility that for sodium may have to be substituted the substance which produces the line in sun-protuberance spectrum. For although there is no direct evidence as to identity of the line near D, if the coincidence were with the orange nitrogen line, it would be reasonable to expect a line in the star corresponding to the yellow line 1180±, yet none has been made out in that position; again, the second green line has probably less claims for visibility than the orange or yellow lines, yet in the star spectrum this line is not less well seen than that coinciding with the chief nitrogen line; these considerations, though perhaps not entitled to great weight, at least lead in the direction of the above inference. Owing to faintness of the general spectrum no dark lines are made out; one in the red is strongly suspected, and occasionally there is an appearance as if of a multitude over the spectrum generally, but they refuse to be seen separately and certainly. The spectroscope has decided that η in no way influences the configuration as now seen. Is not the presence of nitrogen and hydrogen in the star η a significant fact in connection with these changes, which appear to be nothing less than a destruction of nebula specially in its neighbourhood?

Orion has again been examined with an interesting result; the spectroscope proves that in and about the trapezium nebula exists comparable with the bright surrounding nebula. The stars, sharply focused to give a linear spectrum, being threaded on the slit singly or in pairs, or cautiously removed out of the field, it is seen that the bright lines cross the trapezium with little if at all diminished brilliancy. The ordinary telescopic view is therefore an erroneous one, produced by the disturbing effect of the bright group. Jupiter has been examined (generally on moonlight nights); with this object the original Cassegrain image is too faint for good work, but by interposition of a suitable lens the image is condensed at pleasure within certain limits; with the light thus increased the Fraunhofer lines G, F, *b*, E, D, are always easily seen, C also easily on a clear night; the lines to which special attention has been directed are the telluric lines 914 and 838 (for convenience of reference the numbers in Mr. Huggins's Jupiter and sky diagrams are used throughout.) These are the only lines seen with certainty between C and D. The identity of 914 and 838 rests partly on measures and partly on spark comparison, where, for the identification of 914, it is seen that this line is near to the air band 807 of Mr. Huggins's chemical scale. The line 914 is so easily seen, that having in mind Mr. Huggins's statement concerning the difficulty of discerning it at all, originally very imperfect measures on a bad night, and with the apparatus imperfectly adjusted, misleading in the same direction, this line was at first mistaken for 882, from which, however, it is separated far beyond the limit of error in a proper state of adjustment of apparatus. 882 is not seen at all with Jupiter at considerable altitude. On the night of December 29th, however, between the hours of 12.30 and 1, Jupiter being low, 882 was then seen almost as conspicuous as 914, which did not seem to have perceptibly increased in darkness by the additional absorption of the earth's atmosphere. On the night of December 14th (both objects being near the meridian) the spectroscope was turned on Jupiter and the moon alternately several times. On Jupiter 914 and 838 were easily visible, the former (as usual) the more conspicuous; on the moon no line could be certainly made out between C and D.

March 16.—The following papers were read:—"On the Contact of Conics with Surfaces." By William Spottiswoode, M.A., F.R.S. "Tables of the Numerical Values of the Sine-integral, Cosineintegral, and Exponential Integral." By J. W. L. Glaisher, Trinity College, Cambridge. Communicated by Prof. Cayley, LL.D. "Researches on Solar Physics.—No. II. The Positions and Areas of the Spots observed at Kew during the years 1865–66, also the Spotted Area of the Sun's visible disc from the commencement of 1832 up to May 1868." By Warren De la Rue, Ph.D., F.R.S., F.R.A.S., Balfour Stewart, LL.D., F.R.S., F.R.A.S., Superintendent of the Kew Observatory, and Benjamin Loewy, F.R.A.S. The paper commences with a continuation for the years 1864–66 of Tables II. and III. of a previous paper by the same authors; it then proceeds to a discussion of the value of the pictures of the sun made by Hofrath Schwabe, which had been placed at the disposal of the authors, and the result is that these pictures, when compared with simultaneous pictures taken by Carrington and by the Kew heliograph, are found to be of great trustworthiness. From 1832 to 1854 the pictures discussed are those of Schwabe, who was the only observer between these dates; then follows the series taken by Carrington, and lastly the Kew series, which began in 1862. A list is given of nine values of the sun's spotted area for every fortnight, from the beginning of 1832 up to May, 1868, and also a list of three-monthly values of the same, each three-monthly value being the mean of the three-fortnightly values which precede one of the three which follow it. These three-monthly values are also given for every fortnight. A plate is appended to the paper, in which a curve is laid down representing the progress of solar disturbance as derived from the three-monthly values; and another curve is derived from this by a single process of equalisation, representing the progress of the ten-yearly period. The values of the latter curve, corresponding to every fortnight, are also tabulated. From this Table are derived the following epochs of maxima and minima of the longer period:—

Minimum	Nov. 28, 1833.	
Maximum	....	Dec. 21, 1836.
Minimum	Sept. 21, 1843.	
Maximum	....	Nov. 1, 1847.
Minimum	April 21, 1856.	
Maximum	....	Sept. 7, 1859.
Minimum	July 14, 1867.	

This exhibits a variability in the length of the whole period.

Thus we have between 1st and 2nd minimum... ..	9·81 years.
2nd and 3rd do.	......12·58 „
3rd and 4th do.	......10·81 „
Mean of all the periods	.........11·07 years.

Another fact previously noted by Sir J. Herschel is brought to light, namely, that the time between a minimum and the next maximum is less than that from the maximum to the next minimum. Thus the times from the minimum to the maximum are for the three periods 3·06, 4·14, and 3·37, while those from the maximum to the minimum are 6·75, 8·44, and 7·44 years. In all the three periods there are times of secondary maxima after the first minimum; and in order to exhibit this peculiarity statistics are given of the light-curve of R Sagittæ and of β Lyræ, two variable stars which present peculiarities similar to the sun. Finally, the results are tested to see whether they exhibit any trace of planetary influence; and for this purpose 54 conjunctions of Jupiter and Venus, and 90 conjunctions of Venus and Mercury have been made use of with the following result, exhibiting the united effect of the sun's conjunctions, the unit of spotted area being one millionth of the sun's visible hemisphere.

Angular separation.	Excess or Deficiency. Jupiter and Venus.	Venus and Mercury.

Chemical Society, March 3.—Prof. Williamson in the chair. "On Refraction Equivalents." By Dr. Gladstone. Three distinct lines of research had led up to the discovery of these equivalents. The first was the influence of temperature on the refraction of light by liquids; the second, the refraction of mixtures or combinations as compared with that of their constituents; and the third, the refractive indices of different members of homologous series of organic compounds. As to the first of these it was found by the joint labours of Dr. Gladstone and the Rev. Pelham Dale, that the refraction and the dispersion decrease as the temperature rises. Further examination showed a close relation between the change of density and the change of the refractive index minus unity, which the investigators termed the "refractive energy," and which is expressed in the language of opticians as $u-1$. This energy divided by the density, that is $\frac{u-1}{d}$ is called the "specific refractive energy," and is, in the case of liquids, a constant, not affected by temperature. This conclusion was subsequently confirmed by the experiments of Landolt, Wüllner, and Kühlman. As to the second line of research, that of the refraction of mixtures, solutions, and simple combinations, the conclusion was arrived at that here also the nearest approximation to the truth was given by $\frac{u-1}{d}$, and this conclusion has been fully confirmed by the careful experiments of Wüllner. The same general expression holds good also in the case of a gas or a solid in solution, and, indeed, it was expected to be so, for water, phosphorus, and sulphur have the same energies in the liquid and solid states. The question now presented itself, does an elementary substance retain its specific power of retarding rays when it is combined chemically with other elements? An affirmative reply was suggested by many considerations. It was, for instance, found that bromoform ($CHBr_3$) and bibromide of bromethylene ($C_2H_3Br_3$) have almost the same specific refractive energy as bromine itself. On the other hand, however, the investigators observed that isomeric liquids were not always identical in refractive energy, and that the replacement of hydrogen by oxygen in organic compounds effected a much greater optical change in some instances than in others. Hence the conclusion was drawn that the specific refractive energy of every liquid is composed of the specific refractive energies of its component elements, modified by the manner of combination. The third line of research was that of the refractions of different homologous compounds. The experiments of Delffs, of Landolt, and of Gladstone and Dale, have led to the view that in all the series containing the radicals, methyl and its congeners, the specific refractive energies increase as the series advances, and that the amount of optical change is less between the higher than between the members of the lower series. Landolt, adopting Gladstone and Dale's formula for the specific refractive energy, multiplied it by the atomic weight P; and this $P\frac{u-1}{d}$ he designated the "Refraction Equivalent." According to this representation, the refraction equivalent of a body is the sum of the refraction equivalents of its constituent elements. The great advantage of this kind of expression is, that it permits of the easy comparison of the optical properties of different substances. By making these comparisons, Landolt found that the refraction equivalent of carbon is 5·0; that of hydrogen, 1·3; and that of oxygen, 3·0. Direct experiments have given figures very close to these. The way of calculating the refraction equivalent of a compound from these data may be illustrated by ether. $C_4H_{10}O = 4(5{\cdot}0) + 10(1{\cdot}3) + 3{\cdot}0 = 36{\cdot}0$. The refraction equivalent deduced from observation is 36·26. A great variety of liquids have given the same equivalents by calculation as by direct investigation. Yet there are exceptions to this agreement with theory. The whole group of the aromatic hydrocarbons and their derivatives give refraction equivalents much above the calculated numbers. This anomaly must be due to an erroneous representation of the constitution of their nucleus, which cannot be greater than C_6H_3. However, the above method makes it possible to find the refraction equivalent of bodies, which could not otherwise be taken; for instance, of metals. The refraction equivalents of fifty elements have been determined in this way. It is to be remarked that the figures in the following list represent A of the solar system:—

Aluminium	8·4	Iodine	24·5—27·2
Barium	15·8	Iron	12·0—20·1
Bromine	15·3—16·9	Lead	24·8
Calcium	10·4	Magnesium	7·0
Carbon	5·0	Manganese	12·2—26·2
Chlorine	9·9—10·7	Mercury	21·3—29·0
Chromium	15·9—23·0	Nitrogen	4·1— 5·3
Copper	11·6	Oxygen	2·9
Hydrogen	1·3— 3·5	Phosphorus	18·3
Platinum	26·0	Sodium	4·8
Potassium	8·1	Sulphur	16·0
Silicon	7·5— 6·8	Tin	27·0—19·2
Silver	13·5	Zinc	10·2

It will be seen that some of the elements have a double value, and this peculiarity is in most cases coincident with a change of atomicity. Thus, iron in the ferrous salts has the equivalent 12·0, in the ferric salts 20·1, and since the refraction equivalent of iron in potassic ferridcyanide is 11·7, the view suggests itself that the metal is here in the same condition as in the ferrous salts. Great anomalies, however, present themselves in the case of oxygen. Its equivalent in many compounds is 2·9, but in others it comes down to 2·1, and in some cases, as in sulphates and phosphates, it would seem to be a negative quantity. This points to the conclusion that oxygen has the power of greatly modifying the action on light of those elements with which it is combined in a high proportion. On looking over the above list one is struck by the identity of the equivalents of those elements which have the same, or nearly the same, atomic weight. This property is still more prominent when the specific refractive energies of the elements instead of their refraction equivalents are considered. The following pairs may be noted in this respect:—

Iron,	0·214	Aluminium,	0·307	Bromine,	0·191
Manganese,	0·222	Chromium,	0·305	Iodine,	0·193

But the most suggestive comparison is that between the specific refractive energy and the combining proportions of those metals that form salts not decomposable by water. By combining proportion is meant the actual amount which will combine with a certain quantity of a salt radicle. A few of these metals may be quoted here:—

	Specif. refr. energy.	Combining proportion.
Hydrogen	1300	1
Albuminium	307	9·1
Calcium	260	20
Iron	214	28
Sodium	209	23
Potassium	207	39·1
Copper	183	31·7
Silver	125	108
Lead	120	103·5
&c.		

The regularity in the decrease of the numbers in the first column and the corresponding increase in the second column would suggest that the combining proportions of Silver, Lead, &c. ought to be halved in order to bring those elements to about their right places in the list. There is further a remarkable coincidence between the power of a metallic element to refract the rays of light, and its power to saturate the affinities of other bodies; of course, it must be borne in mind that a small combining proportion means a high saturating power.

The names of the officers proposed by the Council of the Chemical Society for election on the 30th March, are:—President: A. W. Williamson. New Vice-Presidents: E. Frankland, A. Matthiessen. New Members of Council: H. Bassett, F. Field, F.R.S.; M. Holzmann, Ph.D.; W. J. Russell, Ph.D.; R. Angus Smith, Ph.D., F.R.S.; John Tyndall, LL.D., F.R.S.

Entomological Society of London, March 7.—Mr. F. P. Pascoe, vice-president, in the chair. The Rev. R. P. Murray and M. J. C. Puls were elected members. Professor Westwood exhibited a number of old locusts, with a view to determine what is the true *Locusta migratoria* of Linnæus. The Rev. H. S. Gorham sent for exhibition specimens of *Sunius neglectus*, a beetle new to Britain, but probably confused in collections with *S. angustatus*. Mr. Albert Müller exhibited a curious acorn-like gall formed on the mid-rib on the underside of the leaf of a species of *Gnetum*. Mr. Janson exhibited a large number of butterflies collected by his son in Nicaragua in November and December last. Mr. Butler exhibited specimens of *Argynnis Adippe* and *Niobe*, in support of his previously expressed opinion that the two forms are but one species. Dr. Wallace exhibited dark varieties of *Melitæa Athalia*, and specimens of *Herminia derivalis*. Mr. Stainton exhibited *Cosmopteryx Sienigiella*, bred in this country from Russian larvæ which fed in reeds. Dr. Wallace exhibited cocoons and silk of several species of silk-producing moths, and addressed the meeting on the progress and science of Sericiculture in this country and in the colonies. The following paper was read: "Descriptions of twelve new exotic species of the Coleopterous family *Pselaphidæ*," by Professor Westwood.

Ethnological Society, March 8.—Professor Huxley, F.R.S., president, in the chair. Captain Campbell, R.E., was announced as a new member. Colonel Lane Fox read a paper "On the opening of two cairns near Bangor, in North Wales." One was situated on the summit of Moel Faban, and contained a cist in which an urn was found, together with several small dressed stones, probably arrow-heads and flakes, worked not in flint, but in the trap and felspathic rocks of the neighbourhood. Other worked stones were found beneath the cist. Professor Ramsay described the lithological characters of the materials. The second cairn examined by the author was called Carnedd Horvel, and contained fragments of an urn surrounded by particles of burnt human bone, but not protected by a cist. Among the speakers who took part in the discussion on this paper were Sir J. Lubbock, Bart., M.P., Professor Ramsay, Mr. J. Evans, Mr. J. W. Flower, Dr. Nicholas, and Mr. R. Hamilton. A paper was then read "On the earliest phases of civilisation," by Mr. H. M. Westropp. The author sought to show that every race passes through an invariable series of phases in definite sequence. These are the barbarous, the hunting, the pastoral, and the agricultural phases, which the author compared with the respective stages of infancy, childhood, youth, and manhood in the individual man. Numerous illustrations were adduced of different races exhibiting these several phases of civilisation in the successive stages of their development.

MANCHESTER

Literary and Philosophical Society, February 22.—Dr. J. P. Joule, president, in the chair, referred to the observations he had made in former years on the progressive rise of the freezing point of one of his thermometers. He had made a further observation, and found that a rise—unmistakeable, though very small—was still taking place after a lapse of twenty-six years since the bulb was blown.—Dr. F. Crace Calvert gave an account of the progress made during the last few months in the production of artificial alizarine, and expressed his opinion that many years must elapse before it can replace madder and its preparations in all their varied applications in calico printing; but ere long the purity of the substance artificially obtained may prove of great service to the calico printer, by enabling him to produce at a cheaper rate than now certain styles of prints as well as new styles and effects. Dr. Schunck remarked that practical success would in a great measure depend on the price of the raw material, anthracene, and on the amount of colouring matter to be obtained from it. The process of manufacture was, however, as far as he could judge, a very simple and easy one, requiring the use of no costly materials. He was convinced that the artificial product was identical with the natural alizarine of madder, the only difference being that the former was generally contaminated with some impurity which prevented its crystallising easily. Purpurine was not formed along with alizarine, as had been supposed. He also exhibited to the meeting some specimens of Turkey-red dyed with artificial alizarine, which had been sent to him by Mr. Perkin, and stated that the latter had already manufactured several tons of the new product. Dr. Schunck referred to a notice in the last number of the *Chemical News*, giving an account of a process for preparing pure alizarine from Turkey-red dyed cotton; and stated that almost the same process was described many years ago by himself. He also claimed to have been the first to point out that Turkey-red, madder pink, and all the finer madder colours are simply compounds of alizarine and fatty acids with bases.

"On the Organic Matter of Human Breath in Health and Disease," by Dr. Arthur Ransome. The vapour of the breath was condensed in a large glass flask surrounded by ice and salt, at a temperature of several degrees below zero. The fluid collected was then analysed for free ammonia, urea, and kindred substances; and for organic ammonia—the method employed being that invented by Messrs. Wanklyn and Chapman for water analysis. The breath of 11 healthy persons and of 17 affected by different disorders was thus examined, and the results were given in two tables. The persons examined were of different sexes and ages, and the time of the day at which the breath was condensed varied. In both health and disease the free ammonia varied considerably; the variation could not be connected with the time of the day, the fasting, or full condition. Urea was sought for in 15 instances—three healthy persons and 12 cases of disease—but it was only found in two cases of kidney disease, in one case of diphtheria, and a faint indication of its presence occurred in a female suffering from catarrh. The quantity of ammonia, arising from the destruction of organic matter, also varied, possibly from the oxidation of albuminous particles by the process of respiration; but in healthy persons there was a remarkable uniformity in the total quantity of ammonia obtained by the process. Amongst adults the maximum quantity per 100 minims of fluid was 0·45 of a millogramme, and the minimum was 0·35. A rough calculation was given of the total quantity of organic matter passing from the lungs in 24 hours—in adults about 3 grs. in 10 oz. of aqueous vapour, a quantity small in itself, but sufficient to make this fluid highly decomposable, and ready to foster the growth of the germs of disease. In disease there was much greater variation in the amount and kind of organic matter given off. In 3 cases of catarrh, 1 of measles, and 1 of diphtheria, the total ammonia obtained was much less than in health—less than 0·2 of a millogramme—a result probably due to the abundance of mucus in those complaints, by which the fine solid particles of the breath were entangled. In two cases of whooping-cough it was also deficient, but as they were both children, the lack of organic matter may have been due to their age. In cases of consumption also the total ammonia was less than in health; but in one case of this disease associated with Bright's Disease a larger amount of organic matter was given off, a portion of it due to urea. In kidney diseases the largest amount of organic matter of all kinds was found in the breath. The ammonia in one case of Bright's Disease was 1·8 millogrammes in 100 minims of fluid, and urea was largely present. Perhaps this fact might be taken as an indication of the need of measures directed to increase the activity of other excretory organs. In one case of ozona or offensive breath, the total quantity of ammonia obtained was greater than in any healthy subject, but the excess was chiefly due to organic matter. One convalescent case of fever was examined, and the total ammonia was found to be deficient. The air of a crowded railway carriage, after 15 minutes' occupation, was also tested by this method, and in about 2 cubic feet 0·3 millogrammes of ammonia and 3 millogrammes of organic matter were found. With reference to the presence of organic matter in the atmosphere, it was pointed out that the subject was in no way a novel one, and that it had, during the last thirty years, been very fully investigated by many observers, more especially by Schwann, Dusch, Schroeder, Helmholtz, Van den Broeck, Pasteur, and Pouchet, but it was shown that it is to Dr. Angus Smith that we owe the discovery of the readiness with which living organisms are formed in the condensed breath of crowded meetings, and the determination of the actual quantity of organic matter in the air of different localities. Mr. Dancer's calculation of the number of spores contained in the air was noticed, but a source of error was pointed out in the readiness with which organisms are developed in suitable fluids, even in the course of a few hours. Observations upon the organic particles of respired air had at different times been made by the author. 1. In 1857 glass plates covered with glycerine had been exposed in different places and examined microscopically. Amongst others in the dome of the Borough Gaol, to which all the respired air in the building is conducted, organised particles from the lungs and various fibres were found in this air. 2. During a crowded meeting at the Free Trade Hall, air from one of the boxes was drawn for two hours through distilled water, and the sediment examined after 36 hours. The following objects were noted:—Fibres, separate cellules, nucleated cells, surrounded by granular matter, numerous epithelial scales from the lungs and skin. 3. The dust from the top of one of the pillars was also examined, and in addition to other objects the same epithelial scales were detected. 4. Several of the specimens of fluid from the lungs were also searched with the microscope. In all of them epithelium in different stages of deterioration was abundantly present, but very few spores were found in any fresh specimen. On the other hand, after the fluid had been kept for a few hours, myriads of vibriones and many spores were found. In a case of diphtheria, confervoid filaments were noticed, and in two other cases, one of measles, and one of whooping cough, abundant specimens of a small-celled torula were found, and these were seen to increase in numbers for two days, after which they ceased to develope. These differences in the nature of the bodies met with probably show some difference in the nature of the fluid given off; but it was pointed out that they afford no proof as yet of the germ theory of disease. They simply show the readiness with which the aqueous vapour of the breath supports fermentation, and the dangers of bad ventilation, especially in hospitals. Dr. E. Lund and Dr. H. Browne stated that they had also made experiments, the results of which were, in general, confirmatory of those obtained by Dr. Ransome.

Microscopical and Natural History Section, January 31.—Mr. John Watson, president, in the chair. Mr. Charles Bailey read a paper "On the natural ropes used in packing cotton bales in Brazil."—Mr. J. Sidebotham exhibited some photographs of Pholas-bored Rocks, and said in reference to a paper by Mr. R. D. Darbishire on rocks bored by Pholas at the Little Orme's Head, that last spring he found many rocks so bored on both the Great and Little Ormes. The holes are most abundant near the tops of the mountains, and none whatever are met with very low down. At first sight the holes on the surface of the rocks having been weather-worn, and sometimes connected by channels with the natural fissures in the rock, it is difficult to say which or whether any of the holes have been caused by boring shells. —An interesting collection of Australian plants from Dr. Mueller, of Melbourne, was exhibited by Mr. H. A. Hurst.

EDINBURGH

Royal Society, March 7.—William Forbes Skene, vice-president, in the chair. The following communications were read: "On the Rate of Mortality of Assured Lives as experienced by Ten Assurance Companies in Scotland from 1815 to 1863," by James Meikle, actuary to the Scottish Provident Institution, communicated by Prof. Tait. In 1863 ten assurance companies contributed their mortality experience, embracing nearly 12,000 deaths, and published the result in May last. The present paper contained observations on the nature of that experience. After comparing the mortalities of the male population of England and Scotland, in which the mortality of males in Scotland was greater than in England up to about the age of thirty-five, the mortality of assured males was compared therewith, and also with the expectations of the Carlisle and the Actuaries' tables, the most general bases of life assurance computations. Assured life experience was shown to be greatly more favourable than the Carlisle up to about the age of fifty, thereafter less favourable; it was slightly more favourable than the Actuaries' at nearly all ages. Similar comparisons were made of the mortality of females. The whole observations on the lives were then thrown into various forms, so as to exhibit the effects of the selection exercised by the offices in assuring only healthy lives; and, after casting out the experience of the years when selection has its greatest force, comparing the remaining observations with the mortality of the population. The rate of mortality on policies effected "*with* participation in profits" was shown to be very much *higher* than on policies effected "*without* participation." The mortality on imperfect lives (those not assured at ordinary rates) was also discussed, and the amount of annual premium required to assure 100*l*. at death given for several classes of diseased lives. Interesting comparisons were also given of the causes of death of assured lives and of the population. It appears that assured lives have died in greater proportion from zymotic complaints, diseases of the brain, heart, and liver; while the populations have died in greater ratio from tubercular and lung diseases. The paper concluded with a description of the manner in which some of the results were adjusted and interpolated. The whole was very fully illustrated by diagrams, and called forth an interesting discussion.—"Brief Notes on Indian Society and Life in the Age when the Hymns of the Rigveda were composed," by John Muir. After stating that although the religious conceptions of the Indians of the Vedic era were in a comparatively simple and undeveloped stage, it would be a mistake to suppose that they had not made considerable advances in civilisation, the writer proceeded to give some account of the country which they occupied, and of the amount of opulence possessed by their kings, and to adduce a variety of particulars illustrative of their social and domestic relations and manners, their dress, food, drink, professions, relating to the tame and wild animals known to them, to their wars, armies, armour, and weapons, and to their poetry and incipient speculation. Some of the topics treated of were illustrated by metrical translations from the hymns of the Rigveda—(1) in praise of charity and liberality, (2) relating to the variety of men's tastes and pursuits, (3) satirically comparing the Brahmins with frogs reviving at the beginning of autumn, (4) descriptive of the miseries of gambling, (5) in celebration of warlike prowess and its instruments, and (6), containing a specimen of early speculation.

DUBLIN

February 28.—Sir Robert Kane, vice-president, in the chair, Professor J. P. O'Reilly exhibited a model and described a plan of a moveable barometer. The secretary read a note supplementary to their former paper "*Eozoon Canadense*, a mineral Pseudomorphite," by Professors W. King and T. H. Rowney, of Queen's College, Galway.

Natural History Society, March 2.—Rev. Professor Houghton, in the chair. Professor Houghton read a paper on the "Pathological lesions observed in the stomach of a lioness." —Professor Traquair exhibited fine specimens of *Calamoischthys* from Old Calabar, and Professor Macalister exhibited a specimen of *Amœida vulgaris*, from Mangerton, county Kerry.

PARIS

Academy of Sciences, March 7.—M. de Saint-Venant read a memoir on the establishment of the equations of the interior movements effected in solid ductile bodies beyond the limits at which elasticity can restore them to their former state. Papers were also communicated by M. Brioschi on the bissection of hyperelliptical functions, by M. Bourget on the algebraical development of the perturbative functions, and by M. Lucas on the calculation of the physical parameters and principal axes in a certain point of an atomic system.—M. Becquerel communicated a memoir on the electromotive forces of various substances, such as pure carbon, gold, platinum, &c., in the presence of water and of various liquids, in which he described the effects produced by plates of the substances above mentioned in contact with distilled water and various solutions.—M. Dubrunfaut presented some remarks upon the colours of rarefied gases submitted to spectrum analysis. He remarked upon the luminosity of hydrogen in Geissler's tubes at various degrees of tenuity, and stated that at its maximum attenuation a blood-red colour is characteristic of pure hydrogen, and that it communicates a similar coloration to the gas surrounding it. He also noticed the variation in the intensity of coloration of hydrogen, according to the calibre of the tubes through which the current passes. The purest nitrogen was stated to give a yellow tint, but usually the peculiarities of this gas are masked by the presence of water or mercury. The Torricellian vacuum was said to furnish the spectra of hydrogen, nitrogen, and mercury. The author also remarked upon some recent communications to the Academy on this subject.—A note by M. J. M. Gaugain on the electromotive force developed by platinum when in contact with various liquids was presented by M. E. Becquerel. The author stated that when one of two plates of platinum is taken out of acidulated water, washed in distilled water and restored to its place, a current is developed, which he ascribed to the presence of the water. He discussed the probable modes of action of this water, and inclined to the opinion that the plate still plunged into acidulated water forms a coat more positive than the platinum itself, which combination is destroyed by the water. He stated, however, that the electro-motive force is greatly increased by the exposure of the washed plate to a temperature of 150° C (=302° F.)—In a note on the illumination of transparent bodies, M. Soret adduced a further evidence in favour of his opinion that the presence of suspended particles takes a preponderant part in these phenomena.—M. Leroy de Boisbandeau communicated some remarks, illustrated by sketches, upon some curious icicles observed by him on the sides of a stone tank.—M. Aug. Houzeau noticed the absence of oxygenated water in the snow which fell at Rouen on several days during the past winter.—A note by Mr. Thudichum was presented, in which the author described an acid which, he stated, exists normally in the urine, and which he proposed to name *Kryptophanic acid*.—M. Jouglet communicated a note on the action of ozone upon nitro-glycerine and other explosive compounds. He found that nitro-glycerine, dynamite, iodide and chloride of nitrogen and some other bodies exploded when put into a vessel containing ozone, whilst picrate of potash was slowly decomposed, and gunpowder was sensibly altered in six weeks.—A note by M. Sacc on the distillation of tartaric acid was presented.—Notes on earthquake shocks observed at Lima and Ancona were communicated by the Minister of Public Instruction.—M. H. Sainte-Clair Deville presented a note by Father Denza, giving an account of a storm of sand accompanying rain and snow, which occurred in various parts of Italy on the 13th and 14th of February. The author remarked upon the periodicity of the phenomenon, and noticed its occurrence in various places; the sand, in all cases, appeared to be identical, and was considered by the author to come from the African deserts. —A note by M. H. Magnan on the cretaceous formation of the French slope of the Pyrenees and of Corbières, and especially on the Neocomian, Aptian, and Albian strata of that region, was presented by M. Daubrée.—MM. A. Roujou and P. A. Julien communicated a note on striæ observed on blocks of Fontainebleau sandstone and other rocks imbedded in the diluvium of the neighbourhood of Paris. These were stated to be the first striated blocks observed near Paris. M. Elie de Beaumont made some remarks upon these blocks.—M. A. Trécul communicated the fourth part of his remarks upon the position of the tracheæ in the ferns and on the ramification and radicular propagation of the rhizomes of some of those plants.—M. Duchartre presented a note by M. E. Prillieux on the influence of blue light upon the production of starch in chlorophyll. The author remarked that the production of starch was generally supposed to be due to the action of the yellow rays, and that blue light had no such effect. He considered that the results upon which this opinion was founded were due to the greater brilliancy of the yellow light, and by exposing a plant of *Spirogyra* deprived of starch to a more brilliant blue light, he found that formation of starch took place.—M. Duchartre also communicated a note by M. C. Cave on the free central placenta of the *Primulaceæ*, in which the author adduces as a further proof of the axial nature of that organ, that, on examination, the parts of recent formation are found to be outside the medullary sheath.—M. Auguste Duméril described some peculiar organs of the branchial apparatus in the Rays belonging to the genus *Cephaloptera*. These organs are the *prebranchial appendages* discovered by M. P. Panceri in *C. giorna*, which M. Duméril had detected in the large Indian *C. Kuhlii*. He stated that they occurred in no other fishes.—M. Pouchet noticed a transformation of the nests of the house martin (*Hirundo urbica*), and maintained that the nests of birds, instead of being, as generally supposed, constructed in the same way from century to century, really undergo certain progressive modifications of structure. In the case of the house martin, he stated that within the last forty years that bird has adopted a new form for its nests. The old nests are in the form of the quarter of a hemisphere, with a very small circular aperture for entrance. The improved nests, according to M. Pouchet, are in the form of the quarter of a hemi-ovoid with the poles much elongated, and the entrance is by a long transverse slit.—A second note on the tracheæ and differential characters of the lungs in birds, by M. Campana, was presented by M. C. Bernard. The author described the various modes of interbronchial communication, the mode of insertion of the pneumatic receptacles upon the lung, and the structure of the parenchyma of the organ.—M. Milne-Edwards communicated an extract from a letter from the Abbé David, giving the diagnosis of a new species of *Crossoptilon* (*C. cærulescens*) discovered by him at Sse-tchuaro.—A note by M. Demarquay, on the reproduction and union of divided tendons was communicated by M. J. Cloquet. The author maintained that the regeneration of a divided tendon is effected by the proliferation of the elements on the inner surface of its sheath, in a manner analogous to the reproduction of bone by the periosteum. M. Dupuis presented some remarks on the confusion which has often occurred between the physicist, J. A. C. Charles, and the geometrician, J. Charles, and communicated some particulars relating to the biography of the two Academicians.

SYDNEY

Royal Society of New South Wales.—Mr. F. B. Miller, F.C.S., one of the assayers of the Sydney Royal Mint, described the practical results of his method for separating silver and gold directly by the use of chlorine gas, a process of which an account was given to the Chemical Society rather more than a year ago. At the Sydney Mint 6,820,198 ounces of gold have been received for coinage from the date of its establishment in May 1855 to December 31, 1868. The average composition of this gold would be about 94⅓ per cent. of gold, 5 per cent. of silver, and ⅔ per cent. of base metals; the gross amount of silver contained in the gold would be about 334,190 ounces, so that about 24,750 ounces of silver per annum have been lost to the colony for the want of a simple process of refinage. The gold now obtained in Queensland, as also that now brought from New Zealand, contains a much larger proportion of silver, so that the present loss to the colony is more nearly 42,000 ounces per year. The experience of the Sydney Mint proves that on the average there is a marked deterioration in the gold proceeding from Victoria, where the fineness is 96 per cent., northwards through New South Wales, where the average is 93½ per cent., to Queensland, average 87¼ per cent. The silver can now be readily separated by passing a stream of chlorine gas into the melted gold for about an hour and a half, as it lies in a crucible heated in an ordinary melting furnace. The chlorine is at first rapidly absorbed, and the process is completed when a brownish yellow vapour appears. The chlorine is conveniently evolved from a self-acting generator, and 2,000 ounces of gold are readily refined in five hours, by three melting furnaces, 98 per cent. of the gold being delivered ready for coinage on the same day. The gold thus refined is perfectly tough, and contains only about one-half per cent. of alloy. The ultimate loss of gold is found to be only 19 parts in 100,000; the loss of silver is 240 in 100,000. The cost of refinage, including the above loss, but excluding rent of premises and expenditure, is five farthings per ounce. The silver is obtained in the form of fused chloride, and is reduced to the metallic state by plates of zinc combined with slabs of the chloride into a galvanic arrangement, devised by Dr. Leibriss. In twenty-four hours the chloride is completely reduced to the state of spongy silver, and 1,400 or 1,500 ounces could thus be readily treated in a day. No acid is required, and the zinc consumed is only 25 per cent. of the chloride reduced. The whole process, having been thoroughly tested at the time, is to be brought into active operation at once. It is already employed by some of the banks in Australia and New Zealand.

DIARY

THURSDAY, MARCH 17.

ROYAL SOCIETY, at 8.30.—On the Law which Regulates the Relative Magnitude of the Areas of the Four Orifices of the Heart: Dr. Herbert Davies.—On the Estimation of Ammonia in Atmospheric Air: H. T. Brown.
ROYAL INSTITUTION, at 3.—Chemistry of Vegetable Products: Prof. Odling.
LINNEAN SOCIETY, at 8.—The Flora and Fauna of Isle Ronde, near Mauritius: Sir Henry Barkly.—On Algæ found in the North Atlantic Ocean: Dr. Dickie.
ZOOLOGICAL SOCIETY, at 4.
CHEMICAL SOCIETY, at 8.—On Artificial Alizarine: W. H. Prekin, F.R.S.—On the Combination of Carbonic Anhydride with Ammonia and Water: Dr. Divers.
NUMISMATIC SOCIETY, at 7.
SOCIETY OF ANTIQUARIES, at 8.30.—On Ancient Round Barrows: Dr. Thurnam.

FRIDAY, MARCH 18.

PHILOLOGICAL SOCIETY, at 8.15.
ROYAL INSTITUTION, at 8.—On the Subway to France; J. F. Bateman, F.R.S.

SATURDAY, MARCH 19.

ROYAL INSTITUTION, at 3.—The Sun: J. Norman Lockyer, F.R.S.

MONDAY, MARCH 21.

LONDON INSTITUTION, at 4.
ROYAL ASIATIC SOCIETY, at 3.
ENTOMOLOGICAL SOCIETY, at 7.

TUESDAY, MARCH 22.

ROYAL INSTITUTION, at 3.—Nervous System: Prof. Rolleston, M.D., F.R.S.
ETHNOLOGICAL SOCIETY, at 8.—On Current British Mythology and Oral Tradition; Mr. Campbell of Islay.
INSTITUTION OF CIVIL ENGINEERS, at 8.
ROYAL MEDICAL AND CHIRURGICAL SOCIETY, at 8.30.

WEDNESDAY, MARCH 23.

GEOLOGISTS' ASSOCIATION, at 8.
SOCIETY OF ARTS, at 8.—On Surface Decoration: W. Pitman.
GEOLOGICAL SOCIETY OF LONDON, at 8.—On the Discovery of Organic Remains in the Caribbean series of Trinidad: R. J. Lechmere Guppy, F.L.S., F.G.S.—On the Palæontology of the Junction-beds of the Lower and Middle Lias in Gloucestershire: Ralph Tate, F.G.S.—On the Geology of the district of Waipara River in New Zealand: T. H. C. Hood, F.G.S.

THURSDAY, MARCH 24.

ZOOLOGICAL SOCIETY, at 8.30.—On the Birds of Veragua: Osbert Salvin.—Exhibition of a metamorphosed Axolotl: W. B. Tegetmeier.—On two rare species of Pheasants recently added to the Society's Collection: Mr. Sclater.

THE TRANSITS OF VENUS IN 1874 *AND* 1882

A PARLIAMENTARY paper issued at the close of last session gives some information on what is intended to be done in the matter of the great approaching astronomical events of 1874 and 1882, which will interest many readers of NATURE. The correspondence on this subject between the Astronomer Royal and the Hydrographer of the Admiralty, and between the Hydrographer and the Secretary to the Admiralty, is given at full length, and together with the appended remarks of Captain Toynbee, Admiral Ommaney, Commander Davis, Mr. Stone, and Mr. Warren De la Rue, well merits careful perusal. On the whole it seems to be at least doubtful whether the requisite Antarctic station for the observation of the transit, which in the opinion of the Astronomer Royal should, if possible, be in the neighbourhood of Mounts Erebus and Terror, can be attained, or if, when attained, it is likely to be possible to make observations from it. But this Antarctic station is only required for the transit of 1882, and there is ample time to make a preparatory Antarctic expedition to ascertain the doubtful point. In the meantime, however, let us see what has been settled about the transit of 1874. For the proper observation of this event the Astronomer Royal informs us that it will be necessary, after making allowance for all the aid that may be expected from foreign and colonial observatories, to organise expeditions to the following five stations:—(1) Oahu (Sandwich Islands), (2) Kerguelen's Island, (3) Rodriguez, (4) Auckland (New Zealand), (5) Alexandria. At the first three of these stations—namely Oahu, Kerguelen's Island, and Rodriguez—it will be necessary to make preparatory observations for twelve months, in order to ascertain the absolute longitudes of these places, which are not exactly known. The total cost of these proposed observing expeditions for the transit of 1874 is estimated by the Hydrographer at 10,404*l.*, a sum which, it must be admitted, is moderate for work of such surpassing importance, and, as the Lords of the Treasury state that they have "no objection to offer" to the proposed expenditure, we may take it for granted it will be so far carried out. But what I wish to call attention to at the present moment is the valuable opportunity thus offered for still further augmenting the importance of this event to the progress of science generally, by converting these proposed astronomical expeditions into expeditions for general scientific observation. At three of the spots to be visited it will be necessary to keep up an observing party, more or less extensive, for upwards of twelve months. Now, it so happens that the three spots thus selected for astronomical observatories are also of very great interest for biological studies. The Sandwich Islands are well known to be the seat of a most peculiar indigenous flora and fauna, which has been hitherto very incompletely explored, rivalling perhaps even that of the Galapagos in eccentricity. They are likewise the seat of some of the most stupendous volcanic phenomena known on the globe. Who can doubt that one or more zoologists, botanists, and geologists would find ample work during a twelvemonth's sojourn in these islands, and would reap a rich harvest of results? The little island of Rodriguez was formerly the residence of a bird allied to the Dodo, and probably of other extinct forms o life. Professor Newton and his brother have, it is true, already made us tolerably well acquainted with the osteology of *Pezophaps*, as this gigantic ground-pigeon is termed. But there is no doubt that a careful exploration of the bone-caves of Rodriguez will lead to still further discoveries as regards *Pezophaps*, and most probably result in bringing to light other unknown extinct inhabitants of the submerged continent, which was the ancient focus of Didine life. Kerguelen's Island, the third point selected for a temporary astronomical observatory, is also in many points worthy of renewed investigation. Although we may probably believe Dr. Hooker, who visited it during Sir James Ross's Antarctic Expedition, left but few plants for future botanists to discover, the seals and whales that frequent its shores, together with the sea-fowl and other inhabitants of the coast, would well occupy the attention of zoologists. It is, moreover, of especial importance that the "abundant fossil remains" of its now extinct forests should be thoroughly investigated, in order to obtain more knowledge of the former distribution of land and water in the South Pacific. I have mentioned only some of the principal and most noticeable points for biological inquiry in each of these three localities. But, as every naturalist knows, in the case of such isolated land-areas as these marine islands, it is of especial importance to the progress of our knowledge of general geographical distribution to have a complete account of every branch of their faunas and floras, both recent and extinct. I beg leave, therefore, to urge upon all who are interested in the progress of science, the importance of not losing the opportunity that now presents itself. The additional expense of attaching two or three qualified Natural History observers (or at any rate collectors) to these three expeditions could not be very great. The numerous American and Russian exploring expeditions are invariably accompanied by zoological and botanical collectors, nor is the money required to publish the results obtained by them grudged by the Governments of these countries. Even poverty-stricken Austria did not send the *Novara* round the world without a competent corps of naturalists, and we are now reaping the fruits of the abundant harvest which they gathered in. Far from lagging behind, wealthy England ought to take the lead in such cases, and instead of its being necessary, when an opportunity of the sort occurs, to take all kinds of extraordinary steps in order to induce the Government to take advantage of it, such things should be done as matters of course.

P. L. S.

PHILOLOGY AND DARWINISM

[The following paper was written nearly half a year ago, before the translation into English of Prof. Schleicher's two pamphlets, by Dr. A. V. W. Bikhers. After reading the article on Dr. Bikhers' translation, by Prof. Max Müller, in a previous number of NATURE, it struck me that many readers might be glad to have some further account of Schleicher's views. F. W. F.]

THE relations of the science of language to the Darwinian hypothesis have been touched upon by one of the most acute and learned of modern scholars, Prof. August Schleicher, of Jena, whose lamented death a year ago,* at the early age of forty-eight, is a severe loss to European science, was an ardent supporter of the doctrine of variability of species. Besides being a most eminent linguist, he had long been interested in practical botany; and as a cultivator of ferns he had enjoyed many opportunities of observing the apparent transformation of natural subdivisions. It was not, however, as a botanist that Mr. Darwin's book was mainly interesting to him, but far more from the light which his theories seemed to throw on the phenomena of language. The first edition of the "Origin of Species" appeared in November 1859, and Prof. Schleicher, three years before he had met with Brown's German translation of it, had in his book, "Die Deutsche Sprache" (pp. 43, 44), called attention to the struggle for existence among words, the disappearance of primitive forms, and the immense development and differentiation which may be produced by ordinary causes in a single family of speech. On receiving Mr. Darwin's book from his friend Prof. Häckel, he wrote him a letter, which has since been published, on "Die Darwinsche Theorie und die Sprachwissenschaft;" and in answer to the objection that he had, in this letter, assumed that languages were material existences, having a real natural life, he wrote a second pamphlet on the "Importance of Language for the Natural History of Mankind."

The general line of illustration which he adopts had probably struck others, and it had certainly struck me before I read or heard of Prof. Schleicher's pamphlet; but as that little work is as yet but slightly known in England, it will probably be interesting to some readers if I sketch the outline of his arguments. There was nothing fanciful or precipitous in Schleicher's writings. He was one of the most strenuous supporters of the strictly scientific character of all true linguistic inquiry; one of the most severe opponents of those vague fancies, imaginative theories, hazardous etymologies, and *à priori* inferences which have thrown suspicion on philological work. He had owed much, even in the study of language, to such books as Schleiden's "Scientific Botany," and the "Physiological Letters" of Carl Vogt; and he wished to found linguistic science on the structure of the organs of articulation and on recognised vital laws. He regarded languages as natural organisms which, in accordance with definite physical influences, and independently of human will, are produced and developed, grow old and die, and therefore manifest the series of phenomena to which we give the name of "life." Hence he regarded Comparative Philology, not as an *historical*, but as a *natural* science; and we think that his views will be shared by all who have added to their linguistic inquiries some sound knowledge of either zoology or botany.

The researches of Sir Charles Lyell have shown that the present condition of the earth's surface is due, not to cataclysms and conflagrations, but to the slow result of natural laws continuing to act during thousands of years. Similarly, Mr. Darwin showed that the existing conditions of species might have been originated by continuous insensible modifications, working for an indefinite period of time. It was the main object of Prof. Schleicher to show that in all essential particulars the working of similar laws accounted for the existing phenomena of languages. The principles of classification apply to language no less than to animal and vegetable organisms. A genus corresponds to a linguistic stem; classes to linguistic families; subspecies to dialects; varieties to minor dialectic peculiarities; and, finally, individuals to those special modes of varying utterances which distinguish man from man.

* He died on Dec. 6, 1868.

Mr. Darwin has constructed an ingenious diagram* to illustrate the immense scope which must be allowed for gradual divergence of characters in animal and vegetable species derived by natural selection from an original genus. Schleicher has made an exactly similar table to serve as a genealogical tree for the Aryan Families of language. But here the philologist has a distinct advantage, and the study of his results may be most suggestive to the naturalist: for the Darwinian diagram is to a great extent ideal and hypothetical; while the table of languages is merely an expression of indisputable discoveries. Any one who has clearly understood the certainty of the fact, that languages at first sight so different as Greek and French, Icelandic and Portuguese, Sanskrit and Lithuanian, are yet connected with each other by close bonds of union, and that the phenomena they exhibit are due to gradual differentiation from a single stock, will undoubtedly be more able to conceive the possibility of Newfoundlands, and Greyhounds, and King Charles's Spaniels, and Wolves being lineal representatives of a common type.

And further than this, the philologist has another very positive advantage over the naturalist. The ethnologist can not only *prove*, where the naturalist must be content to *conjecture*, but can also more easily exemplify the birth of new forms out of anterior ones, and can carry out his examination on a greater scale. There are some languages and families of languages which have been under close observation for two thousand years, and which furnish us with written specimens of forms which have undergone immense subsequent modification. In comparing modern French with the Latin of the XII. Tables, or Mahratti with the Sanskrit of the Vedas, we have a sure and solid basis of observation, in which, by the aid of records incapable of falsification, we can observe the corroding and modifying influence of time on human speech. The effects of foreign influences on different languages even furnish us with some analogy to *crossing*, which is so important an element in all zoological inquiries. In point of fact, the possession of written materials extending over many ages led philologists to be among the first to deny the sudden origin of separate species. The Science of Language offers the most demonstrable and instructive examples of the gradual growth of species from common primitive forms, although it is as impossible in language as it is in zoology to draw certain and definite lines of demarcation between genera, species, and varieties.

It may be asked whether the science of language is able at present to demonstrate the growth of all families from one primitive mother-tongue? The answer must be frankly in the negative, and perhaps one reason for this may lie in the fact that there is not any linguistic family except the Aryan, of which the archetypal forms have been reconstructed from their derivatives.† But, on the other hand, as regards the *morphology* of language, we are

* Origin of Species, p. 130. (4th edition.)
† To effect this was the object of Prof. Schleicher's *Compendium des Vergleichende Grammatik.*

perfectly in a position to show that the rudest forms of the most developed language have sprung, by insensible derivation, from phonetic signs as vague, simple, and monosyllabic as those of Chinese itself. These signs left the mutual *relations* of ideas unexpressed. There were at first no special vocal expressions, no *organs* for the fulfilment of grammatical functions, or the interdistinction of nouns and verbs, much less of conjugation or declension. Such words as *That, gethan, Thuer, Thäter, thätig*, all point back to a root *dha*, which contained in itself the undeveloped germ of all sorts of verbal, nominal, and adverbial modifications. And in this respect the ultimate roots of the Aryan languages closely resemble in character the actual words of those languages which have remained to this day as nearly as possible in their primitive condition. Such roots may without fancy be called speech-cells, in which the rudiments of all special organs are implicitly *involved*, but in which they are as little *developed* as in the germinal vesicles which represent the earliest forms of animal and vegetable life. There may have been multitudes of such sound-cells, as it were, from which different families of language have sprung by special lines of development, just as, according to the Darwinian hypothesis, many primordial cells, presenting a close similarity, may have been the earliest rudiments of all living organisms.

In speaking of the extinction of species and the struggle for existence, Mr. Darwin uses language which may be literally applied—applied without even verbal modification—to the phenomena of languages. Here, no less than in the animal and vegetable kingdom, the dominant forms of the prevailing groups tend to leave many modified descendants, while the imperfection of the weaker groups leads to their gradual disappearance. But the complete extinction of a linguistic type is a slow process, and just as extinct animal forms may leave behind them a few decaying representatives in inaccessible or solitary places, so in the mountain-valleys of the Pyrenees and the Caucasus, we find isolated dialects which may be the fragmentary relics of tongues once spoken in immense districts. But a language once extinct, like an extinct species, can never under any circumstances reappear; and its place is occupied by the nearly related but greatly modified groups of predominant families, which are precisely those which undergo the completest differentiation in the course of their gradual victory over less happily constituted forms. And in consequence of the extinction of languages many *intermediate* forms have perished; the primitive relationships of languages have been disturbed by all sorts of external influences, and consequently languages radically different are now found existing side by side. All this, as every naturalist is well aware, represents a condition of things precisely similar to that which prevails in animated nature.

Mr. Darwin, in his great work, devotes a few words to the classification of languages as affording a confirmation of his theories. It does so to an extent of which probably he was not at first aware. In two capital points, viz., (1), the immense changes which can be effected by infinitesimally gradual modification; and (2) the preservation of the best and strongest form in the struggle for life, Mr. Darwin's hypothesis may be confirmed and verified by the entirely independent researches of the comparative philologist. These are the two points to which Prof. Schleicher wished to draw attention in the pamphlet which I have here epitomised. They do not indeed represent the whole of the linguistic facts which might be adduced on this side of the question, and they leave out of sight others which might be alleged with great force in favour of an opposite view. Some of these I have endeavoured to set forth elsewhere,* and possibly there may be some future opportunity of again bringing this subject before the reader. My present object was to make the views of Prof. Schleicher more widely known than they have yet become among English naturalists and scholars.

F. W. FARRAR.

THE PRIVATE LIFE OF GALILEO

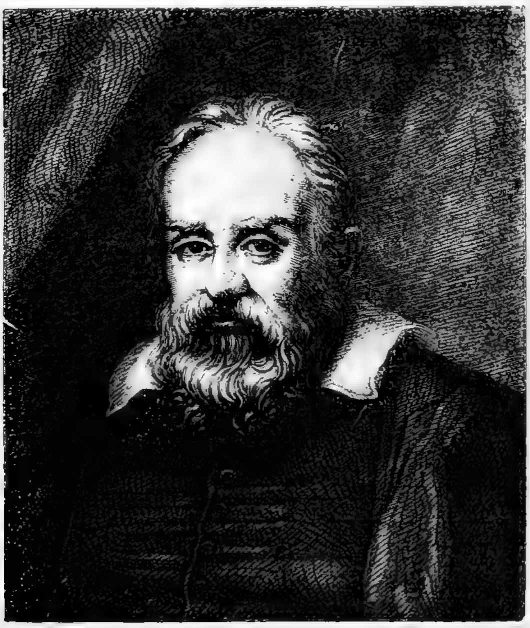
The Private Life of Galileo. Compiled principally from his correspondence and that of his eldest daughter, Sister Maria Celeste, nun in the Franciscan convent of S. Matthew at Arcetri. 307 pp. (London: Macmillan and Co. 1870.)

THE numerous works which have appeared with Galileo for their theme may be divided into three classes. Firstly, those which relate more particularly to his persecution by the Church, the position and influence of the Sacred College in his day, and its attitude towards science. Secondly, those which treat of his scientific labours apart from himself, their nature and character, and their influence on the propagation of truth, the advancement of modern philosophy, and the downfall of Aristotelianism. Thirdly, those which discuss his private life. The first and last of these are often blended, more or less, and of necessity, but we know too little of his scientific labours. M. Parechappe has well remarked, "Le savant s'est effacé dans le martyr." The works of Galileo, if much talked of, are certainly little read—"Il Saggiatore" and the "Dialoghi" are even less read than the "De Augmentis Scientiarum" and the "Novum Organum;" while the "Principia" of Descartes occupies a position of notoriety midway, perhaps, between "Il Saggiatore" and the "Novum Organum," and we have a little difficulty in placing the writings of Hobbes. Yet it is undeniable that the works of these four men have produced a more profound and permanent influence upon human thought than any which preceded them. There is but one epoch in the history of the world to be compared with their epoch; it is that of Aristotle.

The work before us belongs both to the first and third of the above divisions, it relates mainly to the private life of Galileo, and resembles Arduini's "Primogenita di Galileo Galilei," more than any other work on the subject. The account of the private life of Galileo, unlike many such accounts, does not give us much insight into the manners and customs and conditions of society at the time of which it treats, both because Galileo had so little real domestic life, and because the main correspondence which furnishes these private details took place between a nun (who of all persons can know least of the external world) and Galileo himself, and her letters to him have been preserved, while his answers to them have perished. Your great philosopher as a rule is exceedingly

* See a paper on "The Growth and Development of Language" in the *Cambridge Journal of Philology*.

undomestic, and the proofs of this are so common that we need not quote a single example ; the petty details of home weary them, and prevent the abstraction requisite for their labours : so the ancient Brahmans, who reasoned as profoundly as any light of Western civilisation, lived in the solitudes of the forests of Ancient India ; so Descartes withdrew himself from the world, and remained

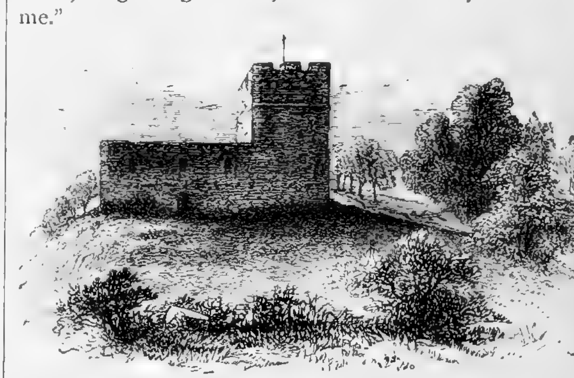


GALILEO
(*From Ramsey's picture in Trinity College, Cambridge*)

buried in the quiet of his country house while he produced his "Meditations."

Galileo also was by no means domestic. Of his three natural children, his son Vincenzio was a constant thorn in his side. He was a lazy fellow, who was always writing to his father for money, and who, Italian-like, preferred to idle away his life in singing and lute-playing, to adopting any profession or attempting to get his own livelihood. We cannot find one good quality in Vincenzio Galileo ; he was mean, selfish, inconsiderate and unnatural in his behaviour towards his father. One example of this is sufficient. He had quartered himself on his father, together with his wife and children, when the plague broke out in the neighbourhood ; whereupon Vincenzio deserted the old man, and went to a more healthy locality, leaving his father to take his chance with the other inhabitants of the district. Galileo's daughters Polissena and Virginia were placed in the Convent of S. Matthew, at Arcetri, in 1614, when the eldest was only thirteen years old ; henceforth they became Sister Maria Celeste and Sister Arcangela. Of the latter we hear but little, but Sister Maria Celeste constantly corresponded with her father, and the greater number of her letters have been preserved, and are now in the Palatine Library at Florence. These letters contain some interesting details of convent life of the period, but of necessity they do not bear upon many of the doings of the outside world ; their general tenor is the same throughout ; they are full of her love for Heaven and for her "dear lord and father," as she was wont to call Galileo, and they almost invariably pass to an opposite extreme of matters exceedingly of the earth, earthy—the baking of cakes, the mending of linen, the getting up of his collars and so on. She tells her father all the minute details of her work, as : "I have been extremely busy at the dinner-napkins. They are nearly finished ; but now I come to putting on the fringe, I find that of the sort I send as a pattern a piece is wanting for two dinner-napkins : that will be four *braccia*." The last paragraph of this desultory letter begins, "These few cakes I send are some I made a few days ago, intending to give them to you when you come to bid us adieu ;" and ends, "I thank Him for everything, and pray that He will give you the highest and best felicity ;" and a postscript immediately follows this—"You can send us any collars that want getting up."

Galileo's villa was very near the convent, and a constant interchange of courtesy seems to have taken place; Galileo sent money and presents of meat and wine, while Sister Maria Celeste sent him plums, and baked pears, and candied fruits, and cakes, and mended his linen and kept his wardrobe in order. Her love for him amounted almost to worship, at least to veneration. When at length, worn out by watching in the convent infirmary, by ill health, and by the many privations inseparable from a convent life, she felt her end approaching, Galileo was in confinement at Siena, and she feared she should see him no more; but he was allowed to retire to his own house, and arrived at Arcetri in time to see his daughter before her death. Writing of this time (1634), Galileo says : "Here I lived on very quietly, frequently paying visits to the neighbouring convent, where I had two daughters who were nuns, and whom I loved dearly; but the eldest in particular, who was a woman of exquisite mind, singular goodness, and most heartily attached to me."



GALILEO'S TOWER

There is much in this "Private Life of Galileo" of great interest in connection with his scientific work, his books, his persecutions and trial by the Sacred College, and his condemnation; but we have preferred to keep strictly to his more private life, as the theme is so large, that if we once touched upon his scientific work and its results, we should require far more space than could be placed at our disposal here.

Galileo continued actively employed to within a few years of his death, in January 1642. During his latter years he was a great sufferer. "I have been in my bed for five weeks," he writes to Diodati, in 1637, "oppressed with weakness and other infirmities, from which my age, seventy-four years, permits me not to hope release. Added to this, *proh dolor!* the sight of my right eye, that eye whose labours (I dare say it) have had such glorious results, is for ever lost. That of the left, which was and is imperfect, is rendered null by a continual weeping." Thus the poor old man complained, until finding that his blindness was incurable, and that his many ills were increasing, he ceased repining, and begged his friends to remember him in their prayers, till his unhappy chequered life was closed by death.

G. FARRER RODWELL.

OUR BOOK SHELF

Reptiles and Birds. A Popular Account of their various Orders, with a Description of the Habits and Economy of the most interesting. By Louis Figuier. Illustrated with 307 woodcuts. Edited and adapted by Parker Gillmore. 1870. (London: Chapman and Hall.)

A VERY pretty book for a drawing-room table. The description of the several families of both reptiles and birds is filled with anecdotes culled from all sorts of writers, some of them sufficiently amusing, others, to say the least, of doubtful accuracy; witness the following in reference to the stork:—"The inhabitants of Smyrna, who know how far the males carry their feelings of conjugal honour, make these birds the subject of rather a cruel amusement. They divert themselves by placing hen's eggs in the nest of the stork. At the sight of this unusual production the male allows a terrible suspicion to gnaw his heart. By the help of his imagination he soon persuades himself that his mate has betrayed him; in spite of the protestations of the poor thing he delivers her over to the other storks who are drawn together by his cries, and the innocent and unfortunate victim is pecked to pieces." We should like to see this cruel amusement played out once to the bitter end, and should then, but not till then, believe it.

The drawings and woodcuts are as excellent as they are numerous.

Beiträge zur Lehre von den Functionen der Nervencentren des Frosches. "Essays on the Functions of the Nerve-centres in the Frog." By. Prof. D. Fried. Goltz, of Konigsberg. pp. 130. (Berlin, Hirschwald, 1869.)

THIS little brochure, which, though small, contains the result of much work, is divided into four sections. 1. On the reflectorial excitation of the voice in frogs. 2. On the physiology of generation in the frog. 3. On the inhibitory influence which can be exerted on the reflex actions; and 4. On the seat of the mind (Seele) in frogs; beside investigations on the centre for the maintenance of equipoise, and the centre for locomotion. It may be observed that notwithstanding the experiments were all undertaken in frogs, those little martyrs to science, yet that some of the results at least have a direct bearing on the functions of the centra in the higher animals, and even on man himself. The results of his experiments in reference to the seat of the mind are at variance with those of Pflüger and others, who hold that the spinal cord participates with the brain in its possession. M. Goltz maintains, on the contrary, that the brain is the *exclusive* seat of all intellectual processes, and consequently, that a frog from which the whole encephalon has been removed, is an organism presenting only a complex series of reflex processes. The removal of the *cerebrum* alone deprives the animal of all voluntary movement, and of all those faculties which are included under the general head of consciousness; it still retains, however, certain powers of co-ordination. If the corpora quadrigemina are then removed, it no longer possesses the power of preserving the equipoise of its body or the accommodation of its movements. The corpora quadrigemina therefore, he concludes, constitute the centre for the maintenance of the equilibrium of the body. The cerebellum, on the other hand, is the centre for locomotion of the whole body.

Schriften der Naturforschenden Gesellschaft in Danzig Neue Folge, Zweiten Bandes, Zweite Heft, 1869.

THE Danzig Natural History Society publishes annually a part of its Transactions, which, although but little known in this country, often contain valuable papers. In the part for 1869, which we have just received, we find an elaborate memoir by Dr. Bail, on the epizootic fungi which affect the caterpillars injurious to forests, and it is some comfort to think, that while these vegetable parasites do nothing but mischief among the silk establishments of the south of Europe, they are regarded as serviceable in other quarters. This part also contains the continuation of M. A. Menge's valuable monograph of the Prussian spiders, of which the author has now described and figured 157 species. This memoir is indispensable to the archæologist, and is in itself a wonderful result of the most minute research—research so minute, in fact, that the author is unfortunately led to magnify the importance of slight differences, and thus to establish a great number of new genera upon very slight grounds. M. Menge also describes and figures a species of scorpion and two species of spiders from amber; each of the latter forms the type of a new genus. Dr. Bail contributes a short but interesting paper on the occurrence of androgynous flowers in monœcious and diœcious plants. Besides some minor communications on subjects connected with natural history, the part contains two memoirs which one would hardly expect to find in the Transactions of a society of naturalists, namely, a description of the construction and theory of a marine distance-measurer, and an investigation of the moon with reference to its ellipsoidal form, by M. E. Kayser, who describes himself as "Astronomer to the Natural History Society of Danzig." The former of these papers is illustrated with three folding plates.

Notes on Microscopic Crystals included in some Minerals. By Isaac Lea. From the Proceedings of the Academy of Natural Sciences of Philadelphia. Read February 16 and May 11, 1869.

IN these two papers the author gives an account of the minute crystals included in sapphire, garnets, and several other minerals, which in some cases are arranged in a number of definite planes, so as to give rise to the appearance seen in the so-called "star sapphires." The essays are illustrated by a plate, which shows the character of the crystals in a very satisfactory manner. The author is, however, not quite correct in thinking that such included crystals had not been previously described by several authors. Söchting, in his excellent work,* gives an account of some facts similar to those observed by Mr. Lea; and Messrs. Sorby and Butler, in their paper on the microscopical structure of rubies, sapphires, &c.† describe "the small plate-like crystals, often triangular in form, with an angle very acute. They are very thin, and arranged parallel to three principal planes of the sapphire," and are thus precisely like those now figured by Mr. Lea. There can be no doubt that the study of the minute crystals included in minerals often throws much light on their origin, and they play a far more important part than is often supposed, and serve to explain some of the discrepancies met with in their chemical composition.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Rotation of a Rigid Body

My previous communication about the rotating ellipsoid to this journal, has attracted the attention of M. Radau. "One touch of *Nature* makes the whole world kin." In a note addressed to me full of true dignity, this gentleman has made much more than sufficient reparation for his previous trifling act of inadvertence, and states that to his great regret he had misunderstood my meaning, in the passage of my memoir in question, and that "sa critique n'est pas fondée." I, on my part, deeply lament the unnecessary tone of acerbity in which my reference to this criticism was couched, and wish I could recall every ungracious expression which it contains. "When I spoke that, I was ill-tempered too."

I will pass over this, to me, painful topic, to say two or three words on the mode in which the rotating ellipsoid may be supposed to roll or *wobble* on a rough plane, with its centre fixed. My solution may remind the reader of Columbus's mode of supporting an egg on its point—or, rather, of a fairer mode which Columbus might have employed, and which would not have necessitated the breaking of the shell, viz., by resting the blade of a knife or rough plate on the upper end of his egg.

So, to make an ellipsoidal or spheroidal top roll, with its centre fixed—say, upon a rough horizontal plane—imagine a second horizontal plane in contact with the upper portion of its surface; then the line joining the two points of contact will pass through the centre of the top. We may conceive a slight perforation in either or each plane at its initial point of contact with the top, and a screw wire introduced through this, and inserted into a female screw in the body to be set rolling (a mode of spinning which Sir C. Wheatstone recommends as the most elegant in any case, and in this case evidently the most eligible). On withdrawing the wire with a jerk, the top may be set in motion about its centre, in such a direction as to remain in contact with the two planes, and if these be sufficiently rough the motion will eventually be reduced to one of pure rolling between them, the axis (*i.e.*, the line joining the two points of contact) continually shifting, but the centre remaining absolutely stationary: for, vertical motion this point cannot have, so long as the top continues to touch both planes, and any slight horizontal motion (if it should chance to take on such at the outset) would be checked and ultimately destroyed by the friction, which would also keep the two points of contact stationary (like the single point of contact of a wheel rolling on a rail), in each successive atom of time. Thus the motion upon the lower plane would in the end be precisely the same as if the upper plane were withdrawn, and the centre of the top kept fixed by some mechanical adjustment. If the spin were not sufficiently vigorous, after a time the rolling top might quit the upper plane, and of course sooner or later by the diminution of the *vis-viva* due to adhesion, resistance of the air, imperfection or deformation of the surfaces, and other disturbing causes, this would take place, but abstracting from these circumstances the principal axes of the spheroidal or ellipsoidal top would move precisely in place and time like the "axes of spontaneous rotation" of any free body of which the top was the "Kinematic Exponent."

I do not pretend to offer an opinion what materials for the planes and rolling body (ground glass and ebony or roughened ebonite have been suggested to me) it would be best to employ, or whether the "wobbling top" could easily be made to exhibit its evolutions. It is enough for a non-effective, unpractical man (as unfortunately I must confess to being) to have shown that there is no intrinsic impossibility in the execution of the conception.

With regard to the friction and pressure: if W be the weight of the body, F and P the friction and pressure in the case of a single plane (the values of which are set out in my memoir, pp. 764—766, "Philosophical Transactions," 1866), it may easily be proved that eventually the friction at each point of contact will be $\frac{F}{2}$, the pressure upwards at the lower point $\frac{P+W}{2}$, and downwards at the upper one $\frac{P-W}{2}$, so that if P should become equal to W the top would quit the upper plane and the experiment come to an end. At p. 766 of my memoir the factor $\sqrt{MA}$ has accidentally dropped out of the expression for P which I mention here, in case any one should feel inclined to consult the memoir in consequence of this note. Mr. Ferrers has taken up my investigations, and given more compendious expressions than mine for F and P; with the aid of these it would probably be not difficult to determine the maximum value of $\frac{F}{P}$ so as to assign the necessary degree of roughness of the confining planes, and also to ascertain under what circumstances P — W would become zero, but I do not feel sufficient interest in the question, nor have I the courage to undertake these calculations with the complicated forms of P and F contained in my memoir. Mr. Ferrers' results are contained in a memoir ordered to be printed in the "Philosophical Transactions," and will shortly appear.

In my memoir will be found an exact kinematical method of reckoning the time of rotation by Poinsot's ellipsoid when the lower surface is made to roll on one fixed plane at the same time that its upper surface is shapened off in a particular way (therein described) so as to roll upon a parallel plane which turns round a fixed axis; this upper plane is compelled to turn by the friction, and acts the part of a moveable dial in marking the time of the free body imaginarily associated with the ellipsoid. I have also shown there that the motion of any free body about a fixed centre may be regarded as compounded of a uniform motion of rotation and the motion of a disc, or, if one pleases, a pair of mutually bisecting cross-wires left to turn freely about their centre. But I fear that NATURE, used to a more succulent diet, has had as much as it can bear upon so dry a topic, and, although having more to say, deem it wiser to bring these remarks to an end.

J. J. SYLVESTER

"Dutch" or "Deutsch"

THERE is a short note in Mr. Huxley's lecture in the last number of NATURE, which I have read several times in the vain hope of finding out its meaning. Mr. Huxley speaks of "the much debated question, did the Germans of Cæsar and Tacitus speak 'Deutsch' (not 'Dutch,' *pace* Mr. Freeman) or Celtic." What has my "peace," or anybody else's peace—save, perhaps, the *Pax Romana*—to do with it?

I do not see why Mr. Huxley brings in my name. He can hardly suppose that I do not know that *Deutsch* is the German form—I can hardly suppose that he does not know that *Dutch* is the English form—of the name otherwise written *Tütsch*, *Teutonicus*, *Theotonicus*, *Theotiscus*, and endless other ways. He can hardly think that I have never opened a modern German book: I can hardly think that he has never opened an English book of the sixteenth or seventeenth century. If he has opened any such book in which matters of this kind are likely to be touched upon, he must surely know that the words *Dutch* and *Dutchman* were then used in a very wide sense. A "Dutchman" might be a native of Holland; he might be a native of Bavaria. And the division into *High Dutch* and *Low Dutch*, or *Nether Dutch*, was then perfectly well understood.

I do not know what Mr. Huxley's objection is. I use the word as one ready made, as more convenient than the Latin for *Teutonic*, and as more easily admitting the addition of the qualifying syllables *High* and *Low*. I should not use *Deutsch* in this sense for two reasons. First, it is not an English form, and I should no more, in writing English, say that certain people talked "Deutsch," than I should say that they talked "Français." Secondly, the word *Deutsch* (like the word *German*) would to most people convey the idea of one particular Teutonic tongue, while I am probably speaking of Teutonic tongues in general. Mr. Huxley's question, "Did the Germans of Cæsar and Tacitus speak *Deutsch?*" may mean either "Did they speak a Teutonic tongue of any kind?" or "Did they speak the particular Teutonic tongue which to most peoples' minds would be suggested by the words *German* or *Deutsch*, namely, the *High-Dutch?*" Which Mr. Huxley means I do not know. For my own part I believe that they spoke Dutch or Teutonic, but *Low* Dutch and not *High*.

EDWARD A. FREEMAN

Somerleaze, Wells, March 21

The American Eclipse

WILL you grant me space for a few words on my spectroscopic observations of the American eclipse, and what seem to me the inferences to be drawn from them? I make the request the more freely because I have met from time to time allusions to them in your journal, and remarks, some of which seem to require my notice, if only to express my appreciation of the considerate courtesy with which they have been treated by gentlemen who differ very widely from my conclusions.

1. Regarding the use of the spectroscope in the observation of "contacts."

I think the language of Mr. Stone and some others in a discussion of the matter at a meeting of the Astronomical Society, reported in your columns in December last, implies a misapprehension. What I have proposed (and executed in the case of the moon) is to use the extinction of the bright C line in the spectrum of the chromosphere as a criterion of contact with the limb of the *photosphere*, not with the upper surface of the chromosphere, which would, of course, as indicated by Mr. Stone, be a perfectly worthless observation.

The advantage of the method lies in this, that it furnishes an easily apprehended phenomenon to be watched for, and gives every advantage of preparation to the observer.

With an instrument of moderate dispersive power, the slit must be normal to the sun's limb, and an accurate knowledge of the expected point of contact is required: with a more powerful instrument the slit can be placed tangential, opened somewhat widely, and thus all difficulty on this score avoided, as I have pointed out in my report. I see by a paper of Mr. Proctor's in the December number of the "Monthly Notices," that Mr. Huggins suggests the same plan.

Perhaps I may remark in passing that the idea of using the spectroscope in this manner to observe the contact of the moon with the sun's disc, was conceived before the event, so that the observation was made deliberately and by pre-arrangement—not at all accidentally, as would rather seem to be implied by one of the opening sentences in the article of Mr. Proctor's above referred to. To M. Faye, however, belongs whatever merit there may be in the method, for he proposed essentially the same thing in January 1869. But I knew nothing of this at the time of the eclipse, nor indeed till long after.

2. The self-luminosity of the Corona.

It is not impossible that the so-called corona may be complex. Some portion of its radiance may *perhaps* originate in our own atmosphere, although I do not yet find myself able to accord with the conclusions of Dr. Gould and Mr. Lockyer in this respect, and am strongly disposed to believe that the *whole* phenomenon is purely solar.

This much appears certain, however, that there exists outside of the chromosphere properly so called (*i.e.*, the envelope of *red hydrogen*), and as distinct from *it*, as it is from the *photosphere*, an immense atmosphere of self-luminous substance, extending to a distance of from 5′ to 8′ from the sun's surface, and probably much further in places—phosphorescent dust or fog in a glowing gas.

In support of this idea I adduce the photograph of Mr. Whipple, taken at Shelbyville, Ky., with an exposure of 40^s. On this, the *photolytic corona* (if I may use the expression to distinguish it from the *visible corona*, whose points of maximum brilliance were, according to Dr. Gould, entirely different), reaches a height of 6′. Prof. Harkness observed the 1474 line in the spectrum of the corona at a distance of nearly 5′ from the sun's limb, and not near to any prominence. I do not know the precise elevation at which I saw it, but it was not less than 3′ or 4′.

Indirectly, also, the idea is confirmed by the spectroscopic observation of Prof. Pickering, who used a single prism instrument, with the slit simply directed towards the sun, not attached to a telescope. He saw only three or four lines, the brightest in the green near E. Now, since this line, when observed by throwing a large image of the sun on the slit, is very faint as compared with C, D_3, and F, its intensity, as seen by him, can only be accounted for by supposing that the luminous area from which it was derived far exceeded that of the chromosphere and prominences.

I have noticed also that some of the observers of the Indian eclipse (Rayet and Pogson) speak of the intensity of the green line. Did they observe in the same manner as Prof. Pickering?

I need hardly add that Prof. Pickering's observation of the non-polarisation of the corona concurs with what has been said.

As to the faint continuous spectrum, I am sure that the reported absence of dark lines was not the result of insufficient observation.

I could not have failed to see D, E, *b*, 1961, F and G had they existed, for in a spectrum of similar brightness formed by a light from a cloud, not only these but many other lines are visible in my instrument. Now, the absence of some of these might, perhaps, be accounted for on the ingenious hypothesis proposed by Mr. Lockyer, and reported in your No. of February 3; but this would not apply to D, E, or G.*

But if we admit the existence of faintly luminous solid or foggy matter near the sun, either meteoric or arising from the cloudy condensation of a non-permanent gas, the whole is at once easy of comprehension.

3. The Auroral Theory of the Corona.

The objection pressed by Mr. Lockyer that the bright line 1474 is only occasionally visible, is, I think, unfounded. At any rate I have never failed to see it myself when looked for, and very seldom to make it visible to others when I have wished to exhibit to them. It is faint, and, like a difficult microscopic object, requires management to bring it out with five prisms; but by placing the slit tangential to the sun's disc, and giving the instrument a slight jar, it is seen to flash out as the limb passes off the slit. It is worth noting too, that it is often especially plain at portions of the limb where the chromosphere is unusually shallow and faint.

But while I think it probable that this line coincides with the aurora line reported by Prof. Winlock at 1550 of Mr. Huggins' scale, I am by no means sure of it. I understand its assigned position rested upon a single observation with a chemical spectroscope, and the probable error of such a determination cannot well be less than ten divisions of Kirchhoff's scale. I have naturally made many attempts to determine its position for myself, but have never seen it except thrice, and then not long enough at a time to complete a measurement. I am only sure that its position lies between 1460 and 1490 of Kirchhoff.

For this reason, although I do not at all abandon the hypothesis, which appears to have other elements of probability in the general appearance of the corona, the necessity of intense electrical disturbances in the solar atmosphere as the result of the powerful vertical currents known to exist there, as well as the curious responsiveness of our terrestrial magnets to solar storms; yet I do not feel in a position to urge it strongly, but rather await developments.

As to the substance which causes this line, I observe that Father Secchi, in a recent communication to the French Academy, is disposed to think it hydrogen; while Mr. Lockyer still believes it to be iron. I am in hopes that experiments now in progress may throw some light on the subject.

May I suggest, in closing this long communication, that it seems to me that valuable observations might be made at the Eclipse of next December, by fitting up telescopes with a ground glass sliding screen, upon which an image of the corona two or three inches in diameter should be thrown; the ground glass having the roughened side next the observer, so that he could sketch upon it with a lead pencil the outlines of the image, the glass being made long enough to allow of several such sketches.

The comparison of a series of such outlines would decide the question of changes in the coronal streamers, as the sketches, being simple tracings, could not but be accurate in their indications of position.

Dartmouth College, N.H., March 1 C. A. YOUNG

P.S.—I think that the position of the line reported by me as 2602 should have been 2581·5, an error of one revolution of the micrometer screw having been made. At any rate on two occasions since the eclipse I have seen a bright line in the latter position, and I have never been able to find one in the former.

Professor Huxley's Address

MAY I be permitted to advert to one view in connection with that part of Professor Huxley's admirable address to the Geological Society, which treats of distributional provinces inhabited by the terrestrial vertebrata, and the subsequent incorporation of these provinces into one another at different periods.

The view to which I refer is that wherein Mr. Huxley attributes the origin of the eocene types to their evolution *during the Mesozoic epoch* in some province which then was isolated from the European area, and their introduction by geographical changes into the European area in the interval between the Mesozoic and Tertiary epochs.

Having brought forward ten years ago the view that the Australian province was an actual and isolated remnant of the Triassic continent and of its mammalian fauna; and that the geographical distribution of organised beings pointed to the inference that other portions of the land tracts of the Mesozoic period, with their more ancient faunæ, had at different times

* Why not? [ED.]

become incorporated with the post-cretaceous continent,* it is with much satisfaction that I find views for the most part so similar developed by Professor Huxley with the ability which marks all his work. Nevertheless, I venture to submit that the view I then advanced as to the period of the origin of the Eocene types is more in accordance with the facts, as far as we know them, than the hypothesis of their origin in a detached province *during* the Mesozoic period.

The view I advanced was that great changes in the distribution of the continents and seas took place at the close of the Palæozoic, and again at the close of the Mesozoic epoch; and so far I am at one with Professor Huxley: but I inferred that the geographical changes taking place at the close of the Mesozoic epoch were accompanied by the formation of a continent extending over all the *geologically known* parts of the globe, whose endurance was so prolonged as to have afforded the necessary time for the evolution upon it of the Eocene types.

In support of this inference I dwelt upon the entire disappearance of the orders *Pterosauria*, *Enaliosauria*, and *Dinosauria* among vertebrates, and of the *Ammonitidæ* among invertebrates; as well as upon the great extinction that took place in various other forms of life. Such a process as the one suggested by Mr. Huxley would lead us to look in Eocene strata for an intermingling of these distantly evolved types with forms belonging to the several orders just named; however much these forms might in their specific, or even in their generic characters, have been changed during the interval in which these distantly evolved types were introduced. But instead of this we find an absolute disappearance of several important orders of life, of which, from their *habitat*, some—especially the *Pterosauria*—would seem to have been independent of geographical changes simply.

Mr. Huxley intimates that he is led to his view by arguments which he had previously used to demonstrate the necessity of the existence of all the Eocene types in some period antecedent to the Eocene; but may we not suppose that the interval thus marked by the disappearance of so many great orders was vast enough even for this evolution? Indeed so much did this great extinction weigh upon me that even the intervention of a vast lapse of time seemed scarcely sufficient; and I felt driven to suppose that these geographical changes in some degree altered the general conditions under which life had previously existed; and that this alteration, while stimulating evolution on the newly-formed continent, contributed to the great extinction which marks the intra-cretaceous and Tertiary epoch.

Subtle as are the causes which have brought into existence the various types of being, those which have produced their extinction are not less so; though they have not yet received that attention which has been directed to the origin of species. I feel how crude were the suggestions I offered in 1860 to explain this great extinction, and how wide a field of conjecture upon the subject is left open; for these orders of life were not only various in their *habitat*, but equally various in their food. We may imagine the extinction of a species to take place from failure of its food, from destruction by enemies, or—and I think this may be a cause more potent than any other, especially with forms possessing great fecundity—by a failure of the reproductive function; just as among men families diminish and eventually leave no descendants. Be the causes, however, what they may, this great extinction requires us, I submit, to suppose the occurrence of an interval of time as great, and accompanied by changes of conditions as complete, as any that we can urge as necessary for the evolution of the Eocene types. Moreover, the cretaceous period itself, whose terrestrial fauna is as yet unknown, may, so far as we yet know to the contrary, have witnessed in the European area the commencement of, or even some progress in, the evolution of the Eocene types.

Brentwood, March 10 SEARLES V. WOOD, Jun.

* "On the probable events which succeeded the close of the Cretaceous period;" read before the Geological Society on February 1st, 1860. The publication of the paper, beyond a brief abstract, having been denied by the Council, the desideratum was kindly supplied by Dr. Francis; and the paper in extenso is given in the *Philosophical Magazine* of March, April, and May, 1862; the title having been changed to "The form and distribution of the Land Tracts during the Secondary and Tertiary periods, &c."

Transactions of the Royal Society of Edinburgh

WITH reference to G.'s letter in the last number of NATURE, I have merely to observe that (as you will see by the accompanying list) the Transactions of the Royal Society of Edinburgh are *regularly* sent to no less than twenty-three different societies, institutions, or museums in London alone—besides being sent to many Honorary and Ordinary Fellows residing there. As regards the special case of the British Museum, I have in my possession at this moment their acknowledgments of receipt of the successive parts of our Transactions up to March 1869, and expect immediately to hear that they have received our last published Part. J. H. BALFOUR, *Sec. R. S. Edin.*

Euclid as a Text-Book

"THE first four books of Euclid: or the principal properties of triangles, and of squares and other parallelograms treated geometrically: the principal properties of the circle and its inscribed and circumscribed figures treated geometrically." Such is the wording of the programme put forth by the University of London, of the Mathematical portion of the examination for matriculation candidates. Whether the papers have ever been drawn up in accordance with it I cannot say, but certainly my experience for the last four or five years has led me to believe that the alternative side has, of late, at least, been altogether ignored.

The slightest inspection of recent papers will show that they are constructed on the Euclidean type, and so long as Euclid was generally taught in schools, I think rightly so. But that such a course should now be persisted in (with such latitude as the programme provides) is hard upon those establishments which have taken up the modern views of the subject, such as those so ably advocated by Professor Hirst,* and Mr. J. M. Wilson of Rugby.† It can hardly be thought that so advanced an examining body as the London University will continue to act as an obstructive—for non-encouragement is almost tantamount to tabooing the subject; and the practical result of persistence, I fear, will be this, that the course pursued will press unfairly upon those schools in which (as in University College School, where Wright's Geometry is now the text-book) Euclid has been almost ‡ discarded. Boys are required to study in their school work this modern geometry, founded on French mathematical works; and yet, seeing what value is set upon the same in the examination papers I am discussing, feel themselves constrained to read Euclid that their prospects of good places may be enhanced.

I am disposed to believe that "something will shortly be done," but the reform, though it ought rightly to commence here, ought not to stop here. Every examining body, if a fair field is to be given to the students of modern geometry, should put forth a scheme similar to that which heads my letter, and not merely put it forth "as a sop to Cerberus," but act upon it and let it be a reality.

University College School R. TUCKER

MECHANICAL PROPERTIES OF ICE, AND THEIR RELATION TO GLACIER MOTION

A FEW weeks ago I prepared for the February number of the *Alpine Journal* a review of the contributions made by the Rev. Canon Moseley to the theory of glacier motion, which have appeared at various times during the last fifteen years in the *Proceedings of the Royal Society* and the *Philosophical Magazine.* Some new facts having come to my knowledge since the publication of my paper, I venture to recur to the subject, and to invite discussion upon those memoirs of Canon Moseley in which he endeavours to prove that the descent of glaciers by their weight alone is a mechanical impossibility.§ The arguments he advances in support of this conclusion may be epitomised as follows:—

If a transverse section of a glacier were to be made, the ice would be found to be moving differently at every point of it. The velocity is greater at the surface than deeper down, at the centre of the surface than the edges. There is a constant displacement of the particles of ice over one another, and alongside one another, to which is opposed the resistance known as *shearing force.* By the property of ice called regelation, where a surface so sheared is

* In his college lectures, and lectures to ladies at St. George's Hall, &c.

† "Euclid as a text-book of Elementary Geometry" (read before the London Mathematical Society, and printed in the *Educational Times*, Sept. 1868), and in his "Elementary Geometry."

‡ *Almost.* In consequence of pressure from without, arising from the circumstances with which my letter deals, Euclid is again read in one class.

§ Proceedings of the Royal Society, Jan. 7, 1869. Philos. Mag., May 1869. Philos. Mag., Jan. 1870.

brought into contact with a similar surface, it unites with it so as to form one continuous mass. Between the resistance to shearing and the force which tends to bring the glacier down there must be a mechanical relation, so that if the shearing resistance were greater, the force would be insufficient to cause the descent. By a series of experiments upon cylinders of ice inserted in a cylindrical hole bored through two pieces of wood perpendicularly to the surface along which the one was made to slide upon the other, it was found that the force necessary to part the ice along the sliding surface varied from 75 to 119 lbs. per square inch. Canon Moseley has calculated that for the Mer de Glace to descend by its own weight, its shear per square inch cannot exceed 1·3193 lbs., and that to produce the actual motion with a shear of 75 lbs. per square inch, a force in aid of the weight and thirty-four times as great must be called into existence, and applied in the direction of motion. For such a force to be produced by the weight of the glacier alone the density of ice would require to be increased more than 400 times.

In this reasoning Canon Moseley has neglected, as it appears to me, the capability of ice when in a state of deliquescence to slide along a surface of small inclination, as demonstrated by the well-known experiment of William Hopkins. It is, however, not the motion of a block of ice as a whole, but the differential motions of its particles that we have now to consider. It occurred to me that the Canon's arguments upon this branch of the question might be put to an easy practical test by subjecting a block of ice to a strain produced by its own gravitation, and observing its behaviour under this condition, and I was fortunate in obtaining the assistance of my friend Mr. A. F. Osler, F.R.S., in carrying out the experiment.

A plank of ice 6 inches in width and $2\frac{3}{8}$ inches in thickness was sawn from the frozen surface of a pond, and supported at each end by bearers exactly six feet apart. From the moment it was placed in position it began to sink and continued to do so until it touched the surface over which it was supported, drawing the bearers with it, so as to make their upper ends converge. At its lowest point it appeared bent at a sharp angle, and it was rigid in its altered form. The total deflection was 7 inches, which had been effected in about as many hours under the influence of a thaw, during which the plank diminished slightly in width and thickness. On observing the under surface of the plank near the point of flexure, I noticed a number of very minute fissures extending a short distance into the ice, but they certainly were not sufficient to account for the flexure of the plank.

The question at once suggested itself, was the change of form in the ice plank due to fracture and regelation? I did not think it was, but the experiment was not decisive. Some weeks afterwards an opportunity occurred of trying it under other conditions. During the last frost we cut out another ice-plank. Its length was 6 feet $9\frac{1}{2}$ inches, its width varied from $6\frac{1}{4}$ to $6\frac{1}{2}$ inches, and its thickness was $1\frac{7}{8}$ inches. Two large bricks, of a width exceeding that of the plank, were set up on end, on a horizontal surface, exactly 6 feet apart, and the plank was laid upon them at five p.m. on the 12th of February. At 3·15 p.m. on the 13th it was continuously curved from end to end, so that it only rested on the edges of the bearers, and the middle point of its upper surface was deflected $1\frac{3}{4}$ inches below the line joining its two extremities. The temperature was 26° F. The curved plank was perfectly rigid, as was proved by taking it off the bearers and inverting it. I examined it again on the two subsequent days with the following results:—

Feb. 14th, 9.30 A.M. Temp. 29° 5 F.
Deflection of upper surface below chord . $2\frac{3}{8}$ inches
,, of lower surface below its original horizontal position . . $2\frac{1}{4}$,,

Feb. 15th, 9.30 A.M. Temp. 30° 0 F.
Deflection of upper surface below chord . $3\frac{5}{8}$ inches
,, of lower surface below its original horizontal position . . $3\frac{1}{8}$,,

During the whole of this interval, in which the temperature never rose above the freezing point, there was no indication of fracture in the plank, nor did the optical continuity of the ice suffer the slightest interruption. On the 15th it began to thaw, and the bearers having become frozen to the ground, and the plank to the bearers, the suspended portion was unable to yield to the strain produced by its gravitation; and when I re-visited the plank on the afternoon of the 15th, it was broken into half-a-dozen pieces.

These experiments were very rough and imperfect; we intend to renew them on some future occasion, and to conduct them with much greater care and proper mechanical appliances, when we hope to be able to bend an ice-plank double, without destroying its continuity.

The following conclusions may fairly be drawn from them:—

1.—A mass of ice may change its form under strains produced by the gravitation of its particles, without becoming fractured, and without returning to its original form when the strain ceases.

2.—The change of form takes place at temperatures both below and above the freezing point, but is greatly accelerated in the latter case.

I shall not now attempt to discuss the nature of the molecular displacements to which the change of form is due. Their occurrence is indisputable; whether or not they are to be dignified by the name of shearing is a mere verbal question of little moment. In a very able paper in the *Philosophical Magazine* for March 1869, Mr. James Croll adduces good reasons for believing that when a mass of ice has a deliquescent surface, its molecules may experience repeated momentary losses of their shearing force. While, therefore, he admits the conclusiveness of Canon Moseley's reasonings for temperatures below freezing, he conceives that ice at all higher temperatures may shear by its own gravitation. It is evident that the former concession in Canon Moseley's favour cannot now be maintained, and that the point to which our experimental researches should be directed is not what amount of force will suddenly rend asunder the molecules of ice beyond the sphere of their mutual attractions, but what amount of force will produce molecular displacement within that sphere, with time allowed for its operation.

If we conceive an ice-plank, instead of being placed horizontally between bearers, to be laid with its narrowest face upon a plane of small inclination, with its upper edge horizontal, and its ends confined between vertical walls converging in the direction of motion, with its under surface deliquescent, so that friction would almost be annihilated; and if we further imagine the diminution of gravity due to resolution along the plane to be compensated by increasing the length or diminishing the thickness of the plank, the plank would alter its form in a way presenting a striking resemblance to the actual movement of a glacier. Its central portions would move more rapidly than its lateral ones; its surface more rapidly than its base; and when the strain upon its particles exceeded their cohesive power, it would fracture obliquely to the axis of the channel.

If the conclusions drawn from the experiments above described are legitimate, plasticity must be admitted by the side of sliding, and fracture and regelation as one of the constituent elements of the theory of glacier motion, and a more important place in that theory must be assigned to the views of the late Principal Forbes than has for some years been conceded to them.

WM. MATHEWS, Jun.

THE INDIAN TOTAL ECLIPSE

THE 37th volume of the memoirs of the Royal Astronomical Society, containing Major Tennant's report on the total eclipse of the sun of August 17th and 18th, 1868, has just been issued, and we are enabled, by the courtesy of the Council of the Society, to lay an illustrated notice of it before our readers.

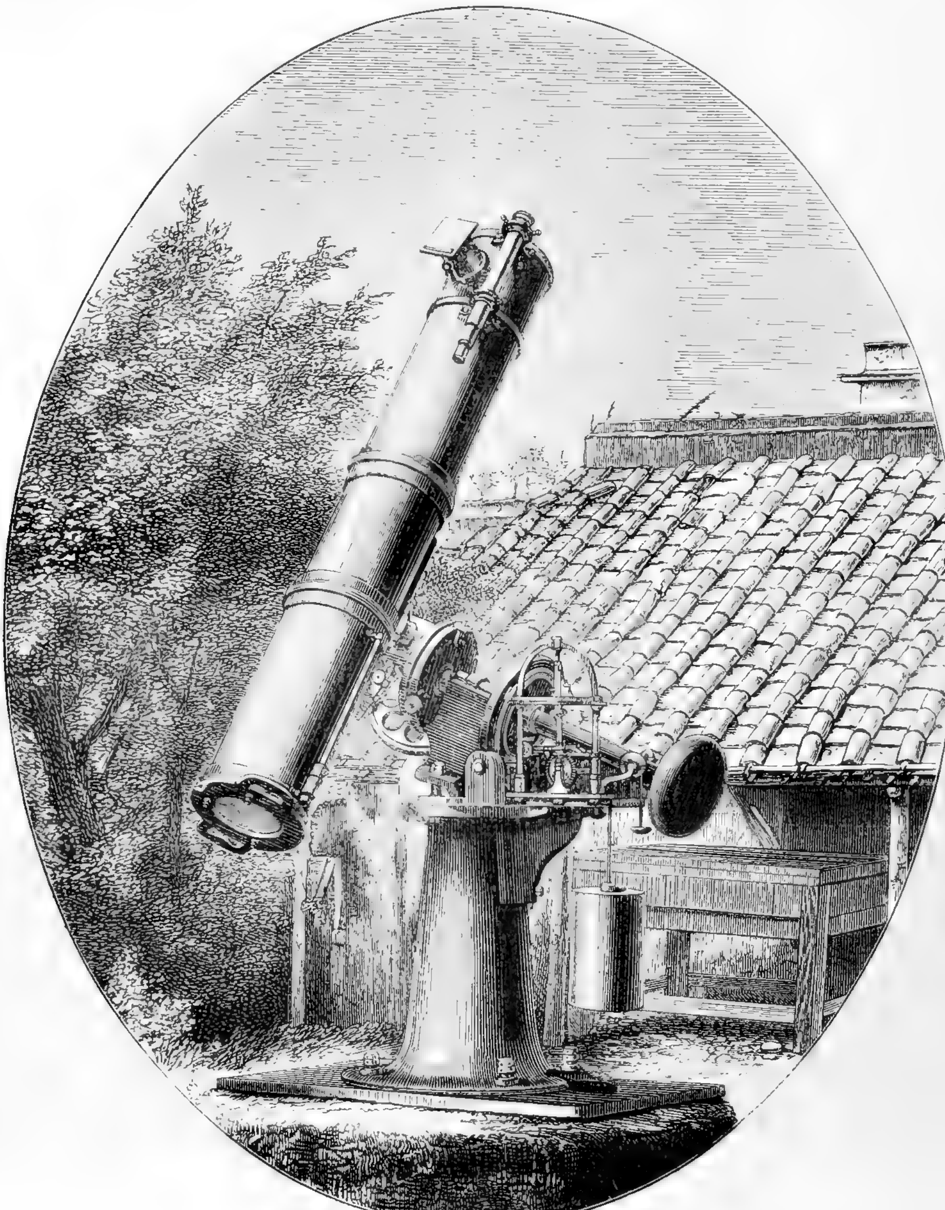

FIG. 1.—THE SILVER GLASS EQUATOREAL

The Indian eclipse was a notable one in the history of astronomy, for as the eclipse of 1860 endorsed the notion that the prominences were solar, so that of 1868 set at rest the gaseous nature of the red flames or red protuberances—so that we have two successive eclipses "settling" two important problems.

Thanks to the care of Mr. De la Rue, Major Tennant was fully provided with the means of photographing the eclipse as well as of determining by means of the spectroscope the nature of the spectrum of the prominences and of the corona. In our notice we may pass over the preface and the narrative of operations which includes the astronomical determination of the position of the observatory, and come to the spectroscopic observations.

We first have the spectrum of the corona. Major Tennant writes:—

Directly I saw the whole moon in the finder I set the cross-wires immediately outside its upper limb. By the time I got to the spectroscope, the cloudy range, seen in the photographs, had vanished from the slit, and I saw a very faint continuous spectrum. Thinking that want of light prevented my seeing the bright lines, which I had fully expected to see in the lower strata of the corona, I opened the jaws of the slit, and repeatedly adjusted by the finder, but without effect. *What I saw was undoubtedly a continuous spectrum, and I saw no lines.** There may have been dark lines, of course, but with so faint a spectrum and the jaws of the slit wide apart, they might escape notice.

We next have the spectrum of the Great Horn :—

One line in the red was so beautiful that it needed an effort to turn my attention to anything else; there was a line in the orange not so well defined, and one in the green which seemed multiple (it must be remembered that I had not time to adjust the jaws of the slit accurately, and that the brilliancy of these lines made them broader by irradiation); beyond, I saw a line just defined, which, as will be seen from the measures before given, must have been near to F, and still further off in the blue I saw a hazy light probably beyond G.

. . . .

The red and yellow lines were evidently C and D, the reading of the green line coincides with that of the brightest line in *b*, instead of the mean of the three, which I read as a verification; the line near to F was in all probability F itself; E was certainly not seen by me. The line in the blue it is useless from my data to speculate upon, I must hope that some one else has identified it.

* In the instructions for Lieut. Herschel his attention was first drawn to the protuberances. I therefore had resolved to attend first to the corona, lest each of us should have only the same partial tale.

It is pleasing to point out how very nearly Major Tennant's observations, as now given, approximate to the true state of the case, which we can now determine any day that the sun shines. He must be entirely congratulated on the degree of success of his spectroscopic observations—observations made, according to his report, under difficulties which he ought not to have encountered. Major Tennant's evidence in favour of the continuous spectrum of the corona has been entirely confirmed by the observations since made in America.

The photographic results we may introduce by a woodcut of the observatory and of the instrument, with speculum of nine inches aperture, mounted by Mr. Browning, with which the photographs were taken.

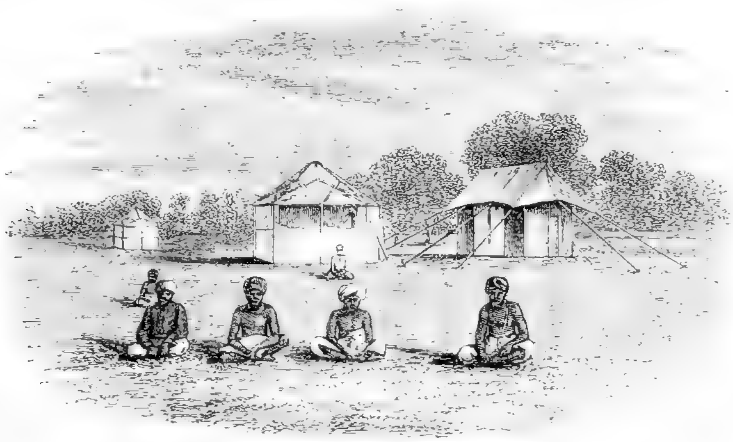

FIG. 2.—OBSERVATORY TENTS

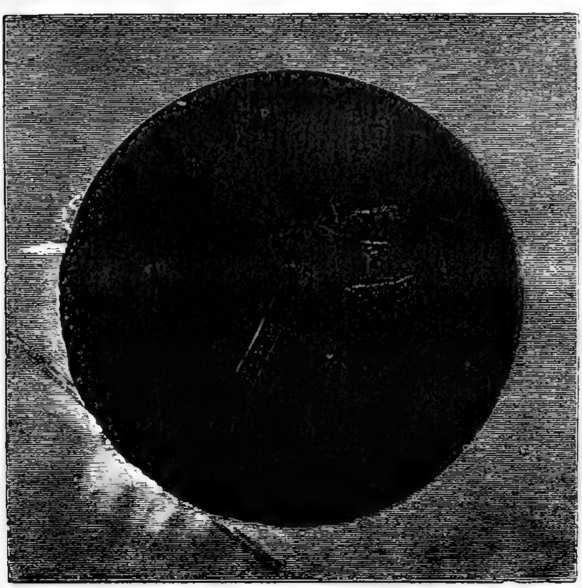

FIG. 3.—ONE OF THE FIRST PHOTOGRAPHS, SHOWING THE GREAT HORN

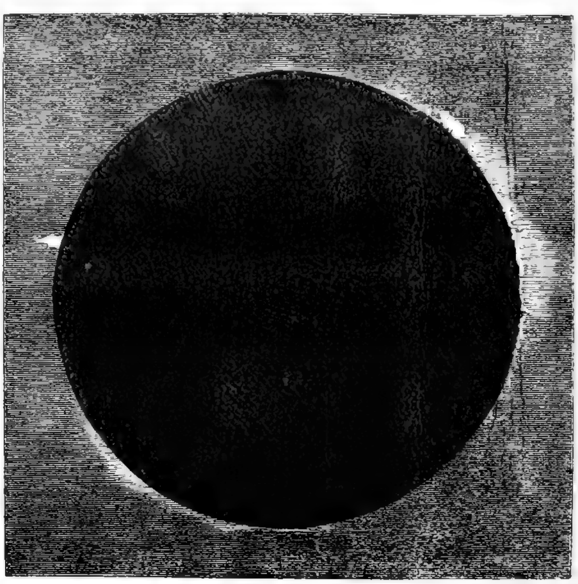

FIG. 4.—THE LAST PHOTOGRAPH TAKEN, SHOWING THE ANIMAL-LIKE PROMINENCE AND THE ECLIPSE OF THE GREAT HORN

The most notable phenomenon visible during the Indian eclipse was the Great Horn visible in Fig. 3, the structure of which was extremely curious. Below it in the drawing we have a part of the chromosphere, including a "flaring," which has been since called a "radiance" by the American astronomers. Fig. 4 was the last photograph taken, and here it is seen that the Great Horn is nearly eclipsed, and that the chromosphere on the opposite side of the sun is now exposed, including a strange animal-like form, which much struck the observers. An examination into the structure of the Great Horn is not the least interesting part of the report.

Major Tennant thus sums up his results :—

First.—The corona is the atmosphere of the sun not self-luminous, but shining by reflected light. It is evidenced both by the spectroscope and polariscope that this is the case, but there is one reservation to be made. The polariscope has shown clearly that the light of the brightest part of the corona is mainly reflected ; but, looking to the flare which is seen in photographs No. 2 and 3, it seems impossible to doubt that in those places there must have been some inherent luminosity in the corona ; unless indeed we consider the flare as a modified form of protuberance. It is, I think, now certain that luminous gas issues from what is more strictly the sun, and I apprehend this flare to be some of this.

Secondly.—The Great Horn certainly was composed of incandescent vapours, and probably all the brilliant protuberances are the same. In the Great Horn these vapours were hydrogen, sodium, and magnesium. It seems to me perfectly certain that the ignited hydrogen issued from the sun itself, and that it carried up with it the light vapours of sodium and magnesium far above the level at which they would naturally lie ; hydrogen naturally would be the very highest of the gaseous vapours, and consequently the coolest ; if, however, it were set free at the surface of the sun it would be intensely hot, and seek, with great violence, to ascend, in which process, if there be a stratum of heated vapours, such as is usually believed to exist round the sun, the hydrogen would partly displace and carry up these vapours, and the lighter would be taken in preference. In fact, in this case it has carried the two lightest, and that of iron, which is so much heavier (I think we may presume this from the absence of the line corresponding to E), was either displaced or dropped sooner than the height at which I observed. Photograph No. 1 shows that there were two jets of vapour concerned in forming this Horn. One, the largest and most northerly, is seen nearly perpendicularly to the limb, and seems also to have been the most luminous ; the other issues about 20,000* miles towards the south, and at an angle. They met at a height of some 16,000* miles, and the result was the rapid vorticose motion, which is evidenced in all the photographs as having existed in the upper portion. I believe I have the good fortune to be the first person to recognise such a phenomenon.

. . . .

I think that gases or vapours issuing quietly from the solar surface would tend locally to raise the superincumbent ignited vapours. In places where they were most abundantly given out the elevation would be greatest, everywhere the gas would leak through in streams, producing occasionally such phenomena as the flare I have spoken of in Nos. 2 and 3. For a time the ignited vapour might, I think, form, as it were, a case for the light included gas, which would be to all appearance inflated like the animal figure in No. 6. Soon, however, the slightly coherent casing would be burst and the gaseous contents would issue freely ; the heavier vapours would, of course, to some extent be carried off by the gas, but would mainly settle down in small masses. Such, I think, is the state depicted in the southern protuberance of No. 1.

I would now draw attention to Plate No. 1, and the glare and luminous stratum. If that glare be from sunlight, it must, I think, be acknowledged that the remaining ray was but small. The luminous nearly even stratum then is not the sun ; but it is intensely bright, so much so, that nowhere is it lost in the solar glare. Its height is but small (I estimate it at 7,200 miles), and I believe it to be the mass of heavy luminous vapours, to whose elective absorption we owe the Fraunhofer lines in the solar spectrum. At the north end of this stratum near the Great Horn, it is broken into beads of light ; † and I am disposed to think these are the veritable Baily's beads, of which I have always felt that the description would be difficult to apply to sunlight ; I mean the statement which has been made of the light being silvery, &c. If these beads are really phenomena of the absorbing stratum, one can well understand the use of such terms.

* These dimensions refer to the projections on a plane perpendicular to the visual ray.

† This is the same place where Captain Branfill saw beads.

In an addendum, in which the author's theory is attempted to be maintained, Major Tennant refers to the work which has been done in this country between the eclipse and the issue of the report. He considers that the sun is surrounded by an atmosphere sufficiently dense to reflect the solar light, but it is not explained why a continuous spectrum and not the solar spectrum is actually reflected; and that the hydrogen is enveloped in a denser atmosphere, resisting its diffusion and expansion, but why the spectrum of this atmosphere is so simple is not explained.

The author concludes by acknowledging the services rendered by Mr. De la Rue in the preparation of the report.

FALL OF A METEORITE

THE Director of the Meteorological Office has forwarded the following extract from a letter from M. Coumbary, Director of the Imperial Meteorological Observatory at Constantinople for publication :—

Constantinople, 9 mars, 1870

Mon cher Monsieur,—Je saisis l'occasion qui m'est offerte pour vous transmettre la communication que vient de nous faire M. Carabella, Directeur des Affaires Etrangères du Vilayet de Tripoli de Barbaru.

" Tripoli, 2 février, 1870

" Le Mutasserif de Mourzouk (Fezzan), latitude 26° N., longitude 12° E. de Paris, nous fait savoir que vers le 25 décembre, 1869, il est tombé à l'est de la ville, vers le soir, un immense globe de feu, mésurant un mètre à peu près de diamètre, et qu'au moment où il a touché terre il s'en est détaché de fortes étincelles qui, en se produisant, claquaient comme des coups de pistolet, et exhalaient une odeur que l'on n'a pas specifiée. Cet aërolithe est tombé à peu de distance d'un groupe de plusieurs arabes, parmi lesquels se trouvait le Chiok-el-Veled de Mourzouk. Ceux-ci en ont été tellement éffrayés qu'ils ont immédiatement déchargé leurs fusils sur ce monstre incompréhensible. Son Excellence Ali Riza Pacha a écrit à Mourzouk pour faire transporter ici l'aërolithe ; au cas probable où il soit trop pesant on le mettra en pièces ; nous vous enverrons tout cela. Il y a un mois de voyage d'ici à Mourzouk. Ce n'est donc que dans deux mois à peu près que nous pourrons vous faire cette expédition. S'il peut vous être de quelque intérêt de le savoir, je vous dirai que quelques voyageurs du Waddad que j'interrogeais m'ont dit que le Sultan du Waddad et tous les grands personnages de sa cour ont des poignards, des sabres et des lances faits avec du fer tombé du ciel, et qu'il en tombe de grandes quantités dans ce pays-là. (Sd.) " L. CARABELLA "

Je crois devoir vous informer qu'au reçu de cette lettre et à la suite des démarches nécessaires, S.A. le Grand Vizir a bien voulu faire donner ordre immédiatement par télégraphe à Tripoli, pour que l'on prenne les mesures nécessaires afin que ce météorite nous parvienne intact.—Recevez, cher monsieur, &c.,

(Sd.) ARISTIDE COUMBARY

NOTES

ON the 5th of March died at Vienna, Joseph Redtenbacher, Professor of Chemistry at the University. He was born in 1810, and studied under Eichig, conjointly with whom he published a determination of the atomic weight of carbon, and several other memoirs. His principal merit consists in the discovery of acrolein and acrylic acid. Most of his papers were published between 1839 and 1848. With his death chemistry in Austria passes entirely into younger hands ; his colleague, Professor Schröber, the discoverer of amorphous phosphorus, having lately been nominated Master of the Mint, and replaced in his chair by Illasiwetz. The succession of Redtenbacher will be divided into two parts, and the building of a new laboratory on the largest scale will open a vast field to the activity of his successors.

THE African traveller, Dr. Nachtigal, writing from Mursuk to the *Cologne Gazette*, on the 29th January last, gives some further particulars relative to the murder of Miss Tinné. He says that Sultan Omur, of Bornu, has sent a *meheri* (courier) to Mursuk, in order to make inquiries respecting the murder. The deceased lady's effects and servants have at length been despatched to Tripoli, though the former have not yet arrived. Yehenouchen, the Tuareg chief, has written to Europe, disclaiming all responsibility for the murder, as he had not promised his protection to Miss Tinné, or urged her to undertake the journey to Rhat. He is ninety years old, says Dr. Nachtigal, and has a great reputation for uprightness in his own country, but on the other hand, it is a fact, that his own nephew, Hadji el Schich, who attacked the unfortunate lady and her caravan, and murdered her after receiving her presents and other marks of friendship, is still living with Yehenouchen, and that the latter had directed the Marabout Hadji Ahmed Bu-Slah, who witnessed the murder without attempting to prevent it, either by word or deed, to provide Miss Tinné with an escort to Rhat.

THE chair of chemistry at Königsberg has been accepted by Dr. Gräbe of Leipzig, known through his papers on chinone and alizarin.

WE regret to announce that Professor Magnus of Berlin has been suffering for several months from a painful disease, which will, most likely, oblige him to interrupt his lectures for some time to come.

WE learn from the *Journal of the Society of Arts* that by the death of Mr. William Gibbs, which took place on the 28th ult., the South Kensington Museum acquires the collection of Roman and Anglo-Saxon antiquities collected by him.

MISS GARRETT has been admitted as a member of the medical staff of the East London Hospital for children, and was appointed one of the physicians on Wednesday last. This is the first hospital in Great Britain which has recognised in this manner the female medical movement.

IN the *Monthly Microscopical Journal* for March is an obituary notice by Mr. Joseph Lister, F.R.S., Professor of Clinical Surgery in the University of Edinburgh, of his father, the late Mr. J. J. Lister, F.R.S., to whom science is so much indebted for improvements in the microscope.

THERE is a project for the establishment of a Scientific College at Perth, intended to combine, on a small scale, the advantages of the *Ecole des hautes Etudes* and *Ecole Normale Supérieure* of Paris.

THE thirty-seventh session of the *Congrès Scientifique de France* will be held at Moulins in August next.

THE *Society of Arts Journal* reports that an International Exhibition of Agricultural Machines will be held at Arnheim, in June, July, and August.

THE *Scientific American* calls attention to an excellent improvement applied to the passenger car of the Beach Pneumatic Transit Company. The car, in size, is about the same as an ordinary street car, and a single zircon light illuminates its interior with brilliancy. Two small cylinders of compressed oxygen and hydrogen are carried on the car, from which pipes extend to a small burner that supports a piece of zircon, not more than a quarter of an inch long and one-eighth of an inch in diameter. Against this little piece of zircon the two gases impinge, and heat it so intensely as to make it glow with a clear and steady light. Those who fancy that underground railway riding in New York is likely to be a dark and dismal affair will receive new impressions on the subject when they enter the premises connected with the Broadway tunnel. One of the great advantages of the zircon light is that it burns like any other light without requiring adjustment. The light carried on the car before mentioned, burns steadily for seven hours without being touched. The zircon pencil lasts for three months, and is, in effect, the wick of the light.

THE annual meeting of the Cotteswold Naturalists' Field Club was held at Gloucester on Feb. 23rd. It was stated that the forthcoming volume of the "Transactions" would contain a most valuable and elaborate paper by Mr. Lucy, F.G.S., which attempts to unravel the intricate history of the distribution of the erratic boulders, boulder drift, quaternary gravels, &c., of the Severn valley, over a given area; a contribution of the highest value to science, and one full of facts of the greatest importance, in elucidating the old physical geography and geology of the Severn valley since the close of the Pliocene epoch. The Transactions would also contain an admirable paper from the pen of Dr. Wright, F.R.S.E., on the "Correlation of the Jurassic beds of France and Switzerland with those of Gloucestershire and Wilts." These papers, both splendidly illustrated by maps and woodcuts, many of which were exhibited to the meeting, were highly eulogised by the president, and referred to as fully maintaining the already high scientific reputation of the "Transactions of the Cotteswold Club." The field meetings for the year have been fixed to take place at Cirencester, Ross, Painswick Hill, Moreton-in-Marsh, and a "foreign meet" at Watchett in Somerset, later in the season, if the weather permit.

A SOMEWHAT violent shock of earthquake was felt at Trieste on the 28th of February, at 12·20 p.m. The oscillatory movement from east to west lasted from two to three seconds. The following day at 8·56 p.m. the motion was repeated with greater violence. There was a loud rolling noise, and articles of furniture were thrown down in the houses.

DR. WILHELM HAMM, an official of the Austrian Ministry of Agriculture, and well known as author of the "Weinbuch" (Leipzig, J. Weber), has constructed a Weinkarte, published by Costenoble, Jena, exhibiting at a glance the topography, climatology, and statistics of wine-growing in Europe and the islands of the Atlantic. The habitats, climates, and quantities produced; the various growths and qualities of each; and the wine measures, &c., are all indicated in this map.

SIR WILLIAM THOMSON, having had his attention directed to the very great differences that exist in the conducting quality of copper wire professing to be of the "highest conductivity," had a large number of specimens carefully tested and the following are some of the results obtained—the quality is indicated by the resistance of a metre length weighing one gramme. The best specimen was one supplied by M. Bréguet, Paris, of which the resistance was ·153 of an ohm per metre weighing one gramme. Specimens from English manufacturers varied as follows:—·165, ·169, ·171, ·178, ·206, ·213, ·221. Seven specimens labelled "highest conductivity," stood as follows:—·156, ·182, ·201, ·205, ·223, and ·258. As it is to the interest of all scientific men that the copper wire used in electrical instruments shall be of the best quality, there should be general co-operation to discourage as much as possible the use of inferior copper. Variations in conductivity like those in the samples of copper mentioned above would produce instruments varying to the extent of 40 per cent.

THE publishers of the *Canadian Naturalist* announce that the periodical is in future to appear quarterly instead of six times a year as heretofore, but the quantity of matter, 480 pages, is not to be diminished. Another and an important particular is, that "the basis of the magazine has been so extended as to include a larger field of popular scientific scope than formerly. Especially with regard to the technology of geological, mining, chemical and agricultural science, new materials will be made available while a general summary of scientific facts and discoveries will form an important feature." An editorial committee, comprising some of the foremost scientific men in Canada, has been appointed and the publication remains, as before, under the "auspices" of the Natural History Society of Montreal. The number just received in this country contains, in addition to a batch of articles on different subjects in natural history, one on the partial eclipse of the sun in August last, as observed at Montreal, by Dr. Smallwood.

AN interesting report on the ravages of the Borer in Coffee estates has just been published by George Bidie, M.B., F.R.G.S. The coffee plant, as is well known, is not indigenous to Southern India, but was first introduced into India upwards of two centuries ago, by a Mussulman pilgrim, Bababooden, who on his return from Mecca brought a few berries in his wallet, and taking up his abode in the hills of Mysore, planted them near his tent, and from these the greater portion of the coffee now growing in Southern India has been derived. It is a native of Caffa in Southern Abyssinia. It is now largely cultivated in Mysore, Cuddoor, Coorg, and other parts along the crests and slopes of the Ghauts. It is a remarkably hardy plant, thriving at various elevations, and under the most different conditions of moisture, soil, and temperature. It is, however, liable to the attacks of certain insects, amongst which the Borer is the most formidable. This is shown by Dr. Bidie to be the larva of a beetle belonging to the Cerambycidæ, and termed the *Xylotrechus quadrupes*. The female lays its eggs in the bark of the plants, hot sunshine favouring their hatching. The larva immediately pierces the bark, and derives its nourishment from the more juicy layers, producing, by the damage it causes, exhaustion of the tree and loss of the crop. The whole duration of the life of the animal from the deposition of the ovum to the death of the beetle does not exceed twelve months. The animal appears to be indigenous, and the causes that have led to the great increase in its ravages during the last few years are drought, want of shade, bad culture, destruction of forest trees in which the insect used to live, and departure of some of its enemies.

THE following changes are announced in the arrangements of the staff of St. Bartholomew's Hospital. One assistant-physician is to have charge of the casualty department; three casualty physicians are to act with him; and one casualty surgeon is to superintend the surgical side. The house-surgeons will have charge of casualty patients.

THE Geographical Society of St. Petersburg has decided to send a scientific expedition into Manchouria and Eastern Mongolia, for the purpose of making archæological and ethnographical researches in those countries. The expedition is to start next April, under the direction of the Archimandrite Palladiy, chief of the Russian mission at Pekin. It is said that the Emperor has contributed 5,000 roubles towards the expenses of the expedition.

THE rainfall of the year ending December 31, 1869, as taken in the neighbourhood of Charing Cross, is registered as follows:—

Height of gauge above ground.	Number of inches fallen.
6 feet	23·760
64 „	22·110

MR. E. W. HILGARD, in his Geological Reconnaissance of Louisiana, finds reason for the assumption that "the Gulf coast has in late quaternary times suffered a depression to the extent of at least 900 feet—perhaps more—and during the terrace epoch a contrary motion to the extent of about half that amount." Elsewhere he remarks, "the age of the great gypsum formation has been the subject of much discussion. It has always seemed to me that the great extent of the area over which the cretaceous beds and underlying gypsum are known to be co-extensive, went far to prove that they belonged substantially to the same epoch. Whatever weight may attach to this argument it is greatly enhanced when we find the crystalline limestone and underlying gypsum not only reappearing in northern Louisiana, but actually accompanying each other beneath the waters of the Gulf of Mexico. Whether the volcanic agencies which even now so frequently disturb that great basin, have been instrumental in reducing the sulphur, distilling the petroleum and crystallising the rock salt of southern Louisiana, may be more profitably discussed when more extensive excavations shall have given us an opportunity of closer inspection of the facts."

IN reference to the electro-deposition of nickel, M. Bouilhet states that Jacobi published a method of obtaining thick coatings of nickel by using perfectly neutral solutions. *Cosmos* points out that nickel is especially abundant in Spain.

*ON THE TEMPERATURE AND ANIMAL LIFE OF THE DEEP SEA**

II.

DURING the first and second cruises of the *Porcupine*, the temperature of the eastern border of the great North Atlantic basin was examined at various depths between from 54 to 2,435 fathoms, and in widely different localities, ranging from lat. 47° to lat. 55°. The bottom-temperature was ascertained at thirty stations, and serial soundings were taken at seven stations; making the total number of observations eighty-four. (Table II., p. 20.) Amongst all these the coincidence of temperatures at corresponding depths is extraordinarily close; the chief differences showing themselves in the temperature of the surface and of the stratum immediately beneath it. A decided superheating is observable in this superficial stratum, not extending to a depth of much more than 70 or 80 fathoms, and more considerable at the southern than at the northern stations. Whether this "superheating" is entirely due to the direct influence of solar heat, or depends in any degree on an extension of the Gulf Stream as far as the southern part of the area examined, is a question which can only be resolved by the determination of its relative amount at different seasons. Between 100 and 500 fathoms, the rate of decrement is very slow, averaging only about 3° in the whole, or three-fourths of a degree for every 100 fathoms; and this body of water has a temperature so much above the isotherm of the northern stations at which the observations were made, as decidedly to indicate that it must have found its way thither from a southern source. Between 500 and 750 fathoms, however, the rate of decrease becomes much more rapid, the reduction being 5·4°, or above 2° per 100 fathoms; while between 750 and 1000 fathoms it amounts to 3·1°, bringing down the temperature at the latter depth to an average of 38·6°. Beneath this there is still a slow progressive reduction with increase of depth, the temperature falling a little more than 2° between 1000 and 2,435 fathoms; so that at the last-named depth, the greatest at which it was ascertained, it was 36·5°.—Thus it is obvious either that the vast body of water occupying the deeper half of the Atlantic basin has been itself derived from a colder region, or that its temperature has been reduced by the diffusion through it of frigid water from a Polar source. The latter supposition best accords with the gradual depression of temperature exhibited between 500 and 1000 fathoms, which corresponds with the "stratum of intermixture" of the cold area.

The temperature soundings recently taken by Commander Chimmo, R.N., and Lieutenant Johnson, R.N., at various points in the North Atlantic basin, when the requisite corrections are applied for the influence of pressure on the bulbs of the unprotected thermometers employed by them, give results which are remarkably accordant with our own; so that it may be stated with confidence that the temperature of the deeper parts of the North Atlantic sea-board is but a very few degrees above the freezing-point.

Now a glance at the North Polar region, as laid down either on a globe, or any projection of which the Pole is the centre, shows that the Polar basin is so much shut in by the northern shores of the European, Asiatic, and American continents,

* A Lecture delivered at the Royal Institution (continued from p. 490).

that its only communication with the North Atlantic basin—besides the circuitous passages leading into Hudson's and Baffin's Bays—is the space which intervenes between the eastern coast of Greenland and the north-western portion of the Scandinavian peninsula. If, therefore, there be any such general interchange of Polar and Equatorial water as that for which we have argued, the Arctic current must flow through the deeper portions of this interspace, at the north of which lies Spitzbergen, whilst Iceland and the Faroes lie in the middle of its southerly expanse. Now in the channel that lies between Greenland and Iceland, the depth is such as to give a free passage to such a frigid stream; but between Iceland and the Faroe Islands there is no depth so great as 300 fathoms at any part, except in a narrow channel at the south-east corner of Iceland; so that an effectual barrier is thus interposed to any movement of frigid water at a depth exceeding this. A similar barrier is presented, not merely by the plateau on which the British Islands rest, but also by the bed of the North Sea; the shallowness of which must give to such a movement a not less effectual check than would be afforded by an actual coast-line uniting the Shetland Islands and Norway. Consequently, it is obvious that a flow of ice-cold water, at a depth exceeding 300 fathoms from the surface, down the north-eastern portion of this interspace, can only find its way southwards through the deeper portion of the channel between the Faroe and Shetland Islands; which will turn it into a W.S.W. direction between the Faroe Islands and the north of Scotland, and finally discharge such part of it as has not been neutralised by the opposing stream coming up from the south-west, into the great North Atlantic basin, where it will meet the Icelandic and Greenland currents, and unite with them in diffusing frigid waters through its deeper portion. In thus spreading itself, however, the frigid water will necessarily mingle with the mass of warmer water with which it meets, and will thus have its own temperature raised, whilst lowering the general temperature of that mass; and hence it is that we do not find the temperature of even the greatest depths of the Atlantic basin nearly so low as that of the comparatively shallow channel which feeds it with Arctic water.

It may be questioned, however, whether the whole body of Arctic water that finds its way through the channels just indicated, could alone maintain so considerable a reduction in the temperature of the enormous mass which lies below 1,000 fathoms in the Atlantic basin; subject as this must be to continual elevation by the surface-action of the sun on its southern portion. And as the few reliable observations on deep-sea temperatures under the equator indicate that even there a temperature not much above 32° prevails, it seems probable that part of the cooling effect is due to the extension of a flow of frigid water from the Antarctic Pole, even north of the Tropic of Cancer. Of such an extension there is evidence in the temperature-soundings recently taken in H.M.S. *Hydra* between Aden and Bombay, where the cooling influence could scarcely have been derived from any other source than the Antarctic area.*

The unrestricted communication which exists between the Antarctic area and the great Southern ocean-basins would involve, if the doctrine of a general Oceanic circulation be admitted, a much more considerable interchange of waters between the Antarctic and Equatorial areas, than is possible in the Northern hemisphere. And of such a free interchange there seems adequate evidence; for it is well known to navigators that there is a perceptible "set" of warm surface-water in all the Southern oceans towards the Antarctic Pole; this "set" being so decided in one part of the Southern Indian Ocean, as to be compared by Captain Maury to the Gulf Stream of the North Atlantic.† Conversely, it would appear from the application of the necessary pressure-correction to the temperatures taken in Sir James Ross's Antarctic expedition, the voyage of the *Venus*, &c., at depths greater than 1,000 fathoms, that the bottom-temperature of the deepest parts of the Southern Oceanic basin really approaches the freezing-point, or is even below it. And if the temperature of the deeper portion of the North Pacific Ocean should be found to exhibit a depression at all corresponding to that of the North Atlantic, it must be attributed entirely to the extension of this Antarctic flow; since the depth

* The lowest temperature actually observed in these soundings was 36½°. The temperature of 33½° given in the previous discourse, as existing below 1,800 fathoms, proves to have been only an estimate formed by Capt. Shortland under the idea that the rate of reduction observed at smaller depths would continue uniform to the bottom, which the serial soundings of the *Porcupine* prove to be by no means the case.

† "Physical Geography of the Sea," §§ 748-750.

of Behring's Strait, as well as its breadth, is so small as to permit no body of Arctic water to issue through that channel.

If further observations should substantiate the general diffusion of a temperature not much above the freezing-point over the deepest portions of the ocean-bed, even in Intertropical regions, as a result of a general deep movement of Polar waters towards the Equator, forming the complement of the surface-movement of Equatorial water towards the Poles, it is obvious that such diffusion must exert a very important influence on the distribution of animal life; and, in particular, that we may expect to meet with forms which have hitherto been reputed essentially Arctic, in the deep seas of even the Intertropical region, and again in the shallower water of the Antarctic area. Such, there is strong reason to believe, will prove the case. In his recent annual address as President of the Royal Society, Sir Edward Sabine cites observations on this point made by Sir James Ross in his Antarctic expedition, as confirmatory of the view entertained by that distinguished navigator, "that water of similar temperature to that of the Arctic and Antarctic seas exists in the depths of the intermediate ocean, and may have formed a channel for the dissemination of species." The "similar temperature" believed by Sir James Ross to have had this general prevalence, seems to have been 39°; whereas the observations made in the *Porcupine* expedition distinctly prove that a temperature even below 30° may be conveyed by Polar streams far into the temperate zone, and that the general temperature of the deepest part of the North Atlantic sea-bed has more of a Polar character than he supposed.

Again, the deep-sea dredgings of the *Porcupine* expedition have shown that many species of mollusks and crustacea previously supposed to be purely Arctic, range southwards in deep water as far as those dredgings extended—namely, to the northern extremity of the Bay of Biscay; and it becomes a question of high interest whether an extension of the same mode of exploration would not bring them up from the abysses of even intertropical seas.

Now, as there must have been deep seas at all geological epochs, and as the physical forces which maintain the oceanic circulation must have been in operation throughout, though modified in their local action by the particular distribution of land and water at each period, it is obvious that the presence of Arctic types of animal life in any marine formation cannot be accepted as furnishing evidence *per se* of the general extension of glacial action into temperate or tropical regions. How far the doctrines now current on this point may need to be modified by the new facts now brought to bear on them, it will be for geologists to determine; the question may be left in their hands with full assurance of a candid reception of the fresh evidence now adduced.

The general results of the dredging operations carried on during the *Porcupine* expedition will now be concisely stated.

In the first place they show conclusively that there is no limit to the depth at which animal life may exist on the ocean-bed; and that the types found at even the greatest depths may be not less elevated in character than those inhabiting shallower waters. It would even be premature yet to affirm that the higher types occur in less abundance and variety than at more moderate depths; for it is by no means impossible that the use of the improved method of collection devised by Captain Calver,* which was employed with extraordinary success in the third cruise, may make as large an addition to our knowledge of the life of the sea-bottom explored by the dredge in the first and second cruises of the *Porcupine*, as it has done in the case of the cold area, where it revealed the astonishing richness of the bottom, which the *Lightning* dredgings of the previous year had led us to regard as comparatively barren.

Secondly, they confirm our previous conclusion that temperature exerts a much greater influence than pressure on the distribution of animal life. Not only have we found the same forms presenting themselves through an enormous vertical range—no amount of fluid pressure being incompatible with their existence—but we have also, by a more complete survey of the relations of the warm and cold areas, established the very marked difference between the faunæ of two contiguous portions of the sea-bed lying at the same depth, which was indicated by the *Lightning* dredgings. It is remarkable, however, that this difference showed itself more in the crustaceans, echinoderms, sponges,

* This consists in the attachment of "hempen tangles" to the dredging apparatus, by which the floor of the ocean is *swept* as well as *scraped*. These tangles often came up loaded, when the dredge was empty.

and foraminifera, than it did in the mollusca, of which a considerable proportion were common to both areas. The abundance and variety of animal life on a bottom of which the temperature is at least 2° (Fahr.) below the freezing-point of fresh water, is a fact which has all the interest of surprise; and it is scarcely less remarkable that the forms of mollusks, echinoderms, and sponges, which seem to be the characteristic inhabitants of this cold area, should attain a very considerable size. The precise limitation of the Globigerina-mud and of the vitreous sponges to the warm area, was a very striking manifestation of the influence of temperature, and has very important geological bearings.

Thirdly, they have largely added to the number of cases in which types that had been regarded as characteristic of earlier geological periods, and to have long since become extinct, prove to be still existing in the depths of the ocean; and greatly increase the probability that an extension of the like method of research to more distant localities would produce even more remarkable revelations of this character.

The doctrine propounded by Professor Wyville Thompson, in the report of the *Lightning* expedition, as to the absolute continuity of the cretaceous formation with the deposit of globigerina-mud at present in progress on the North Atlantic sea-bed, has received such striking confirmation from the discovery of the persistence of numerous cretaceous types, not merely in our own explorations, but also in those carried on by the United States Coast Survey in the Gulf of Mexico, that it may be fairly affirmed that the *onus probandi* rests upon those who assert that the formation of true chalk has ever been interrupted since the cretaceous period. That period is usually considered to have terminated with the elevation of the cretaceous deposits of the European area into dry land. But according to the accepted doctrines of geology, it is highly probable that, coincidently with the elevation of the European area, there was a gradual subsidence of what is now the Atlantic sea-bed; so that the *Globigerinæ* of the former area, with many accompanying types of animal life, would progressively spread themselves over the latter, as its conditions became favourable to their existence. And there seems no reason why they should not have maintained themselves in its deepest parts, through the comparatively small changes of level which took place in this portion of the earth's crust during the Tertiary epoch.

Fourthly, the *Porcupine* explorations have enormously extended our knowledge of the British marine fauna; alike by the discovery of new types, and by the addition of types previously known only as inhabitants of other localities.—The mollusca alone have as yet been fully examined; and Mr. J. Gwyn Jeffreys, whose authority upon this part of the subject is not second to that of any other naturalist, reports as follows:—The total number of species of marine mollusca enumerated in his recently completed "British Conchology" (excluding the Nudibranchs) is 451; and to these the *Porcupine* expedition has added no fewer than 117, or more than one-fourth. Of these as many as fifty-six are undescribed, whilst seven were supposed to be extinct as Tertiary fossils. Sixteen genera, including five which are undescribed, are new to the British seas. "All that I can do," he says, "by continual dredgings in comparatively shallow water during the last sixteen years was to add about eighty species to the number described by Forbes and Hanley. I regard the present (although a large) addition as merely an earnest of future discoveries. In fact the treasury of the deep is inexhaustible." The complete examination of the crustacea, which are in the hands of the Rev. A. M. Norman, and of the annelids, which have been undertaken by M. Claparède and Dr. Macintosh, will probably yield results scarcely less striking. It is, however, in the echinoderms and sponges, which are being examined by Professor Wyville Thomson; in the stony corals, which have been referred to Dr. P. M. Duncan; and in the foraminifera, which constitute the speaker's own speciality, that the most interesting novelties present themselves.

W. B. CARPENTER

SCIENTIFIC SERIALS

THE February number of the *American Naturalist* (Vol. iii. No. 12) contains only three original articles, and of these the first and most important is really a reprint of Professor Wyman's observations on the development of the thornback, with a few introductory remarks on the natural history of the skates, by Mr. F. W. Putnam. The other two are the continuation of Mr. J. A. Allen's notes on the rarer birds of Massachusetts, and a paper on common fresh-water shells, by Mr. E. S. Morse. Professor Williamson's article on *Bathybius* is reprinted from the *Popular Science Review.*

A SHORT paper appears in the last number of Tröschel's *Archiv für Naturgeschichte* from the pen of Dr. A. A. Krohn, on the earliest development of the Botryllus stock, which, as most of our readers are probably aware, constitutes one of the Tunicate Molluscs analogous to the misshapen bodies found so commonly on our sea coasts, and known as "dead men's fingers." Hitherto certain processes found at the anterior end of the larva have been regarded as the germs or buds of new individuals which subsequently become completely differentiated, but M. Krohn shows that these are clavate processes, constituting the first rudiments of the blood-vessels which make their appearance soon after the metamorphosis of the larva. After a short time the vessels begin to branch, each branch terminating in a dilated cœcal enlargement resembling the calyx of the common *Erica tetralix* in form, and at this time a round projection appears on the right side of the body, near the heart, into which a stream of blood from the mother sets, and having circulated around it returns to its starting point. It now, curiously enough, begins, together with the mother animal, to shrink, and finally disappears, and in its place a daughter Botryllus is developed. The daughter Botryllus forms two buds, a right and a left, while itself passes through the same stages as the original mother, becoming also fluid and disappearing. The two buds of this third generation, when fully developed, have their cloacal apertures opposed, and each gives off two buds which are arranged with the parents in a circular manner, and these four buds may again give off others, and so regularly arranged systems of the animals are produced, the vascular system undergoing corresponding development and extension. The blood contains colourless corpuscles, and under certain circumstances a number of dark pigment granules present in the bodies of the successive generations, on undergoing atrophy appear to gain entrance into the circulating fluid.

THE *Revue des Cours Scientifiques* for the 19th inst. contains a report of a lecture by M. Claude Bernard on the history of medical science and its actual condition; of one by M. Harny, on human remains in the tertiary deposits in America, and on the theories of multiple centres of creation; and of one by Dr. Bertillon on the mortality of different departments of France.

IN the just published *Proceedings of the Royal Society of Edinburgh* for the session 1868-69, Professor Allman gives a description of Rhabdopleura, a new genius of Polyzoa. The cœnæcium or common stem consists of a branched tube partly adherent and partly free, the free portion forming tubes of egress through which the polypides move in the acts of exsertion and retraction. In the walls of the adherent portion a rigid chitinous rod is developed along their attached side, from distance to distance, each by a flexible cord or funiculus. The polypides are hippocrepian, and each carries a shield-like process on the hæmal side of its lophophore, external to the tentacular series. In development the polypide at an early stage is included between two fleshy plates on the right and left sides respectively, and which are partially united. For some time the two plates keep pace with the general development of the bud, but ultimately they cease to increase in size, and then remain as the shield-like processes carried by the lophophore of the polyzoon. Professor Allman regards these plates as representing the right and left lobes of the mouth in a Lamellibranchiate Mollusk, from which it follows that the relations of the Polyzoa are more intimate with the Lamellibranchiata than with the Brachiopoda, with which of late years they have been associated, but whose mantle lobes lie dorsally and vertically, instead of lying right and left as in the Lamellibranchiata. The lophophore of the Polyzoa he considers to have its representative in the labial palps of the Lamellibranchiata. The animal was obtained by the Rev. A. Norman and Mr. J. Gwyn Jeffreys in the course of deep-sea dredging in Shetland.

THE *Journal of the Chemical Society* for February is mainly occupied by a long paper by Mr. F. A. Abel, entitled "Contributions to the history of explosive agents," abstracted from the Philosophical Transactions for 1869. There are also shorter articles on nontronite, and on a new chromium oxychloride, by Dr. T. E. Thorpe, and observations on the solution of gases in water by Dr. Williamson.

THE *Monthly Microscopical Journal* for March contains the President's Address, an obituary notice of the late J. J. Lister, F.R.S., and articles on the structure of the stems of the arborescent *Lycopodiaceæ* of the coal measures, by Mr. Carruthers, and on the mode of examining the microscopic structure of plants.

SOCIETIES AND ACADEMIES

London

Royal Society, March 10.—The following paper was read: "On some elementary principles in animal mechanics. No. 3—On the muscular forces employed in parturition," by the Rev. S. Haughton.

March 17.—Papers were read as follows:—"On the law which regulates the relative magnitude of the areas of the four orifices of the heart," by D. H. Davies; and "On the estimation of ammonia in atmospheric air," by Mr. H. T. Brown. The process recommended is by the absorption of the ammonia by extremely dilute sulphuric acid, and the results obtained are said to be far more concordant than those procured by other means.

The Royal Astronomical Society, March 11.—Mr. W. Lassell, president, in the chair. Sixty-three presents were announced as having been received since the third meeting, and the thanks of the society were voted to their respective donors. A communication from Mr. Marsh was then read, in which that observer records the position-angles and apparent distances of the satellites of Uranus. It was ordered that this paper be printed forthwith.—The next paper was by Lieut. Herschel. In a letter to his brother, Prof. Alexander Herschel, the writer remarked on certain singular objects seen to traverse the sun's disc on October 17th and 18th, 1869. He was about to apply his spectroscope to the observation of a solar prominence when his attention was attracted to certain shadows traversing the disc of the sun, which became bright streaks when they had passed beyond it. At first he thought these appearances were due to sparks in the tube of the telescope, but the phenomenon lasted too long for this explanation to be available. He next thought that perhaps a system of meteors might be in transit, and prepared to subject the phenomenon to careful scrutiny. The equatorial was set in motion, the sun's disc being projected on a screen. The shadows were seen persistently traversing the solar disc, but at different velocities, the larger ones travelling most swiftly. There appeared to be two streams. He noticed that when the sun was in focus the objects were indistinct, and that they appeared very distinctly when he focussed on a distant cloud. At length, while he was attentively scrutinising the phenomenon he saw one of the objects come suddenly to a standstill, and then whisk off in a different direction; and then he perceived that the phenomenon he had been examining with such anxious care was not in reality an astronomical phenomenon at all, but consisted merely of a flight of locusts. He considered, however, that not only was the existence of so enormous a swarm of locusts as the duration of the stream indicated, an interesting fact in itself, but that we might find in the occurrence the explanation of many statements which had been made respecting meteors supposed to have transited the sun, and also of some peculiarities noticed by astronomers in America during the total eclipse of last year. Mr. Stone said that it was important when appearances of this sort were noticed that the observer should examine, as Lieut. Herschel had done, whether the objects seen in transit required the same focus as the sun. This was the best way of determining whether the objects were terrestrial or not.—Capt. Noble communicated three short papers to the society. The first had reference to occultations of stars by the moon. The second referred to the visibility of Venus near her inferior conjunction. He could detect only an arc of light less than a semicircle, and saw the body of the planet projected on the sky beyond, the planet appearing sensibly darker than the sky. On March the 3rd he saw the Zodiacal Light for the first time. He was struck by the fact that instead of appearing nearly coincident with the ecliptic, the light seemed inclined at an angle of about twenty degrees to that circle. It seemed, in fact, almost perpendicular to the horizon.—Mr. Browning exhibited some more drawings of Jupiter, remarking on the changes of form and colour which the belts on the planet had exhibited during the past few months. The president inquired whether a picture by Mr. Browning, in which the equatorial belt appeared twice as wide as usual, was not slightly exaggerated; but Mr. Browning remarked that it presented the planet exactly as he had seen it.—Mr. Procter then read a paper entitled "Notes on the Corona and the Zodiacal Light, with suggestions respecting the modes of observation to be applied to the Eclipse of next December." He remarked that if we have in reality sufficient evidence to determine whether the corona is or not a solar appendage, it would be a misfortune, and in a sense discreditable, to science, were the short time at the disposal of observers wasted in futile observations directed to settle a point determinable beforehand. He then expressed his conviction that the corona cannot be a terrestrial phenomenon. He pointed out that the very blackness of the moon as compared with the corona showed that the coronal light is behind the moon. The moon is, in fact, projected on the corona as a background, he urged, whereas the theory that the light is due to atmospheric glare requires that the corona should be a foreground. But passing over this argument, which is liable to the fatal objection of being too simple, he proceeded to inquire whether air which lies between the observer and the corona is in reality illuminated. He showed that all round the sun, for a distance of many degrees, there should be perfect darkness if the illumination of the atmosphere by direct solar light were in question. As to the atmospheric glare due to the chromosphere and prominences, he argued that it must be relatively small because it could bear no higher proportion to the actual light of the chromosphere, than ordinary atmospheric glare bears to actual sunlight, and we know this proportion is very small indeed. Again, as to light reflected from the atmosphere outside the shadow-cone, or from the surface of the earth, he urged that that also must be small, since not any part of the atmosphere above the observer's horizon was illuminated by more than a half-sun, while all the parts near the shadow-cone were in nearly total shadow. But a fatal objection to the view that the corona could be due to either the glare from the prominences or to light reflected from the surrounding air consisted in the fact that such glare ought to cover the moon's disc. He then referred to a number of observations confirming the view that the coronal light is not terrestrial; as the appearance of glare during partial eclipses, this glare always trending on the moon's disc; the relatively greater darkness of the central part of the moon's disc in annular eclipses; the visibility of that part of the moon's disc which lies beyond the sun in partial eclipses, the limb being seen dark on the background of the sky; the visibility of the corona in partial eclipses, even its most distinctive peculiarities having been recognised when the sun's disc is not wholly covered; and several other phenomena. He then adduced evidences to show that a solar appendage which one would expect to appear during total eclipses, actually does exist. First the Zodiacal Light shows that the sun is surrounded by such an appendage. Dr. Balfour Stewart's theory of this object, however physically sound, was opposed, he urged, by too many astronomical objections to be accepted for a moment: an object which exhibits no appreciable parallax, which rises and sets as the celestial objects do, and maintains a position in the heavens having a nearly constant relation to the ecliptic, cannot by any possibility be due to any peculiarity of the earth's atmosphere. Then Leverrier has shown that the motion of Mercury's perihelion indicates the presence of a ring of bodies in the sun's neighbourhood; and Mr. Baxendell has drawn a similar conclusion from the meteorological records of well-known observatories. Lastly, judging of the meteor systems according to the laws of probability, we have every reason to believe that for each one our earth encounters there must be millions whose perihelia lie within the earth's orbit. Since the earth encounters fifty-six such systems, it will be seen how enormous must be the total number. These should be visible during total eclipses, and since they would shine in part by reflected light, and in part through their intrinsic light (for those which come as near the sun as some comets have been observed to do, must be melted or even vaporised by the sun's heat) we have an explanation of the contradictory accounts given by those who have applied the polariscope and the spectroscope to the solar corona. Mr. Stone remarked that there ought to be three sets of observations made with the polariscope next December, since if there were but two the result would probably be contradictory, as was the case with regard to the observations made in India in 1868, and in America last year. Different parts of the corona ought also to be examined.

Zoological Society, March 10.—John Gould, F.R.S., V.P., in the chair. The secretary spoke of the additions to the society's menagerie during the month of February, amongst which were particularly noticed a collared fruit-bat (*Cynonycteris collaris*), born in the society's monkey-house on the 25th inst., being the first instance on record of a birth amongst these animals in captivity, and a kangaroo, believed to belong to a new species, for which the name *Macropus erubescens* was proposed.—Prof. Flower exhibited a drawing of a Cetacean animal lately captured in a mackerel-net off the coast of Cornwall, which he identified with *Globiocephalus rissoanus*—a species hitherto only known to occur in the Mediterranean. The specimen was stated to be an adult female, about eleven feet long.—Mr. Sclater gave some additional details as to the correct locality of Amherst's pheasant (*Thaumalea Amherstiæ*), in reference to Mr. Swinhoe's communication on the same subject at the previous meeting.—Prof. Owen read a memoir containing descriptions of various bones of *Aptornis defossor*, *A. otidiformis*, *Notornis Mantelli* and *Dinornis curtus* obtained from deposits in different parts of New Zealand, and forming the fifteenth part of his series of memoirs on the extinct birds of the genus *Dinornis* and their allies.—Mr. R. Swinhoe read three papers on new or little known birds obtained by him in different parts of the Chinese Empire. The first of these related to new species obtained during a recent voyage up the Yangtze, amongst which were species of *Parus*, *Lanius*, *Ægithalus*, and other genera of *Passeres*. The second contained supplementary remarks on the pied wag-tails (*Motacillæ*) of China, in continuation of a former paper on the same subject. The third paper contained a notice of the different species of shore-plovers (*Ægialitis*) found in China, amongst which was a conspicuous new species obtained on the Yangtze, and proposed to be called *Ægialitis Hartingi*.—Mr. H. B. Sharpe read the second of a series of papers on the birds of Angola, containing an account of collections forwarded from that couutry by Mr. Monteiro. Amongst these was a bush-shrike belonging to the genus *Laniarius*, supposed to be new, and proposed to be called *Laniarius Monteiri*.—Dr. Günther read a note on the locality of the Batrachian recently described by him as *Megalixalus robustus*, which was stated to be from the Seychelles.—Dr. Günther read a paper on the genus *Prototroctes*, which contains two species of fishes from the fresh waters of Southern Australia and New Zealand. In general appearance these fishesr esemble *Coregonus*, but their internal structure had led Dr. Günther to constitute them along with the South American genus *Haplochiton*, a distinct family, *Haplochitonidæ*, which appeared to be the representative of the Salmonoid group in the southern hemisphere.—A communication was read from the Rev. O. P. Cambridge, containing descriptions of three new species of the Arachnida of the genus *Idiops*, in continuation of a former paper on the same subject.

Mathematical Society, March 10.—Professor Cayley, president, in the chair. Mr. E. Bradshaw Smith was elected a member, and Messrs. A. and W. M. Ramsay were admitted into the society. Mr. Tucker (hon. sec.) then read two communications by Mr. Clerk Maxwell, F.R.S.; the one on topographical geometry, which led to a discussion in which Mr. Archibald Smith, F.R.S., and the president took part; the other a note on a case of fluid motion. "In most investigations of fluid motion we consider the velocity at any point of the fluid as defined in magnitude and direction as a function of the coordinates of the point and of the time. We are supposed to be able to take a momentary glance at the system at any time, and to observe the velocities, but are not supposed able to keep our eye on a particular molecule during its motion. This method therefore properly belongs to the theory of a continuous fluid alike in all its parts, in which we measure the velocity by the volume which passes through unit of area rather than by the distance travelled by a molecule in unit of time. The molecular theory, as it supposes each molecule to preserve its identity, requires for its perfection a determination of the position of each molecule at any assigned time. As it is only in certain cases that our present mathematical resources can effect this, I propose to point out a very simple case with the results. Let a cylinder of infinite length and of radius a move with its axis parallel to z, and always passing through the axis of x with a velocity v, uniform or variable in the direction of x through an infinite homogeneous incomprehensible perfect fluid." The solution of the problem involved work hardly suited for the columns of NATURE.—Mr. S. Roberts then discussed the following problem which occurred in his paper on the pedals of conic sections. If two circles are given, one of which passes through the centre of the other, and if a line equal in length to the radius of the latter circle moves with an extremity on each, the locus of any point rigidly connected with the moving line will be composed of a circle and a bicircular quartic having a finite double point. His account of the communication closed with a discussion of the following problem, intimately connected with the subject-matter of the paper:—Given the paths of two points of an indefinite plane, moving in plane space, to find the path of an arbitrary point of the plane. If $F(x,y)=0$, $\phi(x,y)=0$ are the equations of the given path, we have to eliminate θ from

$$F(l\cos\theta + p\sin\theta + X, l\sin\theta - p\cos\theta + Y) = 0$$
$$\phi(l\cos\theta - q\sin\theta + X, l\sin\theta + q\cos\theta + Y) = 0$$

The president, Professor Hirst, Mr. Cotterill, and the author, took part in a discussion on the paper.—Mr. Archibald Smith then made some remarks on the scale for compensation in the Irish Land Bill.

MANCHESTER

Philosophical Society, March 8.—Dr. J. P. Joule, president, in the chair. Sir James Cockle, President of the Queensland Philosophical Society, was elected a corresponding member of the society. A letter was read from Mr. Dancer, on Dr. A. Ransome's paper "On the Organic Matter of Human Breath." Mr. E. W. Binney called the attention of the meeting to the frightfully high death-rate of Manchester and Salford, which continued to increase, notwithstanding the appointment of officers of health, and the doings of the councils of the two towns. A paper was read, "On the Suspension of a Ball by a Jet of Water," by Osborne Reynolds, Professor of Engineering, Owens College.

Microscopical and Natural History Section, February 28.—A paper was read "On some Shell Deposits at Llandudno," by Mr. Joseph Sidebotham.

Physical and Mathematical Section, January 4.—Mr. E. W. Binney, president of the Section, in the chair. A paper was read "On the Rainfall of 1869, at Old Trafford, Manchester," by Mr. G. V. Vernon.

March 1.—Mr. E. W. Binney, president of the Section, in the chair.—A paper was read "On the Results of Rain-gauge and Anemometer Observations made at Eccles, near Manchester, during the year 1869," by Mr. Thomas Mackereth.

HEREFORD

Woolhope Naturalists' Field Club, February 22.—Annual meeting; Mr. James Rankin in the chair. After the usual club business had been transacted, and a committee appointed to report upon the practicability of establishing a local museum, the Rev. F. T. Havergal detailed the progress that had been made with reference to the publication of the *Mappa Mundi*, one of the chief curiosities of the Cathedral. It has been satisfactorily established that the date at which the map was executed was the very commencement of the fourteenth century. It is drawn in accordance with the prevailing notions of geography at that period; the habitable earth is represented as a circular island with the "ocean-stream" flowing around it. Jerusalem is placed in the centre. Asia occupies nearly the whole upper (or eastern) half of the circle, while Europe holds the lower quarter on the left hand, and Africa that on the right. The Hereford map is distinguished from most mediæval maps not only by its great size, but also by its illustrations of objects in natural history, and its numerous inscriptions. It is proposed to publish a fac-simile (obtained by photography) in colours, accompanied by an exhaustive account of the history of the map, and of the legends upon it. The price has been limited to two guineas, and Mr. Stanford, of 6, Charing Cross, London, has been empowered to receive orders.—A paper upon the Reproducton of the Mistletoe, by the Rev. R. Blight, was read, and drawings exhibited which showed the gradual penetration of the parasite through the bark of the Magnolia in search of the sap.—A new *Clavis agaricinorum*, by Mr. Worthington Smith, F.L.S., was also exhibited. Its principle of classification is based on the colour of the spores, and the book is divided into sections respectively coloured white, pink, brown, purple, and black. In each of these sections the typical forms of the different agarics are given, and the identification of any species is thus the work of a moment.—Dr. Bull communicated the discovery of an Agaric entirely new to Britain, the *Cortinarius russus*, which he had met with in several woods near Hereford. He had also collected specimens of the rare *Asarum Europæum*, or *Asarabacca*, near the ruins of Limebrook Priory, a habitat which confirms the belief in its having been a cultivated plant.—At the evening meeting the President reviewed in his address the progress of science during the past year, and referred to the contributions made by different members of the club to various branches of natural history and archæology.—Dr. Bull read an interesting paper upon Deerfold Forest which, when published, will form a very valuable addition to the topography of the county.—The Rev. H. Cooper Key was elected president for the ensuing year.

EDINBURGH

Edinburgh Botanical Society, January 13.—Mr. Robert Brown, V.P., in the chair. The following communications were read:—

1. "Note on the embryo of *Ruscus aculeatus.*" By Professor Dickson.

2. "Notice of plants collected in Spitzbergen and Nova Zembla in the summer of 1869." By William Livesay.

3. "Notice of some botanical excursions with pupils during the summer of 1869." By Professor Balfour.

At the last meeting of the Edinburgh Botanical Society, Dr. Balfour stated that during the course of last summer he made several botanical trips with his pupils, the results of which seemed not unworthy of notice. On 12th June, a party visited Manuel, Woodcockdale, Carriber Glen and Castle, Bowdenhill, Cockleroy and Linlithgow. On 19th June, a party visited Denny, and proceeded up the banks of the Carron as far as the Hermitage. On 26th June, a party of 94 proceeded to Cleghorn, and walked along the banks of the Mouse as far as Cartland Crags, dividing then into two parties, one of which visited Stonebyres and the other Corra Linn. On 3rd July, a party of 50 proceeded by Stirling to Dollar, and thence to the Ochils. On 17th July, an excursion was undertaken to Perth and Dunkeld, and some of the party visited Methven bog. On 22nd July, a party proceeded by Perth and Forfar to Kirriemuir, and thence to Clova, and next day visited Loch Brandy and the mountains above it. In the course of two days a large number of the rarer alpine plants of Scotland was gathered, and in all the other excursions many interesting and rare plants were gathered.

4. "On the botany of the Dominion of Canada and adjacent parts of British America (Part I., *Ranunculaceæ*)." By Professor Lawson, Dalhousie College, Halifax, Nova Scotia.

5. "On the introduction of Ipecacuanha plant (*Cephælis Ipecacuanha*)." By Mr. M'Nab.

6. "Notice of *Sicana odorifera*, Naudin (*Cucurbita odorifera*, Velloso, Flor. Flum.") By Senhor Joaquim Correa de Mello, Camprinas, Province of St. Paulo, Brazil. Communicated by Mr. Daniel Hanbury.

7. Hints for Collecting Cryptogamia. By Prof. Dickie.

8. Miscellaneous communications.—*Ruscus aculeatus.*—*Cones of Abies.*

GLASGOW

Philosophical Society of Glasgow—*Chemical Section*, January 31.—Dr. William Wallace, F.R.S.E., F.C.S., vice-president, in the chair. A paper was read by Mr. John Christie, on "the history of Madder, the various investigations relating to its character and composition, and the proposed sources of Artificial Alizarine." After giving an elaborate account of the progress of the art of dyeing, by the use of the two madder plants, *Rubia cordifolia*, or munjeet, of Bengal, and *Rubia tinctorum* of various European countries, the author proceeded to mention the various persons who had undertaken scientific investigations with a view to determine the number and nature of the colouring ingredients of madder-root. He stated that these investigations commenced about the end of last or beginning of the present century. Watt, Bartholdi, and Haussmann were amongst the earliest investigators. Kuhlman, in 1823, published a complete approximate analysis of madder. He obtained two colouring matters, his *matière colorante rouge*, and a fawn colour, which he did not consider worthy of investigation. Robiquet and Colin published the results of their researches on Alsace madder in 1826. The particular colouring matter of madder they named *alizarine*, and another body, which they considered to be a modification of alizarine, they termed *purpurine.* Gautier de Clanbry and Persoz obtained two colouring matters in the following year—*matière colorante rouge* and *matière colorante rose.* They were the first chemists to prepare madder extract, or *garancine*, a substance which was first manufactured largely at Avignon in 1829. Dr. Schunck obtained no fewer than seven substances from madder, two of them being colouring matters, having the composition indicated by the formulæ $C_{14}H_{10}O_4$, and $C_{32}H_{22}O_{10}$. His results were published in 1848. Debus, by treating Zealand madder, obtained two colouring bodies, which he called Lizaric acid and Oxylizaric acid. Wolff and Strecker obtained alizarine and purpurine; the latter they regarded as oxide of alizarine. The author next enlarged on various series of researches made by Strecker, Schützenberger, and Lanth, P. and E. Depouilly, Dr. Anderson (Glasgow), Rochleder (Prague), and Graebe and Laubermann, which seemed to indicate an approximation towards the accomplishment of a long-wished-for desire—namely, the production of artificial alizarine. Anthracene, one of the coal-tar products, came to be regarded as the starting-point. Graebe and Laubermann obtained a product closely allied to alizarine, and in December 1868 they obtained provisional protection for their process in this country. They employed anthracene ($C_{14}H_{10}$), converting it into anthrachinon ($C_{14}H_8O_2$) by using bichromate of potash. They transformed that body into bibromanthrachinon, ($C_{14}H_6Br_2O_2$), a substitution product; and, by subsequent treatment with potash and an acid, they obtained from it a body which they termed artificial alizarine. In the course of last year other patents were secured by Brönner and Gulzkow, of Frankfort-on-the-Maine, and by W. A. Perkins, F.R.S.; and recently Messrs. Lucius & Co., of Hoechst, near Frankfort, have prepared artificial alizarine by a secret. Mr. Christie concluded his paper by giving an account of numerous investigations which he had made with commercial artificial alizarine in order to test its colorific and other properties, and stated his reasons for regarding the natural and artificial compounds as not being identical. In the discussion which followed, Mr. Hogg and other speakers mentioned facts in support of the identity of the two products, one of the facts being that mordanted cloth dyed with pure artificial alizarine stands soaping better than that dyed with garancine.

PARIS

Academy of Sciences, March 14.—M. Faye presented a memoir on the photographic observation of the transits of Venus, and on an apparatus of M. Laussedat's.—The author noticed the imperfection of Halley's method of observation, which has already been recognised by the German astronomers, suggested the employment of photography as a means of observing the transit of Venus which will take place in 1874, and communicated a letter from M. Laussedat, describing an arrangement by which photographic observations may be taken.—A letter from M. Wolf, of Zurich, accompanying a printed memoir, was read. The author stated that the invention of the bubble-level was to be ascribed to a Frenchman named Capotos, and suggested that a search should be made in France for documents relating to this subject, and to some others to which he referred.—A memoir was read by M. Phillips on the changes of condition of a mixture of a saturated vapour and of its liquid, according to an adiabatic line.—A note by M. Zaliwski was communicated, on the selection of the bodies which should be placed in contact with carbon as the positive pole of a battery. The author stated that these should be oxydising bodies, and among these such as are impressionable by light, such as nitric acid and the manganates of potash, seem to be most efficacious. He described a battery in which the carbon is impregnated with an ammoniacal solution of chloride of silver, dried and treated with nitric acid to remove the excess or ammonia; with pure water this forms a battery of great intensity.—M. de Saint-Venant communicated a note by M. F. André, containing an account of experiments on the velocity of propagation of sound in water in a cast-iron conduit of 0·80M. in diameter. The author found the velocity of propagation to be only 897·80 M. per second—M. H. Sainte-Clair-Deville communicated a second memoir on the "nascent state," in which he discussed the phenomena observed when zinc is brought in contact with a mixture of sulphuric or hydrochloric and nitric acids.—M. E. J. Maumené read a second memoir on a general theory of chemical action.—M. Combes presented a note by M. L. Gruner on the mechanical properties of phosphuretted steels. The author referred to the statements of Sir. W. Fairbairn as to Heaton's steel, and showed by analysis that it contains from 0·002 to 0·003 of phosphorus. He remarked that the favourable character of this steel under the ordinary tests was negatived when the test of a shock was applied to it. M. Boussingault supported the opinions of M. Gruner.—M. A. Milne-Edwards communicated a note on the Ornithological fauna of the Bourbonnais during the middle Tertiary period, in which he stated that the birds of the Miocene deposits of that district possessed a tropical, and especially an African character. He noticed remains of a parrot, a trogon, a sand-grouse, a swift of the group of the Salanganes, a Marabou stork, and a Secretary bird.—M. Leveillé presented a note on the discovery of remains of quaternary man in the manufactories of stone implements at Grand-Pressigny; and M. Richard noticed the discovery of instruments of the Stone age in Arabia and Egypt. The author stated that he has found worked stones at the foot of Mount Sinai, near Cairo, and at Thebes.—M. C. Wœstyn presented a memoir on the means of destroying the contagious miasmata of hospitals, upon which MM. Dumas and Bouillaud made some remarks.—M. Wurtz presented a note by M. Verneuil on the cure of tracumatic tetanus by chloral.—Several other communications were made of which the titles only are given.

BERLIN

German Chemical Society, March 14.—M. Schultz-Sellak has obtained a liquid modification of sulphuric anhydride, which, under ordinary circumstances, speedily passes into the solid form.—M. Tiemann has converted trinitrotoluol into toluylendiamide. The same, conjointly with Mr. Judson, has studied several isomeric dinitrobenzoic acids.—Mr. Genz reported on some derivatives of xylidine.—Dr. Rüdorff showed large crystals of carbonate of ammonium deposited from coal gas.—M. Bornemann exhibited glass tubes which had for some months been exposed to the action of steam under a pressure of eleven atmospheres. The glass showed deep notches and furrows where acted upon by the steam, but was not attacked in those parts which had remained immersed in the water of the boiler.—A curious transformation of forged iron into large crystals has been observed by M. Egelts. A cylinder used in a cotton-mill proved to consist of crystals apparently affecting the form of pentagonic dodecahedra of two or three millimetres in diameter.—Prof. Hoppe Seyler reported on the colouring matter of blood. He has found that hæmato-globulin does not pass directly into hæmatine, as has been supposed until now, but that the latter product derives by oxidation from hæmatochromogen discovered by the author.—Prof. Kekulé and Hideck have converted diazo-amidobenzol into azobenzol.—Dr. Köhler attacked the views lately published by Wanklyn, on the atomicity of sodium.—Dr. Schaer reported on the presence of ozone in the fluor spar of Wölberndorf, Saxony.

PHILADELPHIA

Academy Natural Sciences, January 11.—Professor O. C. Marsh, of Yale College, exhibited a series of specimens of the remains of birds from the Cretaceous and Tertiary of the United States, which showed that this class was well represented during these periods, although no species have yet been described from these formations in this country, and none indeed from older rocks, since it now appears to be well established that the bird-like footprints in the Connecticut Valley were made by Dinosaurian reptiles. Among the specimens shown were the remains of at least five species of Cretaceous birds, although but one or two species have hitherto been described from strata of this age in Europe. The present Cretaceous specimens were all found in the greensand of New Jersey, and with one exception in the middle marl-bed. They are all mineralised, and in the same state of preservation as the bones of extinct reptiles found with them in these deposits, and hence are readily distinguished from the remains of recent birds which have occasionally been found near the surface in the marl excavations of New Jersey. The most interesting of the specimens exhibited was the distal portion of a large and robust tibia, apparently of a swimming bird, about the size of a goose. It was found in the greensand at Birmingham, New Jersey, in the pits of the Pemberton Marl Company. For this new genus and species Professor Marsh proposed the name *Laornis Edvardsianus*. Two species of small wading birds, which appear to have been allied to the Curlews, were also represented each by the distal end of a tibia, and probably by some other less characteristic portions. The larger of these species, which was found in the greensand of the middle marl-bed at Hornerstown, New Jersey, was named *Palæstringa littoralis*. The smaller species, which was called *Palæstringa vetus*, was founded on the specimen mentioned by Dr. Morton in his "Synopsis of Cretaceous Fossils," p. 32, which has since, however, been generally regarded as a recent species. The specimen was found in the lowest marl-bed at Arneytown, New Jersey, and is now in the collection of the Academy. Portions of the humeri of two small and closely-related species, apparently of the Heron family, were part of the series shown. They were found deep in the greensand of the middle marl-bed near Hornerstown, New Jersey, in the pits of the Cream Ridge Marl Company. For the species thus represented the names *Vetardea elegans* and *Vetardea affinis* were proposed. The remains of several species of Tertiary birds were also exhibited by Professor Marsh. Among these was the lower extremity of tibia, closely resembling that of some of the Cranes. It was found in the Miocene o the Niobrara River, by Dr. F. V. Hayden, and is interesting as the only representative of a fossil bird yet detected in the Tertiary deposits west of the Mississippi. This specimen, which belongs to the Academy, indicated a new species, which was named *Grus Haydeni*. Another species of extinct birds was represented by portions of a humerus and radius, also in the collection of the Academy; they were found many years since in the Miocene of Maryland by Mr. T. A. Conrad. This species, which appears to be closely related to the Gulls, was named *Larus Conradii*. Several other interesting specimens of bird remains were shown, but most of them were not sufficiently characteristic to admit of determination. With the exceptions already mentioned, the fossils exhibited belonged to the museum of Yale College.

DIARY

THURSDAY, March 24.

Royal Society, at 8.30.—On the Madreporia dredged up by the expedition in H.M.S. *Porcupine*: Prof. Duncan.
Royal Institution, at 3.—Chemistry of Vegetable Products: Prof. Odling.
Zoological Society, at 8.30.—On the Birds of Veragua: Osbert Salvin.—Exhibition of a metamorphosed Axolotl: W. B. Tegetmeier.—On two rare species of Pheasants recently added to the Society's Collection: Mr. Sclater.
London Institution, at 7.30.—Geology: Dr. Cobbold.
Society of Antiquaries, at 8.30.—On the Greek Inscriptions found at Autun: Rev. W. B. Marriott.

FRIDAY, March 25.

Royal Institution, at 8.—Anglo-Saxon Conquest: Prof. Rolleston.
Quekett Microscopical Society, at 8.30.

SATURDAY, March 26.

Royal Institution, at 3.—The Sun: J. Norman Lockyer, F.R.S.

MONDAY, March 28.

Royal Geographical Society, at 8.30.
Royal Institute of British Architects, at 8.
Institute of Actuaries, at 7.
London Institution, at 4.—Chemistry: Prof. Bloxam.

TUESDAY, March 29.

Royal Institution, at 3.—Nervous System: Prof. Rolleston, M.D., F.R.S.
Institution of Civil Engineers, at 8.—Description of the St. Pancras Station, Midland Railway: W. H. Barlow, M.I.C.E., F.R.S.

WEDNESDAY, March 30.

Society of Arts, at 8.
Chemical Society, at 8.—Anniversary Meeting.

THURSDAY, March 31.

Royal Society, at 8.30.
Society of Antiquaries, at 8.30.

BOOKS RECEIVED

English.—The State, the Poor, and the Country: R. H. Patterson (Blackwood and Sons).—Quarterly Journal of the Geological Society (Longmans).—Photographic Art Journal, No. 1; illustrated (S. Low, Son, and Marston).—Choice and Chance: Rev. W. A. Whitworth (Bell and Daldy).—The Arts in the Middle Ages; illustrated: Paul Lacroix (Chapman and Hall).—United States Geological Survey of Colorado and New Mexico: F. D. Hayden (Washington).—Introductory Text-book to Physical Geography: D. Page (Blackwood and Sons).—Mrs. Loudon's First-book of Botany. Edited by D. Woosten (Bell and Daldy).—Principles of the Science of Colour: W. Benson (Chapman and Hall).

Foreign.—Handbuch der Lehre von den Geweben: S. Stricker.—Für Baum und Wald: M. F. Schleider.—Die Eiszeit der Erde: A. Braun.

CONTENTS

Printed by R. CLAY, SONS, & TAYLOR, at 7 and 8, Bread Street Hill, in the City of London, and published by MACMILLAN & CO. at the Office, 63, Bleecker Street, New York.—THURSDAY, March 24, 1870

THURSDAY, MARCH 31, 1870

THE SIZE OF ATOMS

THE idea of an atom has been so constantly associated with incredible assumptions of infinite strength, absolute rigidity, mystical actions at a distance, and indivisibility, that chemists and many other reasonable naturalists of modern times, losing all patience with it, have dismissed it to the realms of metaphysics, and made it smaller than "anything we can conceive." But if atoms are inconceivably small, why are not all chemical actions infinitely swift? Chemistry is powerless to deal with this question, and many others of paramount importance, if barred, by the hardness of its fundamental assumptions, from contemplating the atom as a real portion of matter occupying a finite space, and forming a not immeasurably small constituent of any palpable body.

More than thirty years ago naturalists were scared by a wild proposition of Cauchy's, that the familiar prismatic colours proved the "sphere of sensible molecular action" in transparent liquids and solids to be comparable with the wave-length of light. The thirty years which have intervened have only confirmed that proposition. They have produced a large number of capable judges; and it is only incapacity to judge in dynamical questions that can admit a doubt of the substantial correctness of Cauchy's conclusion. But the "sphere of molecular action" conveys no very clear idea to the non-mathematical mind. The idea which it conveys to the mathematical mind is, in my opinion, irredeemably false. For I have no faith whatever in attractions and repulsions acting at a distance between centres of force according to various laws. What Cauchy's mathematics really proves is this: that in palpably homogeneous bodies such as glass or water, contiguous portions are not similar when their dimensions are moderately small fractions of the wave-length. Thus in water, contiguous cubes, each of one one-thousandth of a centimetre breadth, are sensibly similar. But contiguous cubes of one ten-millionth of a centimetre must be very sensibly different. So in a solid mass of brickwork, two adjacent lengths of 20,000 centimetres each, may contain, one of them nine hundred and ninety-nine bricks and two half bricks, and the other one thousand bricks: thus two contiguous cubes of 20,000 centimetres breadth may be considered as sensibly similar. But two adjacent lengths of forty centimetres each might contain, one of them one brick and two half bricks, and the other two whole bricks; and contiguous cubes of forty centimetres would be very sensibly dissimilar. In short, optical dynamics leaves no alternative but to admit that the diameter of a molecule, or the distance from the centre of a molecule to the centre of a contiguous molecule in glass, water, or any other of our transparent liquids and solids, exceeds a ten-thousandth of the wave-length, or a two-hundred-millionth of a centimetre.

By experiments on the contact electricity of metals made eight or ten years ago, and described in a letter to Dr. Joule, which was published in the Proceedings of the Literary and Philosophical Society of Manchester, I found that plates of zinc and copper connected with one another by a fine wire attract one another, as would similar pieces of one metal connected with the two plates of a galvanic element, having about three-quarters of the electro-motive force of a Daniel's element.

Measurements published in the Proceedings of the Royal Society for 1860 showed that the attraction between parallel plates of one metal held at a distance apart small in comparison with their diameters, and kept connected with such a galvanic element, would experience an attraction amounting to two ten-thousand-millionths of a gramme weight per area of the opposed surfaces equal to the square of the distance between them. Let a plate of zinc and a plate of copper, each a centimetre square and a hundred-thousandth of a centimetre thick, be placed with a corner of each touching a metal globe of a hundred-thousandth of a centimetre diameter. Let the plates, kept thus in metallic communication with one another be at first wide apart, except at the corners touching the little globe, and let them then be gradually turned round till they are parallel and at a distance of a hundred-thousandth of a centimetre asunder. In this position they will attract one another with a force equal in all to two grammes weight. By abstract dynamics and the theory of energy, it is readily proved that the work done by the changing force of attraction during the motion by which we have supposed this position to be reached, is equal to that of a constant force of two grammes weight acting through a space of a hundred-thousandth of a centimetre; that is to say, to two hundred-thousandths of a centimetre-gramme. Now let a second plate of zinc be brought by a similar process to the other side of the plate of copper; a second plate of copper to the remote side of this second plate of zinc, and so on till a pile is formed consisting of 50,001 plates of zinc and 50,000 plates of copper, separated by 100,000 spaces, each plate and each space one hundred-thousandth of a centimetre thick. The whole work done by electric attraction in the formation of this pile is two centimetre-grammes.

The whole mass of metal is eight grammes. Hence the amount of work is a quarter of a centimetre-gramme per gramme of metal. Now 4,030 centimetre-grammes of work, according to Joule's dynamical equivalent of heat is the amount required to warm a gramme of zinc or copper by one degree centigrade. Hence the work done by the electric attraction could warm the substance by only $\frac{1}{16120}$ of a degree. But now let the thickness of each piece of metal and of each intervening space be a hundred-millionth of a centimetre instead of a hundred-thousandth. The work would be increased a millionfold unless a hundred-millionth of a centimetre approaches the smallness of a molecule. The heat equivalent would therefore be enough to raise the temperature of the material by 62°. This is barely, if at all, admissible, according to our present knowledge, or, rather, want of knowledge, regarding the heat of combination of zinc and copper. But suppose the metal plates and intervening spaces to be made yet four times thinner, that is to say, the thickness of each to be four-hundred-millionth of a centimetre. The work and its heat equivalent will be increased sixteen-fold. It would therefore be 990 times as much as that required to warm the mass by 10 cent., which is very much more than can possibly be produced by zinc and copper in entering into molecular combination. Were there in reality anything like so much heat of combination as this, a mixture of zinc and copper powders would, if melted in any one spot, run together, generating more than heat enough to melt each throughout; just as a large quantity of gunpowder if ignited in any one spot burns throughout without fresh application of heat. Hence plates of zinc and copper of a three-hundred-millionth of a centimetre thick, placed close together alternately, form a near approximation to a chemical combination, if indeed such thin plates could be made without splitting atoms.

The theory of capillary attraction shows that when a bubble—a soap-bubble for instance—is blown larger and larger, work is done by the stretching of a film which resists extension as if it were an elastic membrane with a constant contractile force. This contractile force is to be reckoned as a certain number of units of force per unit of breadth. Observation of the ascent of water in capillary tubes shows that the contractile force of a thin film of water is about sixteen milligrammes weight per millimetre of breadth. Hence the work done in stretching a water film to any degree of thinness, reckoned in millimetre-milligrammes, is equal to sixteen times the number of square millimetres by which the area is augmented, provided the film is not made so thin that there is any sensible diminution of its contractile force. In an article "On the Thermal effect of drawing out a Film of Liquid," published in the Proceedings of the Royal Society for April 1858, I have proved from the second law of thermodynamics that about half as much more energy, in the shape of heat, must be given to the film to prevent it from sinking in temperature while it is being drawn out. Hence the intrinsic energy of a mass of water in the shape of a film kept at constant temperature increases by twenty-four milligramme-millimetres for every square millimetre added to its area.

Suppose then a film to be given with a thickness of a millimetre, and suppose its area to be augmented ten thousand and one fold: the work done per square millimetre of the original film, that is to say per milligramme of the mass, would be 240,000 millimetre-milligrammes. The heat equivalent of this is more than half a degree centigrade of elevation of temperature of the substance. The thickness to which the film is reduced on this supposition is very approximately a ten-thousandth of a millimetre. The commonest observation on the soap-bubble (which in contractile force differs no doubt very little from pure water) shows that there is no sensible diminution of contractile force by reduction of the thickness to the ten-thousandth of a millimetre; inasmuch as the thickness which gives the first maximum brightness round the black spot seen where the bubble is thinnest, is only about an eight-thousandth of a millimetre.

The very moderate amount of work shown in the preceding estimates is quite consistent with this deduction. But suppose now the film to be further stretched, until its thickness is reduced to a twenty-millionth of a millimetre. The work spent in doing this is two thousand times more than that which we have just calculated. The heat equivalent is 1,130 times the quantity required to raise the temperature of the liquid by one degree centigrade. This is far more than we can admit as a possible amount of work done in the extension of a liquid film, A smaller amount of work spent on the liquid would convert it into vapour at ordinary atmospheric pressure. The conclusion is unavoidable, that a water-film falls off greatly in its contractile force before it is reduced to a thickness of a twenty-millionth of a millimetre. It is scarcely possible, upon any conceivable molecular theory, that there can be any considerable falling off in the contractile force as long as there are several molecules in the thickness. It is therefore probable that there are not several molecules in a thickness of a twenty-millionth of a millimetre of water.

The kinetic theory of gases suggested a hundred years ago by Daniel Bernouilli has, during the last quarter of a century, been worked out by Herapath, Joule, Clausius, and Maxwell, to so great perfection that we now find in it satisfactory explanations of all non-chemical properties of gases. However difficult it may be even to imagine what kind of thing the molecule is, we may regard it as an established truth of science that a gas consists of moving molecules disturbed from rectilineal paths and constant velocities by collisions or mutual influences, so rare that the mean length of proximately rectilineal portions of the path of each molecule is many times greater than the average distance from the centre of each molecule to the centre of the molecule nearest it at any time. If, for a moment, we suppose the molecules to be hard elastic globes all of one size, influencing one another only through actual contact, we have for each molecule simply a zigzag path composed of rectilineal portions, with abrupt changes of direction. On this supposition Clausius proves, by a simple application of the calculus of probabilities, that the average length of the free path of a particle from collision to collision bears to the diameter of each globe, the ratio of the whole space in which the globes move, to eight times the sum of the volumes of the globes. It follows that the number of the globes in unit volume is equal to the square of this ratio divided by the volume of a sphere whose radius is equal to that average length of free path. But we cannot believe that the individual molecules of gases in general, or even of any one gas, are hard elastic globes. Any two of the moving particles or molecules must act upon one another somehow, so that when they pass very near one another they shall produce considerable deflexion of the path and change in the velocity of each. This mutual action (called force) is different at different distances, and must vary, according to variations of the distance, so as to fulfil some definite law. If the particles were hard elastic globes acting upon one another only by contact, the law of force would be—zero force when the distance from centre to centre exceeds the sum of the radii, and infinite repulsion for any distance less than the sum of the radii. This hypothesis, with its "hard and fast" demarcation between no force and infinite force, seems to require mitigation. Without entering on the theory of vortex atoms at present, I may at least say that soft elastic solids, not necessarily globular, are more promising than infinitely hard elastic globes. And, happily, we are not left merely to our fancy as to what we are to accept for probable in respect to the law of force. If the particles were hard elastic globes, the average time from collision to collision would be inversely as the average velocity of the particles. But Maxwell's experiments on the variation of the viscosities of gases with change of temperature prove that the mean time from collision to collision is independent of the velocity, if we give the name collision to those mutual actions only which produce something more than a certain specified degree of deflection of the line of motion. This law could be fulfilled by soft elastic particles (globular or not globular); but, as we have seen, not by hard elastic globes. Such details, however, are beyond the scope of our present argument. What we want now is rough approximations to absolute values, whether of time or space or mass—not delicate differential results. By Joule, Maxwell, and Clausius we know that the average velocity of the molecules of oxygen or nitrogen or common air, at ordinary atmospheric temperature and pressure, is about 50,000 centimetres per second, and the average time from collision to collision a five-thousand-millionth of a second. Hence the average length of path of each molecule beween collisions is about $\frac{1}{100000}$ of a centimetre. Now, having left the idea of hard globes, according to which the dimensions of a molecule and the distinction between collision and no collision are perfectly sharp, something of apparent circumlocution must take the place of these simple terms.

First, it is to be remarked that two molecules in collision will exercise a mutual repulsion in virtue of which the distance between their centres, after being diminished to a minimum, will begin to increase as the molecules leave one another. This minimum distance would be equal to the sum of the radii, if the molecules were infinitely hard elastic spheres; but in reality we must suppose it to be very different in different collisions. Considering only the case of equal molecules, we might, then, define the radius of a molecule as half the average shortest distance reached in a vast number of collisions. The definition I adopt for the present is not precisely this, but is chosen so as to make as simple as possible the statement I have to make of a combination of the results of Clausius and Maxwell. Having defined the radius of a gaseous molecule, I call the double of the radius the diameter; and the volume of a globe of the same radius or diameter I call the volume of the molecule.

The experiments of Cagniard de la Tour, Faraday, Regnault, and Andrews, on the condensation of gases do not allow us to believe that any of the ordinary gases could be made forty thousand times denser than at ordinary atmospheric pressure and temperature, without reducing the whole volume to something less than the sum of the volume of the gaseous molecules, as now defined. Hence, according to the grand theorem of Clausius quoted above, the average length of path from collision to collision cannot be more than five thousand times the diameter of the gaseous molecule; and the number of molecules in unit of volume cannot exceed 25,000,000 divided by the volume of a globe whose radius is that average length of path. Taking now the preceding estimate, $\frac{1}{100000}$ of a centimetre, for the average length of path from collision to collision, we conclude that the diameter of the gaseous molecule cannot be less than $\frac{1}{500000000}$ of a centimetre; nor the number of molecules in a cubic centimetre of the gas (at ordinary density) greater than 6×10^{21} (or six thousand million million million).

The densities of known liquids and solids are from five hundred to sixteen thousand times that of atmospheric air at ordinary pressure and temperature; and, therefore, the number of molecules in a cubic centimetre may be from 3×10^{24} to 10^{26} (that is, from three million million million million to a hundred million million million million). From this (if we assume for a moment a cubic arrangement of molecules), the distance from centre to nearest centre in solids and liquids may be estimated at from $\frac{1}{140000000}$ to $\frac{1}{460000000}$ of a centimetre.

The four lines of argument which I have now indicated, lead all to substantially the same estimate of the dimensions of molecular structure. Jointly they establish with what we cannot but regard as a very high degree of probability the conclusion that, in any ordinary liquid, transparent solid, or seemingly opaque solid, the mean distance between the centres of contiguous molecules is less than the hundred-millionth, and greater than the two thousand-millionth of a centimetre.

To form some conception of the degree of coarse-grainedness indicated by this conclusion, imagine a rain drop, or a globe of glass as large as a pea, to be magnified up to the size of the earth, each constituent molecule being magnified in the same proportion. The magnified structure would be coarser grained than a heap of small shot, but probably less coarse grained than a heap of cricket-balls. W. T.

FRESENIUS'S ANALYSIS

Qualitative Chemical Analysis. By Dr. C. Remigius Fresenius. Seventh Edition. Edited by Arthur Vacher. 8vo., pp. viii. and 264. (London: Churchill, 1869.)

Quantitative Chemical Analysis. By Dr. C. Remigius Fresenius. Fifth edition. Edited by Arthur Vacher. 8vo., pp. viii. and 377. (London: Churchill, 1870.)

Anleitung zur qualitativen chemischen Analyse. By Dr. C. Remigius Fresenius. 8vo., pp. xii. and 240, with 43 woodcuts; price 4*s*. (Brunswick, 1869. London: Williams and Norgate.)

IN no branch of chemistry, perhaps, has more useful progress been made of late years than in analysis. The other departments of the science, technical and organic chemistry, for instance, have been cultivated with assiduity and even ostentation; while the study of analysis, invaluable and necessary as it is, has been comparatively neglected as humble and unadorned. Much of this apathy has no doubt arisen from the mechanical nature of the task of analytical discovery, which commonly requires a greater share of industry than intellectual effort. The gradual introduction of refined physical methods has, however, commenced, and will no doubt complete an entire change in the aspect of this subject.

Chemists will not need to be reminded of the obligations they owe to Fresenius, whose analytical manuals are deservedly known, and in common use in almost every laboratory. The enormous amount of special results they contain is hardly conceivable to an outsider, who will not readily appreciate the respect paid to them by grateful practitioners. The thirteenth edition (of which the first instalment has just reached us) has been retouched and improved, and is in every way worthy of the confidence of chemists. Its appearance has, however, suggested to us some reflections which might, not improbably, be carried out with advantage. Few readers will fail to observe that the dimensions of the book and the subject have both increased, and at a rate that will necessitate a remedy in the course of a few years. Possibly it may be agreed that, in addressing a single book to four kinds of students, the author has performed a somewhat superfluous task for three of them. Those who are engaged in pharmacy, the arts, manufactures, and agriculture, will all find here much more than they respectively require. The inconvenience obviously admits of easy removal; each class ought to have a handbook suited to its own peculiar demands, and to those alone. The mere economy of time thus effected would be an additional recommendation to such a step. Moreover, it would allow of altering, for the sake of the purely chemical student, the entire system of nomenclature and notation. These admittedly belong to a period that has passed away; and their presence in the book universally interferes much with its proper utility in the laboratory. The apology in the preface will hardly be accepted by teachers; neither can we suppose that the author, if writing specially, would say of chemistry that it is "the science which acquaints us with the substances of which our earth consists, their composition and decomposition, and mutual deportment generally." It is time that this barren and lifeless definition ceased to be adopted by every instructor. There is, indeed, a quaint mediæval tone about the whole of the book.

The historical reader will notice under the section devoted to "Operations," titles and processes and explanations that abound as we trace our steps backwards from Thénard. The practical investigator might regret the omission of Bunsen's method of filtration, of argentic sulphate as a common impurity in the nitrate, of the formation of Claudet's body as a test for cobalt. We see a condenser figured which could not easily be used with a continuous stream of water, and has been long abandoned in laboratories. Again, hydric nitrate is said to be purified by distilling at the temperature of ebullition; which does not, however, occur unless under that point. We may, nevertheless, assure the experimenter that he will not find in Dr. Fresenius's work more than a few errors of the kind which affect him. There is evidence throughout it of accumulated care and forethought, and the writer's clear exposition and systematic procedure are a proof both of unsparing labour and severe economy.

The author's two German treatises have hitherto been presented to the English student in the form of translations, which portrayed the characteristic features of the originals with satisfactory fidelity. But, for the reasons we have already intimated, there has been a general desire for such changes as would make each of these volumes a handy laboratory book. Mr. Vacher has boldly taken upon himself this task of dual reform, having "specially striven to meet the present wants of English students." He has no doubt succeeded in making two thoroughly English books, which will be most valuable to students; but they can no longer be legitimately termed editions of Fresenius, which they resemble only as a pen-and-ink sketch resembles a perfect picture. That the editor himself is to a certain extent conscious of this is tolerably apparent from the following passages, which are too important to be left unnoticed:—"The present edition has been entirely re-written and much condensed. . . . The metals have been grouped anew, and the old grouping of the acids has been abandoned. . . . The processes have been made as far as possible complete in themselves, so as to obviate constant reference to different pages of the book. Several new figures have been added, and the number of tables has been increased. I have endeavoured to render the arrangement as simple as possible" (preface to "Quantitative Analysis"). And again, "The language has been condensed, the notation and nomenclature have been modernised, the arrangement has been simplified. The consideration of rare inorganic bodies and of organic has been deferred to the latter part of the volume, where a section has been devoted to each. . . . The cause of analysis has been simplified in description, and the preliminary examination has been curtailed. . . . All the facts and, except in one or two trivial instances, all the processes given in this edition have the authority of Fresenius, but the principal changes in the arrangement have been made on my own responsibility" (preface to the "Qualitative Analysis"). Editions for which the editor is thus far responsible, while the reputed author is responsible for a part only of the *facts* (not the whole of them, as Mr. Vacher states), ought not to bear Fresenius's name in any other than a subordinate manner, all these works are, in reality, outlines of analytical chemistry on the basis of Fresenius.

Mr. Vacher has, on the whole, however, carried out successfully the various changes he had in view. The adoption of the prevailing notation is in itself an improvement, teachers having hitherto been compelled to use one interpretation for symbols in the lecture-room, and another in the laboratory. He has not, however, quite so well fulfilled his promise as to the nomenclature, which is still unsystematic, and therefore misleading. For example, at p. 3 ("Quantitative Analysis") we find *calcium chloride*, at p. 27 *carbonate of calcium*; at p. 40 *ferrous sulphide*, at p. 42 *sulphide of manganese*, at p. 40 *ferric oxide*, at p. 44 *alumina*. At p. 54 the word "acid" undergoes a very sudden transformation; "Ignited titanic *acid* does not dissolve in hydrochloric acid." These instances of haste, of which there are not a few, ought to be removed from the next edition.

It seems hardly probable that these large analytical treatises will be perfectly available for the use of students until they are divided into separate works. Subjects such as water analysis, manure analysis, volumetric analysis, assaying, &c., require, as we have said, a separate treatment. Mere condensation, however ably performed, will not accomplish a widely useful end. Mr. Vacher, nevertheless, deserves much credit for a hazardous experiment, which, though not altogether unimpeachable, is a real service to chemistry.

Our general impression of analysis is, that, both in point of scientific form and literary expression, it needs a strong stimulus from other quarters.

OUR BOOK SHELF

The Literature and Curiosities of Dreams. A commonplace Book of Speculations, concerning the mystery of Dreams and Visions, records of Curious and well-authenticated Dreams, and Notes on the various modes of Interpretation adopted in Ancient and Modern Times. By Frank Seafield, M.A. 2nd. Ed. Revised; pp. 518. (London: Lockwood and Co. 1869.)

IN this book the author has gathered together almost every kind of information on the subject of which it treats. The compilation of it has doubtless been a labour of love, and the author's great object has been to select, from all sources, whatever is most characteristic of his opinions which have been held on the subject of Dreams, and also all the best examples upon which these opinions have been founded. He tells us that no amount of research has been considered irksome or irrelevant, so that, in his opinion, "there is nothing extant in the way of dream-speculation or anecdote which is not fairly and impartially represented." The book is, in fact, a rich and methodically arranged storehouse of dreams and of opinions thereon, which will be valued by many who are merely curious, as well as by those who are more seriously interested about their causes and phenomena. It is likely to serve as a book of reference, or as one which may be had recourse to in spare half-hours, rather than as a work which will be taken up to be at once read and mastered.

Untersuchungen über Psychologie. Anmerkungen zu Robert Zimmermann's "Philosophische Propädeutik." Mit Rücksicht auf Herbart, J. H. v. Fichte, Ulrici, Fechner, Lindner, Drbal, Flüget, Nahlowsky, Lange, Darwin, C. Vogt, L. Büchner, Moleschott, Lotze, Hoppe, u.s.w. Von Dr. F. A. v. Hartsen. (Leipzig, 1869.)

Untersuchungen über Logik. Mit Rücksicht auf Apelt, Bolzaus, Drbal, Gratry, Kuno Fischer, Hegel, Herbart, Kant, Maudsley, J. Stuart Mill, Strümpell, W. Schuppe, Trendenburgh, Ueberweg, R. Zimmermann, u.s.w. Von Dr. F. A. v. Hartsen. (Leipzig, 1869.)

THESE publications by Dr. Hartsen are somewhat discursive criticisms of disputed matters in psychology and logic, and of the opinions of the different authorities whose names are mentioned on the title-pages. Neither of them lays claim to give a systematic account of the subject with which it deals, and both of them have the character of critical articles suited to a review, rather than of treatises. The "Psychological Inquiries" consist entirely of discussions upon Zimmermann's "Empirical Psychology," paragraph by paragraph, references being made to the numbered paragraphs in the original work. It will be obvious that this plan of procedure is rather trying to the reader who is obliged to guess from the critical observations at the nature of the opinions that are in question, and whose interest is not easily kept up in so desultory a disquisition. Nevertheless, if he is content to persevere, he will meet with much that is suggestive and instructive. The "Logical Inquiries," though not systematic and complete, will in like manner repay perusal; they are contributions to the foundation of a system of scientific logic.

Kurzes Lehrbuch der Physiologie des Menschen. Von Dr. E. Larisch. (Marburg: Oscar Ehrhardt. London: Williams and Norgate.)

THIS is very similar to Budge's little work, but smaller, and written in more of a narrative style. It therefore contains less matter, and this is especially the case in the part relating to the nervous system. Dr. Larisch has not the scientific eminence of Prof. Budge, and therefore speaks with less authority; on the other hand, he is free from the temptation of attaching too much importance to his own researches and views.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Formation of Ground Ice

I THINK the enclosed letter contains as good a description of the formation of ground ice as I have hitherto seen; I therefore send it to you, thinking it of sufficient interest to appear in NATURE. JOHN TYNDALL

Royal Institution, March 27

To PROFESSOR TYNDALL

I have been engaged since September last in making a survey for the Intercolonial railway, up the valley of the Matapediac, a stream about two hundred feet in width and four or five feet in depth, which discharges into the Restijinche river, about twenty miles above the head of the Baie des Chaleures.

The Matapediac, which is fed by large fresh water springs, runs over a rocky bottom covered with loose stones, ranging in size from coarse gravel to boulders as large as a hogshead, and the average current is about four miles an hour.

Early in November last the temperature went down in one night to 12°F., and on going out of camp the following morning I noticed large quantities of what appeared to be snow saturated with water floating down the stream, but not a particle of snow had fallen near us or for many miles round, as far as I could see by the mountain tops, nor had any ice formed on the surface of the river.

The water opposite where I stood was about six feet deep, and perfectly clear, so that I could see every stone on the bottom, and with the exception of the floating slush, the river was as it had been the previous day when the temperature was about 50° F.; I got into a canoe and paddled with the current for half a mile or so, and in shooting some small rapids, where the water in places was not more than two or three feet deep, I noticed on the bottom, masses of the slush clustered round and between the boulders, and a slight touch with the paddle was sufficient to free these clusters, when they rose to the surface, and were carried away by the current. I continued down the stream for three or four miles, and noticed the same thing in every rapid, where the water was shallow and *ruffled* by stones at the bottom.

The buoyancy of this slush was such that when detached from the bottom it rose so rapidly as to force itself well out of the water, and then floated off about half submerged.

I watched this forming of slush for many days, and in several cases found small stones imbedded in the floating slush, having been torn from the bottom when the buoyancy of the slush, aided by the running water, caused it to rise.

The temperature continued getting lower daily, and the slush in the rapids formed more rapidly than it was carried away, so much so that a bar or dam was formed across the river at each rapid, backing up the water in some cases five and six feet, when it generally found an outlet over the adjoining land, and into its natural bed again, or the head of water became sufficient to tear away the obstruction, which by this time had become a solid frozen mass.

All this time, no properly crystallised ice had formed on the surface of the river, the current being too rapid, but the slush or "anchor ice" as the trappers call it, was forming in deeper water than it had formed in before, indeed all over the river bottom, and was rising and floating away as I have already described. Eventually the temperature got down to two and three degrees below zero, when the river *surface* began to freeze in the eddies and along the edges, and the open water space became narrower every day, and was filled with floating "anchor ice" and detached masses of solid ice, which here and there became jammed and frozen together, so as to form ice-bridges on which we could cross.

These ice-bridges served as booms to stop much of the floating ice, which froze solid the moment it came to rest; and in this manner the river at last became completely frozen over for about forty miles of its length, but not until after we had experienced five weeks of steady cold, with the thermometer never above +12° F., and frequently down to −16° F.

It is just possible that what I have endeavoured to describe may suggest something to you, or it may be an old story; if so, please pardon the intrusion. W. G. THOMPSON

Dalhousie, N.B., February 18

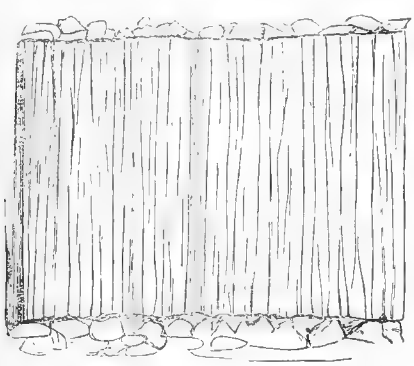
Prismatic Ice—Sandstone Boulder in Granite

WALKING over the Rough Tors of Dartmoor a few days since in company with a friend, Mr. Walter Morrison, M.P., we observed two phenomena which it appears to us should be recorded, since if they have been met with before, we believe that the occurrence of either is infrequent.

In a small roadside quarry, most probably excavated for the purpose of obtaining stones for metalling the road, we observed some granite undergoing the process of decomposition. The stratification of the superincumbent mass struck us as being peculiar, and we entered the quarry to examine it.

The near examination exhibited to us that the surface of the granite had been elevated to the extent of an inch and a half from the rock by means of ice. The whole of the ice, which formed a very extensive bed, was made up of a series of small needle-like prisms, which stood upon their end like minute basaltic columns. These prisms were all perpendicular to the surface of the rock on which they stood; that is, those that were situated on the side of the quarry projected horizontally, while those at our feet stood in a position vertical to the floor. These latter, instead of being on a rock, were upon the surface of granitic gravel, the débris of the surrounding rocks. And in the same manner as the ice mass had forced out the surface of rock at the sides of the quarry, it had raised up the entire surface of the gravel; and this so completely, that we only observed it in consequence of examining it for comparison, since the ice was strong enough to bear our weight when not increased by irregular motion.

It was to us new and interesting to find the ice assuming this basaltic form, and occupying the position in which we found it, in relation to the rock and gravel over which



a. Débris on the surface of the *b* Crystalline ice.
c. Surface of rock.

it lay. Water in freezing will put on almost any description of crystalline appearance; there is no reason then why upright needle-like prisms may not be as frequent as any other, but that it should put on this form in this position can only be explained when we know how the water that formed the ice got to that position. In trying to obtain this information, we observed that the lines of the stratification in the softer parts corresponded above and below the ice, and that those on the surface of the ice agreed with those at the base. This would demonstrate that the water did not arrive in that position as water flows over the surface of the rock. Had that been the case, the outer crust would, if it had not fallen off, have been moved a degree lower, which would have coincided with the spot at the base from which it was removed. The only way in which, therefore, the formation of the ice appears possible, consistently with existing facts, is by the water having percolated through the decomposing granite rock. There, oozing gradually, it only froze when it came to the surface, while the weight of water behind had power to lift off the external crust of rock. This again was forced outward by the water still pressing behind, the whole freezing only when it passed out through the rock. One and, I must admit, a strong objection to this idea lies in the circumstance that the gravel at the bottom of the quarry was elevated in the same manner; there cannot have been at the bottom of the quarry a weight of water from behind pressing the basaltic prisms outward. Whatever may be the cause of the phenomenon, there can be no doubt but that it must be an immensely powerful agent in the disintegration of rocks.*

The second feature that appears to be worthy of being recorded is that of a water-worn sandstone pebble imbedded in a mass of granite. On the summit of the hill near Warren Tor, we came upon the remains of a cairn, most of the stones of which had been carted away, apparently for the purpose of being built into a house that has recently been erected near it. The stones generally consisted, like those common to all the cairns of the moor, of angular pieces of granite of irregular shape and size, but mostly of such proportions as could be conveniently conveyed by hand. Lying near what appeared to have been the centre of the cairn were two other slabs of granite of much larger proportions. These were about four feet long by two and a half broad, and from eight to twelve inches thick, and appeared to us to have been the remains of the kistvaen, over which the stones were heaped. In one of these granite slabs my companion pointed out to me the presence of a large water-worn boulder pebble of sandstone. The pebble was about ten inches long by five wide at its longest and broadest diameters. It projected from the surface of the granite some two inches, or thereabout, but the form of the stone was suggestive of the larger part being still imbedded in the granite. The stone narrows somewhat towards one extremity, and at that extremity it is cracked across. The pebble is of blue sandstone, smooth but not polished on the surface, and at its contact with the granite exhibits no alteration of character.

The granite is of the grey colour that is so common on Dartmoor. It is of a coarse quality, containing numerous large crystals of felspar, locally known by the name of horses' teeth. The granite generally appears as if it had been deposited round the pebble, the crystalline character taking a bend somewhat conformable to the curves of the pebble.

The original rock from which the pebble was derived it is difficult to determine. In its general appearance the pebble bears a resemblance to those found on the pebble ridge of Northam Burrows, in North Devon. Unfortunately the granite slab itself is not in its natural bed. But since it forms part of an ancient monumental erection, and was placed in its present position long before the period when the transition of heavy weights could be easily accomplished, it is more than probable that the slab was procured from the neighbouring Tor.

The surface of the granite slab is very clean, being free from lichen and dendrital growths. But that it was weather-worn before it was placed in its present position, I think that there can be little doubt. Had it been artificially split, supposing that our ancient people had the knowledge and skill to have split the rock, they could not have done so without breaking the pebble as well.

Mr. Sorby demonstrated some five or six years since the presence of water in the hollows existing in crystals in granite, and thus came to the conclusion that granite must have been formed under a heat of less than 500 degrees. This heat is still, it appears to me, sufficient to convert all the water upon the surface of the earth into steam. But the rounded and smoothed character of the pebble of which we are speaking is evidence that water was present in its liquid state when it was rubbed into its present rounded form. It also demonstrates that the pebble was in existence as a hard rock before the granite was formed. Thus it would seem clear that when this granite was formed, the temperature of the earth must have cooled down to below the boiling point of water.

Plymouth, March. C. SPENCE BATE

* Since this was written I have seen Mr. Bonney's letter on Prismatic Ice. The wind during our walk was N.E. The quarry lay in a sheltered position. The temperature was probably as Mr. Bonney states.

Apparent Size of the Moon

THE public have what are called "views" on everything in the world and out of it. De Morgan well says that, on the question "whether there be volcanoes on the unseen side of the moon larger than those on our side," the odds are, that the first comer has a pretty stiff opinion in three seconds. Does anyone believe that the moon is made of green cheese? One woman hailing from this enlightened neighbourhood told my wife that she thought the moon was *made of blood!* She was not a Latter-day Saint, either.

If opinions differ as to the moon's constituents, they are not very divergent as to her apparent size. Mr. Thomas K. Abbott, of Trinity College, Dublin, in his singularly learned and able work called "Sight and Touch," 1864, p. 57, collates the opinions of Heraclitus, Aristotle, and Cicero, who all assign to the moon's apparent diameter the length of a foot. He quotes, too, from Arthur Collier's *Clavis Universalis* the expression, "the moon which I see is a little figure of light, no bigger than a trencher." The old-fashioned trencher was about a foot in diameter. The late Sir William Rowan Hamilton pointed out to me this passage in Descartes' "Dioptricæ," cap. VI. § xx.:—"Abque hoc patet ex eo quod Luna et Sol, qui sunt e numero corporum remotissimorum, quæ contueamur, ... *pedales ut plurimum, vel ad summum bipedales* nobis videantur," &c. Bishop Berkeley, as Philonous, asks Hylas, "Since, according to you, men judge of the reality of things by their senses, how can a man be mistaken in thinking the moon a plain, lucid surface, about a foot in diameter?" Many more such cases could be cited from ancients and moderns, all concurring in assigning a foot, or something between one foot and two feet, to the apparent diameter of the moon. Let me now cite two recent cases. A law-clerk, whose lay notions certainly owed very little to books, told me that the moon always appeared to him of the size of a door-handle. This would give, at most, a diameter of three inches. An eminent astronomer tried his daughter with the question. She replied that the moon looked to her about *half a degree*. He said, "Come, you learned that from astronomy; but answer as a girl of common sense." She now replied, "A small saucer." That would be some four or five inches in diameter.

I suppose I was too early spoiled by trigonometry to enter into the merits of this style of estimate. Look at the moon as I may, I cannot compare her to anything definite, as a door-handle, a saucer, or a trencher. Judging by the distance at which we ordinarily see such things in the use of them, they all seem to me to be enormously too large. Looking at the moon through my window, sitting three or four yards from it, I should guess that a wafer stuck on it would eclipse her. My own conviction is that in the ordinary estimate (or rather comparison), there is no reference, the most covert or subconscious, to any standard of distance. True, thirty-six or thirty-seven yards would be the distance at which Arthur Collier's trencher would subtend the same angle as the moon. But who thinks of this in connection with a trencher, which is usually under a man's nose or on the kitchen rack or shelf, at a distance not exceeding four or five yards? In another letter I will, if you will allow me, call attention to some of the *veræ causæ* which are probably concomitant in these popular estimates; and this I shall do in respect to the apparently augmented size of the moon's disc on the horizon. Meanwhile, let me ask as a preliminary to that inquiry, is it a matter of fact that *to the naked eye* the moon does subtend the same angle at the horizon as at positions near the zenith? I am unable to perform the measurement myself, not merely for want of a proper instrument, but by reason of the fact that I always see in the moon a multitude of discs partially overlapping each other, five of which I can distinctly count. It would be awkward to find that one was attempting to solve an imaginary problem, like the Royal Society over King Charles's fish.

Ilford, March 24 C. M. INGLEBY

THE "lurking idea" of Mr. G. C. Thompson, that the moon looks about the size of a fourpenny piece, seems to me to show that those views of it have made most impression on him which he has taken when standing a few feet from the window, when it would cover some such space: while others, with the one foot or two feet idea, have been more wrought upon by unconscious measurement of it against trees in the garden, or house chimneys along the street. I do not think we can get beyond this, in regard to a "personal equation." As to the apparent difference between the moon near the horizon and the moon in mid-sky, your correspondents have not yet referred to the theory that the felt degree of convergence of the eyes is one help toward measuring distance; which, however, soon ceases as the object is more remote, and the convergence insensible: and that, in looking at the moon along the earth's surface, we feel that she lies beyond this limit by comparison with the objects which intervene, while in looking up through free air there is no such gradation to guide us; that, therefore, we assign, unconsciously, a greater distance to her, *i.e.*, a greater "lurking idea" of estimated magnitude for the same apparent surface, in the former case than in the latter. I write from a dim recollection of one of Sir Sidney Smith's lectures on Moral Philosophy, but I suppose the notion is trite to experts. Is there anything in it? J. R.

Concomitant Sounds and Colours.

THE investigation of the points of resemblance between two sciences, has its value and assists the development of both. Music gains by being thus raised from a mere sentimental recreation to the dignity of a science, but the science of colours may perhaps gain even more than music by the comparison, and this because the ear, in most persons, can distinguish with more precision a discord in sound, than the eye can in colour.

In the most ancient times it was well known that concomitant sounds produce a resultant whose vibrations are generated by the interference of the sonorous waves of the primaries. This physical fact was not only known but employed in the construction of Gregorian *Cantilenas*, whose succession of intervals shows a deep penetration of this truth.

The law of combination of the vibrations of concomitant sounds may be stated thus:—The resultant of two sounds has, as its number of vibrations, the difference between those of its primaries. Also any number of sounds combined two and two together, the 1st with the 2nd, the 2nd with the 3rd and so on, will form a series of resultants, which similarly combined two and two together form a second series of resultants; so that (continuing this process) we finally arrive at a single resultant which is that of the original combination. This law has been tested experimentally by Hallström and Scheibler. I considered that it might be useful to express this law by a general formula, so I will give it in this place.

If we have n sounds whose vibrations are $x_1, x_2, x_3, \ldots x_n$, all in ascending order as to *pitch*, then the resultant will be

$$R = (x - 1)_{n-2} (x_2 - x),$$

where the suffixes must be treated as indices, and $(x - 1)_{n-2}$ expanded according to the binomial theorem.

R is not, however, a resultant in the strict sense requiring the vanishing of the primary sounds; it might, perhaps, be better called the *Residuant* of the combination. It is thus the measure of the imperfection of the combination which is, more or less, a discord according as R is less or more nearly related to the primaries.

If we apply this formula we shall easily see that the tonic and subdominant generate a note two octaves below the subdominant: for example, C and F generate $\frac{F}{4}$. Also CEG, CGC^2, and CDE and all similar combinations in which the vibrations stand in arithmetical progression generate no residuant, hence, combinations of this class are perfectly consonant and are called by Boethius *equisonal concords*. (The combination CDE is discordant enough on a modern instrument, but I mean CDE tuned perfectly without temperament.)

Supposing then that an impression is made upon the retina by two or more colours in juxtaposition, analogous to that produced on the auditory nerve by two or more simultaneous sounds. We shall perceive that two complementary colours placed side by side ought to increase in intensity that one whose vibrations are the most rapid. Red and green, for instance, should give intensity to the green, since D and G generate $\frac{G}{4}$. Moreover, the colours corresponding to the *equisonal concords* ought to give us the most harmonious combinations; these are they:—

Violet	placed	between two	yellows,
Red	,,	,,	greens,
Orange	,,	,,	blues,
Yellow	,,	,,	indigo-blues,
Green	,,	,,	violets,
Blue	,,	,,	reds.

Yellow and indigo-violet ought always to be discordant, as they correspond with the discord F B or *tritone*. Again—

Violet, orange, green
Yellow, blue, violet
Indigo-blue, red, yellow
Violet, red, orange
Yellow, green, blue
Indigo-blue, violet, red.

} All correspond to equisonal concords and should form perfectly harmonious combinations.

It will be noticed that these tints must be precisely of the same shade as those in Newton's image; the slightest variation would destroy the harmony of colour. I have no doubt if pigments were made of tints identical with the ring-colours, the beauty of these combinations would be appreciated by all who used them.

It will be noticed also that D, F, A generate $\frac{B\flat}{16}$, or red, yellow, blue generate indigo-blue. A, C, E generate $\frac{F}{16}$, or blue, violet, orange generate yellow. I need not increase the length of my paper by more examples, but leave the field open to all who choose to test the above formula as regards its application to combinations of colour.

In conclusion, I wish to make the following suggestion.

Should it be admitted that the musical scale, in its perfect division into intervals under the law of harmonical progression, finds its counterpart in Newton's rings rather than in the prismatic spectrum, would not a spectroscope, constructed so as to give the image of these rings, be a more perfect instrument for the comparison of colours than that in present use? We might also have a double spectroscope, capable of giving the images of the secondary rings produced by the refraction of homogeneous light, the cube roots of whose diameters give the series which corresponds to that of the musical scale.

We should in this way be able to know the melody which corresponds to the light of any particular star, provided that the light be strong enough to produce the images of the secondary rings.

W. S. OKELY

Rome, February 18

Analogy of Colour and Music

AT the close of my short article on the Analogy of Colour and Music, published in your journal of January 13, I ventured to ask for the opinion of physicists on the subject. Accordingly I, for one, am much indebted to the many able contributors who thereupon addressed you. The correspondence having apparently ceased, I will now ask your permission to say a few words.

Although I do not attach too much importance to the closely approximate ratios, given in my paper, between the wave-lengths of colour and the notes of the diatonic scale, yet I think nothing said by your correspondents seriously affects my main argument.

The most important objection is that urged by Mr. Monro (NATURE, No. 14), who regards the correspondence of the two ratios as a mere coincidence, depending on the mode by which Prof. Listing obtained his scale of wave-lengths of the colours. By an ingenious calculation, Mr. Monro shows that Listing most probably "divided his spectrum into seven equal parts upon some scale which varies inversely as the wave-lengths; . . . so that it nearly corresponds with the ratios of the musical scale because these approximately form a harmonic progression." When I wrote my article I had not read Listing's paper, but, as stated, quoted his numbers from a recent memoir by Thalen. The perusal of his original paper shows me that Listing obtained his numbers in the following manner, which I think Mr. Monro will see confirms his calculation, but overrides his criticism:—

Employing pure spectra, and using every precaution, Listing experimentally determines the transition places and the central region of each colour, Fraunhofer's lines being used as landmarks. The observations are repeated upon the normal spectrum obtained by diffraction, and are checked by the independent observations of others, and by repetitions at different times. In this way the remarkable fact is disclosed that the numbers of vibrations at the transition spots form an *arithmetical progression* throughout the entire series of colours. For reasons given he adopts the following scale of colours—brown, red, orange, yellow, green, cyanogen, indigo, and lavender, and states as a law that this series can be physically expressed by an arithmetical progression of eight numbers, in which the last is the double of the first. He then proceeds to discover the constant factor by which this series can be turned into absolute values. After considerable care, and upon grounds fully detailed, he selects $48\frac{1}{2}$ billions as the number of vibrations per second expressing the range of each colour. The possible error he shows to be $\pm$ 0·038—taking billions as unity—and this, though apparently a large error, is actually less than $\frac{1}{7}$th of the interval between the two D lines.

The number of vibrations corresponding to the extreme limit of colour at the red end, he fixes, upon Helmholtz's and Angstrom's authority, at 363·9 billions per second, or a wave-length of 819·8 millionths of a millimetre. By adding to the former number half the colour interval—namely, $24\frac{1}{4}$ billions—the normal centre of the first colour is obtained; $48\frac{1}{2}$ billions added to that gives the centre of the next colour, and so on. These, and also the limits of each colour, are tabulated along with the corresponding wave-lengths.

Listing closes his paper with the statement of a general law, that while the successive vibrations of the series of colours in the spectrum form an arithmetical progression, the same is also true of the logarithms of the vibrations corresponding to each musical note in the so-called chromatic scale. Hence he concludes that although physiologically and pyschologically there may be differences, yet there is an indisputable *physical* basis for the analogy between tones and colours. From this very imperfect outline it will be seen that the entire memoir is a remarkable one, and I am surprised no translation of it has appeared. It is certainly the most important contribution to the analogy that I have met with, and renders my little paper on the subject quite unnecessary.

Mr. Okely, writing to the next number of NATURE, gives some additional evidence in favour of the analogy, but thinks my process of taking the mean of the limiting wave-lengths of each colour, in order to obtain the average wave-length, is "very rough." Mr. Okely does not tell us what he would do in such a case, but turns aside to become the champion of the widths of Newton's rings, charging me with having treated too summarily this old and famous ally of the analogy. But to this, my next critic, Mr. Sedley Taylor, replies, although other considerations also influenced me in neglecting this analogy.

Mr. Taylor, however, believes that he has deprived my comparison of any serious importance, for the following reason:—In the musical scale, he observes, "a very slight departure from accurate pitch in any concord provokes a harsh dissonance;" but "any part of any one colour-division produces an equally harmonious effect on the eye," because "in the spectrum there is very little, if any, change of tint except close to the extremities of any one colour." Whilst it would be certainly unwise to push the analogy too far, I think Mr. Taylor is here mistaken. There *is* a very material difference of tint in different parts of any one colour in the spectrum. Regarded alone, any region of the spectrum, like any single musical note, is, of course, equally agreeable; but it is not the case that an equally harmonious effect on the eye is produced by the combination of *any* part of any one colour-division with some other colour.

Mr. Stuart, in an interesting letter, points out a close relationship, discovered by Prof. Mossotti, between the intensities of the light in different parts of a normal spectrum and the notes of the diatonic scale. Finally, Dr. Chaumont, in an early part of this discussion, showed, what indeed had been noticed elsewhere, that if the ratios I give be accepted, then the once-called primary colours, red, yellow, and blue, correspond to the notes of the common chord; whilst the modern triad, red, green, and blue, correspond to the tonic, sub-dominant and dominant, that is to say, to the three notes which in music constitute the fundamental base of the scale.

In addition to what has been brought forward in this correspondence, there are some valuable remarks on the analogy in one of Dr. Thomas Young's memoirs, "Philosophical Transactions, 1802"; in Chevreul's work on the "Principles of Harmony of Colour"; in a recent brochure by Dr. Macdonald on "Sound and Colour"; and, lastly and chiefly, in §19 of Helmholtz's "Physiological Optics." In this last a list is given of authorities who have written on the subject since the time of Newton.

Reviewing what has been done in this matter, there are therefore, I believe, many good grounds for asserting the existence of a physical basis for the analogy between colour and tone. Opposed, it is true, are many mental differences: such, for example, as that of the judgment, which is far more prompt and correct in determining a colour than a note; then also colour primarily involves only the conception of *space*, music the conception of *time*. Nevertheless against all this we may place the facts that the source of harmony in colour, as in music, is purely a question of *relative* impressions; and a painting and a melody evoke a succession of ideas that have a remarkable similarity.

Woodlands, Isleworth, March 13

W. F. BARRETT

THE METROPOLITAN MAIN DRAINAGE

THE magnitude of the underground works of London is scarcely understood by the public in general. They occasionally hear of this or that sewer or pumping station being completed, but as the greater portion of them is hidden beneath the surface of the ground, nothing but a personal inspection during the process of construction can give any adequate idea of the vastness and intricacy of our drainage system. The following facts, collected from the engineer's papers on the subject and reports to the Metropolitan Board of Works, may present to the mind some notion of these great works. There are about 1,400 miles of sewers in London, 82 miles of which are intercepting sewers of "The Main Drainage." The area drained by the intercepting sewers is about 100 square miles. The total amount of sewage and rainfall which they will carry off is 63 million cubic feet per day, or equal to a lake as large as Hyde Park four feet in depth. There have been consumed in their construction about 340 million bricks, and upwards of 900,000 cubic yards of concrete. The total engine-power employed is 2,380 nominal horse-power, but this will soon be increased by about 400 horse-power on the construction of the Pimlico pumping station. The cost of these works when completed will be a little over 4,000,000*l*.

The accompanying map shows the position of the main intercepting sewers, pumping stations, outfalls, &c., and it will be seen that they run east and west, the reason for this being that the main sewers in existence before the construction of the main drainage, emptied themselves into the Thames, running more or less at right angles to it, and consequently, by constructing the intercepting sewers parallel to it, they would cross all the main outlets and cut off their sewage. In carrying out this scheme the great object to be kept in view was to discharge as much sewage as possible by gravitation, in order to avoid the great expense of pumping. To this end three lines of sewers are constructed on each side of the Thames, called respectively the High, Middle, and Low Level sewers, together with their branches. On the north side the High and Middle Level discharge their sewage by gravitation; that of the Low Level, which joins them at Abbey Mills, being pumped up a height of 36 feet into the Upper Level, when all three flow through the Northern Outfall Sewer to the reservoirs at Barking, and discharge their contents into the river by gravitation. On the south side the Low Level sewer meets the High and Middle Level at Deptford, where its contents are pumped a height of 18 feet into the Outfall Sewer, which carries the three streams to Crossness, where they can discharge by gravitation; but as this can only be done at low water, they are generally pumped a height of 20 feet into the reservoirs. Such is the general outline of the Main Drainage scheme, as being carried out by Mr. Bazalgette, the able engineer of the Metropolitan Board of Works.

Before commencing these works a large number of experiments and observations had to be made in order to decide the numerous knotty points that suggested themselves: such as the determination of the position of the outfalls, the shape and inclination of the sewers, the amount of sewage and rainfall to be provided for, the amount to be pumped, &c., &c., each requiring a great amount of labour and study. The results arrived at, and which were acted upon, may be summed up as follows:—That it was necessary to take the sewage down the river as far as Barking Creek; that its lowest mean velocity should be 1½ miles per hour; the quantity of sewage to be intercepted was, in populous districts, 750,000 gallons per square mile per day; the amount of rainfall to be provided for was a quarter of an inch per day; the form of the sewers was to be circular, and the sewage was to be discharged at or about the time of high water. The above are a few of the principles upon which the Main Drainage of London is based.

THE WORKS.—The High Lever Sewer North commences near Hampstead Hill, where it intercepts the Fleet Sewer. It varies in size from 4ft. in diameter to 9ft. 6in. by 12ft., is about seven miles long, and drains an area of about ten square miles in its course from Hampstead to its junction with the Middle Level at Old Ford. It passes under three railways, the New River, and Sir George Duckett's Canal, in the last case the top of the sewer is within 2 ft. of the waters in the canal.

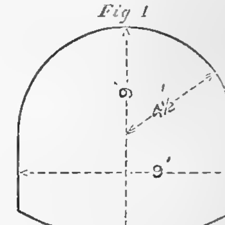
The Middle Level Sewer commences near Kensal Green and flows to its junction with the High Level at Old Ford. The total length of the main line, together with the Piccadilly branch, is about 11½ miles; the area drained is 17½ square miles; in form it varies from 4ft. 6in. by 3ft. to 9ft. 6in. by 12ft. Six miles of this sewer were constructed in tunnel. In its course it passes under two canals and one railway, and over the Metropolitan line, across which it was carried without interfering with the traffic, the bottom of the sewer being only a few inches above the chimneys of the engines.

At the junction of the High and Middle Level sewers there is a large "penstock" and "weir" chamber, for the purpose (should occasion demand) of letting storm waters or all the sewage flow into the River Lea. It is 150ft. in length, 40ft. wide, and 36ft. high, and fitted with five large penstocks or valves, which are raised or lowered by machinery.

The Low Level North will commence by a junction with the Western Drainage near Cremorne, and flow along the intended Chelsea Embankment to Pimlico, where its contents will be pumped up a height of 17½ feet into the remaining length, which will flow *viâ* the Thames Embankment to Abbey Mills. Its length, including branches, is about 12¼ miles, and it varies in size from 6ft. 9in. to 10ft. 3in. diameter. The area drained by it, including the Western Drainage, the sewage of which it receives, is 24½ square miles. This sewer is by far the most interesting on the north side, in consequence of the large works in connection with it. In the first place, it receives the drainage of the Isle of Dogs, in consequence of which, what was formerly little better than a marsh is now perfectly habitable; in the second place, it will pass along the two new embankments, viz., Chelsea and the Northern Thames; and in the third, its contents will be twice lifted by steam power, the lift at Pimlico being over 17ft., and that at Abbey Mills 36ft. At Blackfriars Bridge, where it intercepts the Fleet, there will be a large penstock-chamber fitted with four penstocks and as many tide flaps, to prevent the return of the tide at high water. A large portion of this sewer, namely, that extending from Blackfriars to Abbey Mills, will be executed for the most part in tunnel.

The Northern Outfall Sewer, which receives the whole of the sewage on the north side of the Thames, is totally unlike any other portion of the Main Drainage system, being entirely above the ordinary level of the ground. The first length, from B to C (see plan), consists of a double line of sewers, each being 9ft. by 9ft. of the section shown in Fig. 1 running parallel to each other; at C it receives the contents of the Low Level, and from this point to the reservoirs at Barking it is of the section shown in Fig. 2, which is three parallel culverts 9ft. by 9ft. built upon a concrete foundation and covered by an earthen embankment, the top of which would serve as a road or railway. In its course to Barking it crosses the River Lea and six streams, four railways, and ten roads. Fig. 3 gives a general idea of the method adopted for carrying the sewers over the streams, railways, &c. It consists of three cast-iron culverts carried between four wrought-iron girders, the top being covered with cast-iron plates, which support the ballasting, roadway, &c.; the parapets are ornamented with cast-iron mouldings.

Fig 1



The contents of this sewer are received by the reservoirs at Barking. These are about 9½ acres in extent, and 16¾ft.

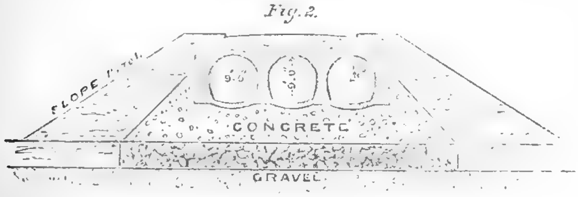
THE MAIN DRAINAGE OF LONDON

deep, covered in by brick arches, the floor being paved with stone. Attached to each is an outlet fitted with penstocks, &c. The Abbey Mills pumping station is a work of such magnitude and importance that but a scanty idea can be given of it here: suffice it to say, that there are eight engines employed, of a gross power of 1,140 horse-power, which work sixteen double-acting pumps of 3ft. 10½in. diameter and 4½ft. stroke. The engines are supplied by sixteen boilers, each being 8ft. diameter and 30ft. long. The engine and boilers, coal stores, &c., are enclosed in a fine block of buildings beautifully decorated.

Fig. 2.

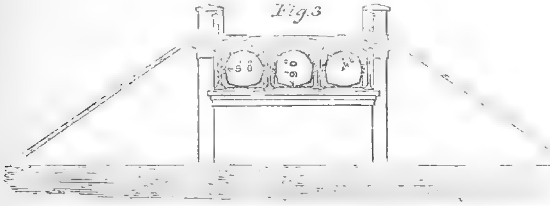


The Southern High Level, or Effra Branch Sewer, commences at Dulwich, and flows in a south-easterly direction to a junction with the Middle Level or High Level main line at New Cross. It is 4½ miles in length, ¼ mile of which is in tunnel. It varies in size from 7ft. diameter to a form similar to one of the culverts in Fig. 2, only the dimensions are 10ft. 6in. by 10ft. 6in.

The Southern Middle Level, or High Level main line, commences at Clapham, and flows under Deptford Creek to the Outfall Sewer. It, together with the High Level, drains an area of about 20 square miles. It is carried under Deptford Creek by four 3ft. 6in. diameter iron pipes. Overflows for storm waters are provided, which discharge into the Creek, if necessary.

The Low Level Sewer South commences at Putney, and flows to Deptford pumping station, where its contents are pumped up a height of 18 feet, by four engines 125 horse-power each, into the Outfall Sewer. Its length is about 10 miles, and it drains an area of about 20 square miles, the greater portion of which is considerably below high-water mark. It varies in size from one culvert 4 ft. in diameter, to two, each 7ft. by 7ft. The soil in which it was executed was exceedingly treacherous in places, being greatly charged with water: in one case sufficient engine-power had to be employed to pump ten million gallons per day, in order to keep the works clear of water. The Bermondsey branch of this sewer is two miles in length,

Fig. 3



and from 5ft. to 5ft. 6in. diameter. It joins the Low Level at High Street, Deptford.

The Southern Outfall Sewer, which receives the contents of the High, Middle, and Low Level sewers, flows from Deptford to the reservoirs at Crossness. Unlike the Northern Outfall, it is underground for its entire length. It is 11ft. 6in. diameter, and 7¾ miles in length. One mile of it was constructed in tunnel under the town of Woolwich. The outfall of this sewer is of such a level as to allow of the sewage being discharged at low water, but it will be pumped into the reservoirs, and there stored till high water.

The Crossness pumping station reservoirs are situated on the northern side of Erith Marshes at the point marked P on the map. They extend over 6½ acres. The reservoirs are similar to those at Barking. There are four beam engines employed of 125 horse-power each, which drive eight pumps, each pump having four compound plungers. The engines are supplied by twelve Cornish boilers 30ft. long and 8ft. diameter. The ordinary amount of sewage to be lifted is about 60,000 gallons per minute, the lift varying from 10ft. to 30ft., which necessitated a peculiar construction in the pumps. The sewage is delivered from the pumps into the reservoirs till high water, when it is discharged into the river. The foundations for the reservoirs, &c., had to be sunk 25ft. below the surface, as the ground consists of peat and sand. On the top of the reservoirs are built the manager's, schoolmaster's, and labourers' cottages, coal stores, school, and workshops, the centre space being laid out as ornamental gardens, the whole forming quite a village of some hundred inhabitants.

NOTES

THE last number of the Proceedings of the Royal Society contains the names of the 53 candidates, from among whom, 15 will be selected by the council for election into the society. The list is a varied one, and there is as usual a large number of medical candidates—21; Art and Literature being also represented. Here is the list:—William Baker, C.E., E. M. Barry, R.A., Rev. Francis Bashforth, B.D., B. E. Brodhurst, F.R.C.S., Samuel Brown, P.I.A., James Brunlees, C.E., F. T. Buckland, M.R.C.S., G.W. Callender, F.R.C.S., Commander W. Chimmo, R.N., F. Le G. Clark, F.R.C.S., Henry Dircks, Alex. Fleming, M.D., P. Le Neve Foster, Sir Charle Fox, C.E., William Froude, T. M. Goodeve, E. H. Greenhow, M.D., E. T. Higgins, M.R.C.S., Rev. Thomas Hincks, Charles Horne, Rev. A. Hume, LL.D., James Jago, M.D., W. S. Jevons, George Johnson, M.D., M. K. King, M.D., J. A. Langridge, C.E., N. S. Maskelyne, M. T. Masters, M.D., Major F. G. Montgomerie, R.E., Alfred Newton, Andrew Noble, Thomas Nunnely, F.R.C.S., E. L. Ormerod, M.D., Captain Sherard Osborn, R.N., Rev. Stephen Parkinson, B.D., Captain R. M. Parsons, R.E., W. O. Priestly, M.D., C.B. Radcliffe, M.D., W. H. Ransom, M.D., E. J. Reed, C.B., W. J. Russell, Ph.D., R. H. Scott, John Shortt, M.D., Edward Thomas, C. F. Varley, C.E., G. F. Verdon, C.B., Augustus Voelcker, Ph.D., Viscount Walden, P.Z.S., G. C. Wallich, M.D., A. T. H. Waters, M.D., Samuel Wilks, M.D., Captain C. W. Wilson, R.E., and John Wood, F.R.C.S.

THE *Pall Mall Gazette* has very properly called public attention to Lord Kinnaird's imputation of dishonesty brought against the late Master of the Mint, the lamented Graham. The good old rule, *de mortuis nil nisi bonum*, is one with which Lord Kinnaird does not seem to be acquainted; it is charitable, indeed, to suppose that he sinned in ignorance. He probably also does not know that Graham was a far greater man than he, and that Graham's name will live long after Lord Kinnaird's has been forgotten.

ON Saturday the members of Working Men's Clubs visited the British Museum, under the guidance of Professor Owen and Mr. Henry Woodward. Professor Owen explained the nature of the extinct animals. The next visit will be made to the National Gallery, under the guidance of Mr. Francis Turner Palgrave.

THE examinations for the gold and bronze medals offered as prizes for proficiency in Physical and Political Geography, by the Royal Geographical Society, were held on Monday last, 28th inst. Forty-one schools had been invited to compete, out of which number nineteen accepted, sending a total of fifty-nine candidates: thirty-four in Physical, and twenty-five in Political Geography. The names of the successful candidates will be announced at the ensuing anniversary meeting.

IN the introductory lecture to his course of Comparative Anatomy, delivered at the Royal College of Surgeons, Prof. Flower discusses the objection to the theory of the origin of species by the process of natural selection, founded on the existence of corresponding types of structure in the Monodelphous and Didelphous sections of mammalia. He considers the probabilities, instead of being against the independent origin of such similar structures, are exceedingly in their favour. The lecturer lays down as a valuable guiding principle in morphological studies, that when we wish to discover the distinguishing characters between different organisms, it is necessary to examine them in their most fully developed condition; if, on the other hand, our object is to trace their resemblance, their intimate relationships, we must study them in their early embryonic stages.

THE *Revue des Cours Scientifiques* reports that the Sars subscription now approaches 9,000 francs. Subscriptions have been received from Germany, Hungary, and America. In France nearly all the professors of higher instruction in science have subscribed to it.

WE have received from the Royal Society a report of Prof. Duncan's important paper on the Madrepores of the *Porcupine* Expedition. We shall return to this subject after completing Dr. Carpenter's report of the more general results of the expedition.

PROF. TYNDALL will have much to answer for in the results that may be expected from the spread of his "dust and disease" theory. It is stated by the *Athenæum* that a new idea has been broached in a recent lecture by Mr. Bloxam, the lecturer on chemistry to the department of artillery studies. He suggests that the committee on explosives, abandoning gun cotton, should collect the germs of small-pox and similar malignant diseases, in cotton or other dust-collecting substances, and load shells with them. We should then hear of an enemy dislodged from his position by a volley of typhus, or a few rounds of Asiatic cholera. We shall expect to receive the particulars of a new "Sale of Poisons" Act, imposing the strictest regulations on the sale by chemists of packets of "cholera germs" or "small-pox seed." Probably none will be allowed to be sold without bearing the stamp of the Royal Institution, certifying that they have been examined by the microscope and are warranted to be the genuine article.

WE have received from Professor H. A. Newton, of Yale College, a report on the meteor-display of November last, from which it appears that the cloudy weather prevented continuous observations in most parts of the United States. In the few stations, however, where the skies were clear, the observers furnish ample testimony to the appearance of unusual numbers of meteors on the morning of Nov. 14, the display continuing for several hours. The most successful observations were made at Pensacola, Florida, where they were observed in extraordinary numbers from 1·15 till dawn, most numerously between 3 and 4 a.m.; at Santa Barbara, California, where 556 meteors were observed between 1·18 and 3·43 a.m.; and at Fredericton, New Brunswick. Prof. Newton remarks that if the whole number coming during the twelve or more hours of the display had been condensed into an hour or two, as in 1866, we should have had a like though not equally brilliant shower.

THE Council of the University of Otago, New Zealand, announces that it is now prepared to consider applications from candidates for two of the professorial chairs to be instituted for classics, including Greek, Latin, the English language and literature; and for Mathematics and Natural Philosophy. The salary attached to each chair will be 600*l.* per annum, which will commence to run from the date of embarkation, besides the class fees, which have been fixed at 3*l.* 3*s.* for attendance on each professor, per term of six months, commencing in the beginning of May of each year. An adequate allowance will be made for passage money and outfit. All candidates must be graduates of some established and recognised university. No religious test will, however, be required from any person to entitle him to hold office in the university, or to graduate or to hold any advantage or privilege thereof. Applications from candidates must be addressed to John Auld, Esq., W.S., Edinburgh, agent of the Province of Otago in Britain, and must be accompanied with testimonials and certificates. They must be in his hands on or before the 1st day of April next. Further information relative to the university and the statistics of the province will be afforded on application to the agent.

BY the provisions of the late Dr. William J. Walker's foundation two prizes are annually offered by the Boston Society of Natural History for the best memoirs, written in the English language, on subjects proposed by a Committee appointed by the Council. For the best memoir presented, a prize of sixty dollars may be awarded; if, however, the memoir be one of marked merit, the amount may be increased, at the discretion of the Committee, to one hundred dollars. For the memoir next in value a sum not exceeding fifty dollars may be given; but neither of these prizes is to be awarded unless the papers under consideration are deemed of adequate merit. Memoirs offered in competition for these prizes must be forwarded on or before April 1st, of the years specified below, prepaid and addressed "Boston Society of Natural History, for the Committee on the Walker Prizes, Boston, Mass." Each memoir must be accompanied by a sealed envelope enclosing the author's name, and superscribed by a motto corresponding to one borne by the manuscript. Subject of the Annual Prize for 1870: "The reproduction and migration of *Trichina spiralis.*" Subject of the Annual Prize for 1871: "On the mode of the natural distribution of plants over the earth."

THE following are the Afternoon Scientific Lectures of the Royal Dublin Society, to be delivered during April and May, at four o'clock on Saturdays, in the Lecture Theatre. April 2nd, Dr. J. Emerson Reynolds, "On Ozone, Nature's bleaching agent and disinfectant." April 9th, Dr. H. Minchin, "On some interesting phenomena of sound. April 16th, Prof. E. Hull, "On the extension of the Coal-fields of England under the newer formations." April 30th, Prof. Wyville Thomson, "On the Cruise of the *Porcupine.*" May 7th, Mr. H. N. Draper, "On Colours from coal-tar." May 14th, Mr. C. R. C. Tichborne, "On Atmospheric Dust."

A COURSE of lectures for women on the science and practice of music, by Mr. Sullivan, will be delivered at South Kensington, under the patronage of the Science and Art Department, shortly after the close of Prof. Oliver's course on botany. It will include a class for part-singing.

WE have received a pamphlet entitled "Proposals for the Illumination of Beacons and Buoys," by Mr. Thomas Stevenson, F.R.S.E. The author discusses the different sources of illuminations for beacons and buoys, and the different applications of sound for warnings during fogs. The subject is a highly important one, and we purpose to return to it at an early period.

ACCORDING to the *British Medical Journal*, Sir W. Fergusson is about to resign the chair of systematic surgery at the Medical School of King's College, and Mr. Partridge his appointment as surgeon to the hospital. Sir William will, however, be appointed professor of clinical surgery, while Mr. Partridge still retains the chair of anatomy. Mr. Wood is expected to succeed Sir W. Fergusson as professor of systematic surgery;

he will also be appointed to the rank of full surgeon to the hospital. Two vacancies will therefore occur, that of assistant-surgeon to the hospital, and demonstrator of anatomy.

WE learn from *Van Nostrand's Eclectic Engineering Magazine* (New York) that the Darien Canal project is reviving. The United States steamer *Nipsic*, attached to the South Atlantic squadron, is under orders to proceed to the Isthmus of Darien to make surveys and explorations, with a view to determine the best location for an inter-oceanic canal. A similar survey on the Pacific shore of the Isthmus will be made at a future day.

M. FAVRE has recently detected evidences of the glacial period in the Caucasus, and M. Ed. Collomb finds traces, in the form of moraines and erratic blocks, of its having existed with great severity in the central plateau of France. This plateau forms an almost circular geological island 300 kilometres in diameter; its altitude increases progressively from north to south, and it is terminated on the south and west side by a barrier, the highest points of which, the Mézenc, the Plomb du Cantal, and the Mont d'Or rise to a height of from 1,750 to 1,900 metres (5,700 to 6,200 feet), above the level of the sea.

THE sense of taste has rarely been submitted to scientific examination, or at all events has attracted far less attention than its sister senses of sight and hearing, perhaps on account of the impossibility of treating it mathematically. That it differs to a remarkable extent in different individuals is, however, as every culinary artist would acknowledge, a matter of fact; and it is also well known that it is capable of extraordinary cultivation in some men, as shown by wine- and tea-tasters obtaining lucrative posts from the delicacy of their discrimination. Recently Dr. Keppler has published a paper in Pflüger's "Archives of Physiology," in which he gives the details of a number of experiments he performed with a view of determining the limits of gustatory discrimination for sapid substances in various degrees of concentration. In these experiments he first made a standard solution, and then successively employed weaker or stronger solutions, which were tasted with due precautions, sometimes before and sometimes after the standard solution, until no perception of flavour was distinguished. The substances he selected were common salt, quinine, phosphoric acid, and glycerine, all of them, be it observed, destitute of odour, which plays so important a part, often overlooked, in our ideas of the flavour of particular objects. In one series of experiments the solutions were taken freely into the mouth, rolled over all parts of the membrane lining it, and then discharged. In a second series the solutions, were more carefully applied to the surface of the tongue alone by means of a camel's hair brush. It was found in both cases that when a difference of 2·5 per cent. existed between the standard solution and the experimental one, the observers were able to form a correct judgment on the point that there *was* a difference in 53 per cent. of the trials, but when there was a difference between the two solutions amounting to 10 per cent., the answers were rightly given in 80 per cent. of all the trials. A more correct judgment was given when the standard solution was tasted before than after the experimental one with common salt and quinine, and the acuteness in the perception of a difference was greater when the trial solution was stronger than when weaker, but the opposite held good for the other substances.

WE learn from the *Gardener's Chronicle* that the Royal Horticultural Society has decided to retain a portion of the old Chiswick garden, comprising the ground occupied by the glass-houses, and extending sufficiently eastwards and southwards to include the large vinery and the fruit-room.

M. DUCLAUX has lately been experimenting on the effect of certain gases in retarding the incubation of silkworms' eggs. He has also been trying the effect of cold upon the same organisms, and finds that instead of retarding the period of incubation, it accelerated it: in fact, that eggs laid in autumn and left to themselves would only incubate in spring; but if subjected to the action of a freezing mixture for forty days, they would hatch into larvæ immediately afterwards, on being submitted to the action of a gentle heat. If these experiments are confirmed, M. Duclaux will have undoubtedly discovered an entirely new principle in physiology: that cold has a vivifying influence. Hitherto physiologists have always believed that its action was diametrically opposite.

THE journal of the Proceedings of the Asiatic Society of Bengal for January has an interesting article by Dr. F. Skoliczka on the Kjökenmöddings of the Andaman Islands.

THE *Journal of the Scottish Meteorological Society* has some interesting papers on the cold of last summer in Ireland, and upon the thunderstorms of Scotland. The part also contains a report on the Meteorology of Scotland and a minute of the meeting of the Council.

THE *American Gas Light Journal* reports that at a recent meeting of the Lyceum of Natural History of New York, Mr. Loew stated that ozone is produced copiously by blowing a strong current of air into the flame of a Bunsen's burner. He also communicated that he had observed the decomposition of sulphurous acid with production of sulphuric acid and deposition of sulphur, when an aqueous solution of the gas was exposed for two months to sunlight.

THE hardness of metals may now be ascertained by the aid of an instrument invented by a French engineer. It consists of a drill turned by a machine of a certain and uniform strength. The instrument indicates the number of revolutions made by the drill. From this, compared with the length of the bore-hole produced, the hardness of the metal is estimated. It is said that a great proportion of the rails now employed in France are tested by this instrument.

*ON THE TEMPERATURE AND ANIMAL LIFE OF THE DEEP SEA**

III.

AN enormous addition has been made to the list of British *Echinodermata* by the discovery in our own seas of a number of species which had been previously known only as Norwegian or Arctic; and these often occurred in extraordinary abundance. One of the most interesting of these was the large and beautiful feather-star, the *Antedon* (*Comatula*) *Eschrichtii*, hitherto known only as inhabiting the shores of Greenland and Iceland, but now found over all parts of our cold area. On the other hand, the influence of temperature was marked not only by the absence of many of the characteristically southern types of this group, but by the dwarfing of others to such an extent that the dwarfed specimens might be regarded as specifically distinct, if it were not for their precise conformity in structure to those of the ordinary type. Thus the *Solaster papposa* was reduced from a diameter of six inches to two, and had never more than ten rays, instead of from twelve to fifteen; and *Asterocanthion violaceus* and *Cribella oculata* were reduced in like proportion. But, in addition, several echinoderms have been obtained which are altogether new to science, most of them of very considerable interest. The discovery, at the depth of 2,435 fathoms, of a living crinoid of the Apiocrinite type, closely allied to the little rhizocrinus (the discovery of which by the Norwegian naturalists was the starting-point of our own deep-sea explorations), but generically differing from it, cannot but be accounted a phenomenon of the greatest interest alike to the zoologist and the palæontologist. Another remarkable representative of a type supposed to have become extinct, occurred at depths of 440 and 550 fathoms in the warm area; being a large *echinidan* of the *diadema* kind, the "test" of which is composed of plates separated from one another by membrane, instead of being connected by suture, so as to resemble an armour of flexible chain-mail, instead of the inflexible cuirass with which the

* A Lecture delivered at the Royal Institution (continued from p. 540).

ordinary echinida are invested. This type bears a strong resemblance to the very singular fossil from the white chalk, described by the late Dr. S. P. Woodward, under the name of *Echinothuria floris*. Specimens were also obtained, both in the first and third cruises, of a most interesting *clypeastroid*, which is closely allied to the *infulaster*—specially characteristic of the later chalk.* These constitute only a sample of the interesting novelties belonging to this group, which our explorations brought to light.

Besides further additions to the remarkable group of vitreous sponges, which were made in the area over which the Globigerina-mud extends, a peculiar and novel form of sponge was found to be one of the most generally diffused inhabitants of the cold area. This sponge is distinguished by the possession of a firm branching axis, of a pale sea-green colour, rising from a spreading root, and extending itself like a shrub or a large branching gorgonia. The axis is loaded with siliceous spicules; and spicules of the same form are contained in the soft flesh which clothes it.

The foraminifera collected in the *Porcupine* expedition present features of no less interest, though their scale is so much smaller. The enormous mass of Globigerina-mud (sometimes almost pure, sometimes mixed with sand) that everywhere covers the deep-sea bottom in the region explored, save where its temperature is reduced nearly to the freezing-point, may be judged of from the fact that in one instance the dredge brought up half-a-ton of it from a depth of 767 fathoms. The resemblance of this deposit to chalk is greatly strengthened by the recognition of several characteristically cretaceous types among the foraminifera scattered through the mass of *Globigerinæ* of which it is principally composed; as also of the *Xanthidia*, frequently preserved in flints. Not many absolute novelties presented themselves among the foraminifera that form true calcareous shells; the chief point of interest being the occurrence of certain types of high organisation at great depths, and their attainment of a size that is only paralleled in much warmer latitudes, or in the Tertiary or yet older formations. This is especially the case with the Cristellarian group, which has a long geological range; and also with the Milioline, of which specimens of unprecedented size presented themselves. The most interesting novelty was a beautiful Orbitolite, which, when complete, must have had the diameter of a sixpence, but which, from its extreme tenuity, always broke in the process of collection. Of Arenaceous Foraminifera, however, which construct tests by cementing together sand-grains, instead of producing shells, the number of new types is such as seriously to task our power of inventing appropriate generic names. Many of these types have a remarkable resemblance to forms previously known in the chalk, the nature of which had not been recognsied. Some of them throw an important light on the structure of two gigantic Arenaceous types from the upper greensand, recently described by the speaker and Mr. H. B. Brady, an account of which will appear in the forthcoming part of the "Philosophical Transactions;" and there is one which can be certainly identified with a form lately discovered by Mr. H. B. Brady in a clay-bed of the carboniferous limestone.

The question now arises, whether—as there must have been deep seas in all geological periods, and as the changes which modified the climate and depth of the sea-bottom were for the most part very gradual—we may not carry back the continuity of the accumulation of Globigerina-mud on some part or other of the ocean bed into geological epochs still more remote; and whether it has not had the same large share in the production of the earlier calcareous deposits, that it has undoubtedly had in that of the later. The foraminiferal origin of certain beds of the carboniferous limestone, for example, appears to be indicated by the presence of *Globigerinæ*, long since observed by Professor Phillips in sections of them, as well as by the fact just stated. The subcrystalline character of these rocks cannot be regarded as in any way antagonistic to such an idea of their origin, since it is perfectly well known that all traces of the organic origin of calcareous rocks may be completely removed by subsequent metamorphism, —as in the chalk of the Antrim coast.

What is the source of nutriment for the vast mass of animal life covering the abyssal sea-bed, is a question of the greatest biological interest. That animals have no power of themselves generating the organic compounds which serve as the materials of their bodies—and that the production of these materials from the carbonic acid, water, and ammonia of the inorganic world, under the influence of light, is the special attribute of vegetation —is a doctrine so generally accepted, that to call it in question would be esteemed a physiological heresy. There is no difficulty in accounting for the alimentation of the higher animal types, with such an unlimited supply of food as is afforded by the *Globigerinæ* and the sponges in the midst of which they live, and on which many of them are known to feed. Given the Protozoa, everything else is explicable. But the question returns,—on what do these Protozoa live?

The hypothesis has been advanced that the food of the abyssal Protozoa is derived from diatoms and other forms of minute plants, which, ordinarily living at or near the surface, may, by subsiding to the depths, carry down to the animals of the sea-bed the supplies they require. Our examination of the surface-waters, however, has afforded no evidence of the existence of such mycrophytic vegetation in quantity at all sufficient to supply the vast demand; and the most careful search in the Globigerina-mud has failed to bring to light more than a very small number of specimens of these siliceous envelopes of Diatoms, which would most assuredly have revealed themselves in abundance, had these Protophytes served as a principal component of the food of the Protozoa that have their dwelling-place on the sea-bed. Another hypothesis has been suggested, that these Protozoa which are so near the border of the vegetable kingdom, may be able, like plants, to generate organic compounds for themselves, manufacturing their own food, so to speak, from inorganic materials. But it is scarcely conceivable that they could do this without the agency of light; and as it is obviously the want of that agency which excludes the possibility of vegetation in the abysses of the ocean, the same deficiency would prevent animals from carrying on the like process.

A possible solution of this difficulty, offered by Professor Wyville Thomson in a lecture delivered last spring, has received so remarkable a confirmation from the researches made in the *Porcupine* expedition, that it may now be put forth with considerable confidence. It is, he remarked, the distinctive character of the Protozoa, that "they have no special organs of nutrition, but that they absorb water through the whole surface of their jelly-like bodies. Most of these animals secrete exquisitely-formed skeletons, sometimes of lime, sometimes of silica. There is no doubt that they extract both of these substances from the sea-water, although silica often exists there in quantity so small as to elude detection by chemical tests. All sea-water contains a certain amount of organic matter in solution. Its sources are obvious. All rivers contain a large quantity; every shore is surrounded by a fringe, which averages about a mile in width, of olive and red sea-weeds; in the middle of the Atlantic there is a marine meadow, the Sargosso Sea, extending over 3,000,000 of square miles; the sea is full of animals which are constantly dying and decaying; and the water of the Gulf Stream, especially, courses round coasts where the supply of organic matter is enormous. It is, therefore, quite intelligible that a world of animals should live in these dark abysses: but it is a necessary condition that they should chiefly belong to a class capable of being supported by absorption through the surface, of matter in solution; developing but little heat, and incurring a very small amount of waste by any manifestation of vital activity. According to this view, it seems highly probable that at all periods of the earth's history some form of the Protozoa—rhizopods, sponges, or both—predominated over all other forms of animal life in the depths of the sea; whether spreading, compact, and reef-like, as in the Laurentian and Palæozoic *Eozoon;* or in the form of myriads of separate organisms, as in the *Globigerinæ* and *Ventriculites* of the chalk."*

During each cruise of the *Porcupine*, samples of sea-water obtained from various depths, as well as from the surface, at stations far removed from land, were submitted to the Permanganate test, after the method of Prof. W. A. Miller, with an addition suggested by Dr. Angus Smith for the purpose of distinguishing the organic matter in a state of decomposition from that which is only decomposable; with the result of showing the uniform presence of an appreciable quantity of matter of the latter kind, which, not having passed into a state of decomposition, may be assimilable as food by animals, being, in fact, protoplasm in a state of extreme dilution. And the careful analyses of larger quantities collected during the third cruise, which have been since made by

* This was believed at the time to be an entirely new discovery; but since the return of the *Porcupine* we have learned that a type generically, if not specifically, the same, had been obtained by Count Pourtales during his most recent dredgings in the Gulf of Mexico, and had been described by Mr. Alex. Agassiz under the name *Pourtalesia miranda*.

* "The Depths of the Sea," a lecture delivered in the theatre of the Royal Dublin Society, April 10, 1869.

Dr. Frankland, have fully confirmed these results, by demonstrating the highly azotized character of this organic matter, which presents itself in samples of sea-water taken up at from 500 to 750 fathoms' depth, in such a proportion that its universal diffusion through the oceanic waters may be safely predicted.

Until, therefore, any other more probable hypothesis shall have been proposed, the sustenance of animal life on the ocean-bottom at any depth may be fairly accounted for on the supposition of Prof. Wyville Thomson, that the protozoic portion of that fauna is nourished by direct absorption from the dilute protoplasm diffused through the whole mass of oceanic waters, just as it draws from the same mass the mineral ingredients of the skeletons it forms. This diffused protoplasm, however, must be continually undergoing decomposition, and must be as continually renewed; and the source of that renewal must lie in the surface-life of plants and animals, by which (as pointed out by Prof. Wyville Thomson) fresh supplies of organic matter must be continually imparted to the oceanic waters, being carried down even to their greatest depths by that liquid diffusion which was so admirably investigated by the late Professor Graham.

Not only, however, has the nutrition of the abyssal fauna to be explained; its respiration also has to be accounted for; and on this process also the results of the analyses of the gases of the sea-water made during the *Porcupine* expedition throw very important light. Samples were collected not only at the surface, under a great variety of circumstances, but also from great depths; and the gases expelled by boiling were subjected to analysis according to the method of Prof. W. A. Miller—the adaptation of his apparatus to the exigencies of ship-board having been successfully accomplished during the first cruise by Mr. W. L. Carpenter. The general average of thirty analyses of surface-water gives the following as the percentage proportions:—25·1 oxygen, 54·2 nitrogen, 20·7 carbonic acid. This proportion, however, was subject to great variations, as will be presently shown. As a general rule, the proportion of oxygen was found to diminish, and that of carbonic acid to increase, with the depth; the results of analyses of intermediate waters giving a percentage of 20·0 oxygen, 52·8 nitrogen, and 26·2 carbonic acid; whilst the results of analyses of bottom-waters gave 19·5 oxygen, 52·6 nitrogen, and 27·9 carbonic acid. But bottom-water at a comparatively small depth often contained as much carbonic acid and as little oxygen as intermediate water at much greater depths; and the proportion of carbonic acid to oxygen in bottom-water was found to bear a much closer relation to the abundance of animal life (especially of the more elevated types), as shown by the dredge, than to its depth. This was very strikingly shown in an instance in which analyses were made of the gases contained in samples of water collected at every fifty fathoms, from 400 fathoms to the bottom at 862 fathoms, the percentage results being as follows:—

	750 fath.	800 fath.	Bottom 862 fath.
Oxygen	18·8	17·8	17·2
Nitrogen	49·3	48·5	34·5
Carbonic Acid	31·9	33·7	48·3

The extraordinarily augmented percentage of carbonic acid in the stratum of water here immediately overlying the sea-bed was accompanied by a great abundance of animal life. On the other hand, the lowest percentage of carbonic acid found in bottom-water, viz. 7·9, was accompanied by a "very bad haul." In several cases in which the depths were nearly the same, the analyst ventured a prediction as to the abundance, or otherwise, of animal life, from the proportion of carbonic acid in the bottom-water; and his prediction proved in every instance correct.

It would appear, therefore, that the increase in the proportion of carbonic acid and the diminution in that of the oxygen, in the abyssal waters of the ocean, is due to the respiratory process, which is no less a necessary condition of the existence of animal life on the sea-bed, than is the presence of food-material for its sustenance. And it is further obvious that the continued consumption of oxygen and liberation of carbonic acid would soon render the stratum of water immediately above the bottom completely irrespirable—in the absence of any antagonistic process of vegetation—were it not for the upward diffusion of the carbonic acid through the intermediate waters to the surface, and the downward diffusion of oxygen from the surface to the depths below. A continual interchange will take place at the surface between the gases of the sea-water and those of the atmosphere; and thus the respiration of the abyssal fauna is provided for by a process of diffusion, which may have to operate through three miles or more of intervening water.

The varying proportions of carbonic acid and oxygen in the surface-waters are doubtless to be accounted for in part by the differences in the amount and character of the animal life existing beneath; but a comparison of the results of the analyses made during the agitation of the surface by wind, with those made in calm weather, showed so decided a reduction in the proportion of carbonic acid, with an increase in that of oxygen, under the former condition, as almost unequivocally to indicate that superficial disturbance of the sea by atmospheric movement is absolutely necessary for its purification from the noxious effects of animal decomposition. Of this view a most unexpected and remarkable confirmation has been afforded by the following circumstance:—In one of the analyses of surface-water made during the second cruise, the percentage of carbonic acid fell as low as 3·3, while that of oxygen rose as high as 37·1; and in a like analysis made during the third cruise, the percentage of carbonic acid was 5·6, while that of oxygen was 45·3. As the results of every other analysis of surface-water were in marked contrast to these, it became a question whether they should not be thrown out as erroneous; until it was recollected that, whilst the samples of surface-water had been generally taken from the bow of the vessel, they had been drawn in these two instances from abaft the paddles, and had thus been subjected to such a violent agitation in contact with the atmosphere, as would pre-eminently favour their thorough aëration.

Hence, then, it may be affirmed that every disturbance of the ocean-surface by atmospheric movement, from the gentlest ripple to the most tremendous storm-wave, contributes, in proportion to its amount, to the maintenance of animal life in its abyssal depths —doing, in fact, for the aëration of the fluids of their inhabitants, just what is done by the heaving and falling of the walls of our own chest for the aëration of the blood which courses through our lungs. A perpetual calm would be as fatal to their continued existence as the forcible stoppage of all respiratory movement would be to our own. And thus universal stagnation would become universal death.

Thus it has been shown that the bed of the deep sea, even in the immediate neighbourhood of our own shores, is an area of which the conditions have until lately been as completely unknown as those of the ice-bound regions of the poles, or of the densest forests, the most arid deserts, the most inaccessible mountain-summits, that lie between the tropics; and further, that by the systematic employment of the sounding-apparatus, the thermometer, and the dredge, almost as complete a knowledge can be gained of those conditions, as if the explorer could himself visit the abyssal depths he desires to examine. Of the important discoveries in almost every department of science, but more particularly in what Mr. Kingsley has well termed Bio-Geology, which may be anticipated from the continuation and extension of an inquiry of which the mere commencement has yielded such an abundant harvest, the speaker felt it scarcely possible to form too high an expectation. And, in conclusion, he referred to the systematic and energetic prosecution of deep-sea explorations by the United States Coast Survey and by the Swedish Government —the results of which prove to be singularly accordant with those now briefly expounded—as showing that other maritime powers are strongly interested in the subject; and expressed the earnest hope that the liberal assistance of Her Majesty's Government, which has already enabled British naturalists to obtain the lead in this inquiry, would be so continued as to enable them to keep it in the future. In particular, he called attention to the suggestion lately thrown out by M. Alex. Agassiz, that an arrangement might be made by our own Admiralty with the naval authorities of the United States, by which a thorough survey, physical and biological, of the North Atlantic should be divided between the two countries; so that British and American explorers, prosecuting in a spirit of generous rivalry labours most important to the science of the future, might meet and shake hands on the Mid-Ocean.

W. B. CARPENTER

NOTE.—Tables I. and II. on the following page give the Temperature of the Sea at different Depths—(I.) in the Channel between the North of Scotland, the Shetland Isles, and the Faroe Islands (the Roman Numericals indicate the *Lightning* Temperature-Soundings, corrected for pressure); and (II.) near the Western margin of the North Atlantic Basin, as ascertained by *Serial* and by *Bottom* Soundings.

PHYSICS

Mechanical Theory of Heat

WE translate the following passages from a paper by Dr. Meyer, of Heilbronn:—

It has been inferred from the meteorite theory, which supposes the sun to derive its heat from the impact of planeto-kosmic masses, that the entire machine of creation must eventually come to a standstill. I gladly seize the opportunity which now offers itself, to state that I do not share this view. The doctrine of the development of heat by the collision of spatially separate masses, has but just arisen, has therefore advanced but little, and cannot yet serve as an appropriate foundation for so comprehensive a consequence. I will briefly state what may be said, from my own point of view, as to the stability of the universe. Its final cessation will occur, when all the ponderable matter it contains is combined in a single mass; whereupon, as we may readily perceive, the whole of its existing *vis viva* would be uniformly distributed in the form of heat throughout the mass, which would thus attain an eternal equilibrium.

But how could such a combination happen? Five years have passed since Brayley, of London (and Reuschle just recently in a number of the German quarterly journal), stated, that if masses of the magnitude of our sun, or only half as great, were to come into collision, so enormous would be the effect, that all cohesion would be at an end, and the molecules would fly off into infinite space. Now we have every reason to suppose that, in the ceaseless course of time, and in an unlimited expanse, this kind of destruction or partial ruin of worlds has taken place, and is actually in progress. We have a striking proof of it in the observation of meteorites with a hyperbolic path. On this point I would refer to the important memoir of Prof. Heis, of Münster. "The large fire-ball which was seen on the evening of March 4, 1863, in Holland, Germany, Belgium, and England (Halle, 1863)." The true heliocentric motion of this meteorite amounted to 9.145 geographical miles per second. A body lying between the earth's orbit and the sun, and owing its motion solely to the attraction of the latter, cannot have a greater rate than 5·8 geographical miles; so that the fire-ball above referred to must have entered the sphere of attraction of our sun with an initial velocity of 7 geographical miles per second. Now, whence could it have derived such a motion?

In order to throw light on this question, we might imagine a peculiar progressive movement of the whole solar system in space, or have recourse to a movement round a so-called central sun. But we cannot suppose any such accumulation exists sufficiently large to confer an appreciable velocity on our sun at the distance of the fixed stars. Moreover, if our earth possessed a distant motion towards space in addition to its centripetal motion towards the sun, the light which reaches it from the fixed stars would present phenomena of aberration different from those actually observed. Were this proved, meteors with a hyperbolic path would be so many fiery couriers, living witnesses of a conflict somewhere and sometime happening in strength sufficient to explode and scatter the molecules in every direction. If we also consider that the radiating power of the sun's body, as of all the fixed stars, is connected with the consumption of collided masses, yet that consumption has not therefore ceased, since throughout the disturbance, large masses of debris continually reach our world.

All the phenomena of terrestrial motion, except volcanic action and the ebb and flow of the tides, are eventually derived from the sun. One of these, which we are about to consider more particularly, is an electric current on the surface of the earth. That it actually exists is evident from the direction of the magnetic needle, as also from the immediate observations of Lamont. But as there can be no action without corresponding cause, it follows that this remarkable expenditure of electric effort must be attended with as large a compensation. We have, then, to consider our earth as being, in this respect, a huge and permanently efficient electric machine. I do not here refer to the local phenomenon of thunderstorms.

For a constant source of the constant disturbance of electrical equilibrium in the earth's body, we can only have recourse to the unceasing flow of air between the tropics, known under the name of the trade-winds. The lowest layer of the trade-wind assumes, by friction on the surface of the sea, an opposite electrical condition. This air, however, heated by the sun, and dislodged by the colder current setting beneath it, rises and directs its course to the poles, where its high electric tension originates the beautiful phenomenon of the aurora. It must now be observed that, on account of the physical condition of the earth's surface, the electromotor activity of the southern hemisphere must be throughout much stronger than in the northern; whence it happens, that not only on both hemispheres between pole and equator, but also between the north and south poles themselves, a continual disturbance of electric equilibrium occurs; and it is this by which the direction of the needle is determined. The narrow belt between the north and south-east trades—called by Dove the zone of calms—may be termed, for present purposes, the meteorological equator. This is known not to coincide with the geographical equator, but to oscillate slowly about a limit of 1 to $1\frac{1}{2}$ degrees north of it. The *experimentum crucis* for the theory—or, as we will only term it at present the hypothesis—here adduced of the trade-winds as the source of terrestrial magnetism, would consist in establishing that the known alterations which the magnetic pole, as well as declination, gradually undergo, are accompanied by parallel changes of our magnetic equator. But work of this description cannot be accomplished by a single private individual, and I must content myself with having brought the subject forward.

Amagat on the law of Mariotte

PROFESSOR E. H. AMAGAT has published the results of some experiments, still in progress, on the influence of temperature on departures from the law of Mariotte. The researches of Regnault have shown that this law is not rigorously obeyed by any gas excepting hydrogen; in all other cases compressibility increases with pressure, that is, when the gas approaches its temperature of ebullition. This phenomenon has received various explanations. It has been considered as resulting from reciprocal molecular attraction; it has also been elucidated by a theory which was first enunciated by Daniel Bernouilli, but has received successive additions at the hands of Joule, Krœnig, and Clausius. The theory in question takes into account not only the movements of translation of molecules, but their rotatory and internal movements, as well as the possible movements of imponderable fluids. If we admit the first explanation, then, as attraction only depends on the mean distance of the molecules, the departure from the law in any single case must be the same at any temperature, provided the initial and final volumes are the same. In other words, let V be a given volume of gas at the temperature t and pressure p. Reduce this volume to V' by a pressure p',' the temperature remaining unchanged. On heating the gas to t, it will expand; let P be the pressure necessary to restore the volume to V, and P' the corresponding pressure. If the departure be only a function of the volume, it is clear that we must have

$$\frac{pV}{p'V'} = \frac{PV}{P'V'}.$$

As $\frac{V}{V'}$ is common to both sides of this equation, it is only necessary to compare $\frac{p}{p'}$ with $\frac{P}{P'}$. The author has done this in the case of sulphur dioxide, ammonia, and carbon dioxide. In the instance of sulphur dioxide—

$$\left.\begin{array}{l}\text{at } 14^\circ,\ \frac{p}{p'} = 0\cdot50838 \\ \text{at } 98^\circ,\ \frac{P}{P'} = 0\cdot50277\end{array}\right\}\ \text{difference, } 0\cdot00561.$$

(This difference corresponds to an observed height of more than one centimetre of mercury.) For ammonia—

$$\left.\begin{array}{l}\text{at } 13^\circ,\ \frac{p}{p'} = 0\cdot50731 \\ \text{at } 97^\circ,\ \frac{P}{P'} = 0\cdot50402\end{array}\right\}\ \text{difference, } 0\cdot00329.$$

For carbonic dioxide—

$$\left.\begin{array}{l}\text{at } 13^\circ,\ \frac{p}{p'} = 0\cdot50981 \\ \text{at } 97^\circ,\ \frac{P}{P'} = 0\cdot50402^*\end{array}\right\}\ \text{difference, } 0\cdot00210.$$

It appears from the preceding numbers that the departure is not only a function of the volume, but also of the temperature at which the experiment is performed. This result agrees, however, with the second theory. In fact, the *vis viva* of the molecules being greater as the temperature rises, it may be readily conceived that the loss due to their collision is relatively smaller than the augmentation of pressure on the walls of the enclosing vessel, due to the augmentation of *vis viva*, this being true even when, as the rate is accelerated, the molecular collisions become more numerous.

* This number is obviously a misprint.

In a new series of experiments, M. Amagat kept the initial and final pressures as nearly as possible the same in each case, thus obtaining the influence of temperature alone. He then arrived at the following general results:—

1. That near 100°, sulphur dioxide and ammonia depart but little from Mariotte's law, yet more so than air at the ordinary temperature.
2. That near 100°, carbon dioxide is almost a perfect gas.
3. That near 100°, air exactly follows the law.

The author is convinced that the higher the temperature of liquefaction of a gas is found to be (under the same pressure), the less does it depart from the law of Mariotte at the same distance from its point of liquefaction.*—[Archives des Sciences physiques et naturelles, 139, p. 169.]

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, March 17.—Mr. Carruthers exhibited a section of a fossil *Osmunda* from the eocene beds of Herne Bay, in which not only the forms of the cells were preserved, but the contents of the cells, and even the starch-granules. Before its conservation it had been attacked by a parasitic fungus, the mycelium of which is preserved, in precisely the same condition as it would be in a recent specimen.—Dr. Hooker read a further communication from Sir Henry Barkly on the Flora and Fauna of Round Island. The highest point of the island is 1,049 feet above the level of the sea; the summit is smooth, with three large and remarkable blocks of granite. It is entirely composed of tufa, mixed with volcanic sand in perfectly preserved strata. The deeper ravines are crowded with lofty palms. Of the twenty-six flowering plants gathered, the greater number belong to the orders *Gramineæ*, *Pandanaceæ*, *Palmaceæ*, *Ebenaceæ*, *Cinchonaceæ*, *Compositæ*, and *Asclepiadeæ*. The proportion of Endogens to Exogens is very large, namely, twelve to fourteen; but this proportion by no means represents the enormous preponderance of the former in individuals, probably amounting to 99 per cent. Some of the Exogens are specifically identical with those of the Mauritius, but few of the Endogens; those of the former class which are common to the two islands have probably been introduced at some remote period. Of the three cryptogamic plants observed, one was a moss, probably a *Sphagnum*, one a *Selaginella*, certainly a new species, and one a widely-spread fern, *Adiantum caudatum*. Of the five grasses the most abundant is identical with the Indian Lemon-grass. The *Cyperaceæ* are represented by one species, *Scirpus maritimus*. The *Pandanaceæ* are very remarkable; *Pandanus utilis* occurs, but in one spot only, rare, and no doubt introduced, whilst the other, an allied species (*P. Vandermeerckii*, is quite peculiar to the islet). Of Palms there are no less than three species, probably all peculiar, the most remarkable being the bottle-stemmed species (a *Hyophorbe*) already described as peculiar to the island. The only other Endogen belongs to the order *Liliaceæ*, and is an aloe, growing on the summit, and probably a new species. Of *Ebenaceæ* there are three species, and two Asclepiads with trailing stems; one species of *Myrsineæ*, new; two *Compositæ*, one of them a *Sonchus*, both probably introduced; one species of *Combretaceæ* and one of *Myrtaceæ*; two *Cinchoneæ*, and a small tree about twelve feet high, resembling the *Blackwellia* of Mauritius. It will be seen that while the genera of the Round Island Flora are Mauritian, the species are mostly peculiar. It is probable that the whole group of islands—Mauritius, Bourbon, Round Island, Ile de Serpents, Rodriguez, with the smaller islets, and probably Madagascar—are fragments of a vast continent. As regards the Fauna, there are no indigenous mammalia, although goats and rabbits have been introduced and have multiplied exceedingly, and no land birds, not even the Mauritian pigeons. The island seems, on the other hand—perhaps from the absence of mammalia and birds—very favourable to reptile life. Of Chelonians, a female land-tortoise had previously been captured on the island. Four distinct Saurians were found, the largest exceeding a foot in length, a native of

* With the above results compare those obtained by Andrews (Proceedings of the Royal Society, xviii. 42).

Madagascar, but not of Mauritius or Bourbon; one species, at least, is altogether new. The four Ophidians are all undescribed, no authentic evidence being known of any such having at any time been indigenous to the Mauritius group. No Batrachians were discovered, and the time was too short to collect the Fish which abounded in the freshwater pools. Only one Gasteropod was collected, probably *Cyclostoma hemistoma*. Of Arachnida, the spiders are numerous and interesting, of four kinds, belonging to as many different families, two common to Mauritius and two not; also three scorpions, one measuring five inches, none of them Mauritian. Only one Myriapod was captured, a centipede six inches in length, belonging to India, but found also in Rodriguez. There were six Coleoptera, none of them Mauritian, though not very dissimilar. Of Orthoptera, one *Plasma*, peculiar to the island, and a grasshopper, also thought to be new. The Neuroptera included only one specimen of a dragon fly, and the Hymenoptera only a single bee. Generally speaking, the Fauna was of the type of the Malayan archipelago, with greater resemblance to that of Madagascar than of Mauritius or Bourbon. The reptiles have been sent to Mr. Gunther of the British Museum for examination and description, and specimens of the plants to the Kew Herbarium. Thus it will be seen that this little islet, not a mile in diameter, and only thirteen distant from the great island of Mauritius, is unique in respect of the peculiarity of both its animal and vegetable productions. In the matter of Ophidians it is especially so; the absence of them in other oceanic islets throughout the globe being one of the most remarkable features of their history.

Royal Geographical Society, March 14.—Sir R. I. Murchison, Bart., president, in the chair. The following new Fellows were elected:—Charles Ashton; William J. Anderson; Louis Alford; Charles Fairbridge; Charles W. Gray; Edward Gellatly; J. G. Gibson; T. D. Murray; Rev. W. R. Tilson Marsh, M.A.; M. the Chevalier de Overbeck; Robert T. Pigott; Albert Walker; Thomas Watson; Peter T. Wills. The President, Sir Roderick Murchison, read an official letter he had that day received from Lord Clarendon, stating that a severe outbreak of cholera had occurred in East Africa, at Zanzibar, and on the neighbouring mainland, which it was feared would delay the progress of Dr. Livingstone, inasmuch as the native carriers who were taking supplies to him had been attacked by the epidemic. Sir Roderick stated that there was little probability of the disease reaching the remote interior district where Livingstone remained waiting for the Zanzibar caravan. The following paper was read: "On Morrell's Antarctic Voyage, and on the advantages of steam navigation in future Antarctic Explorations," by Captain R. V. Hamilton, R.N. According to the author, a remarkable narrative of a voyage in high southern latitudes by Benjamin Morrell, in the *Wasp* sealing schooner, published at New York in 1832, had been hitherto overlooked by all concerned in Antarctic exploration. Even Morrell's celebrated countryman, Commodore Wilkes, seemed not to have been aware of this publication, which appeared before he sailed on his voyage of discovery. Captain Hamilton had laid down Morrell's route on a South Polar chart, and found that it intersected several times the land said afterwards to have been discovered by Wilkes. The portion of the Antarctic Ocean navigated was between 66° and 70° 14' lat., and between 105° E. long. and the meridian of Greenwich. South of 64° he found less ice, and in 69° 11' there was no field-ice visible. Captain Hamilton concluded that the Antarctic lands seen by Wilkes and others were mostly islands, and that one or other of them would offer a suitable site for the observation of the approaching Transit of Venus. The employment of steam-vessels, he contended, would add very greatly to the safety of the expedition as well as the facility of reaching the high southern latitudes. The great barrier of ice surrounding the South Polar lands, he believed, was not glacier ice, but an enormous floe. In the discussion which followed, Commander J. E. Davis (of Sir James Ross's Expedition) dissected many of Morrell's statements about well-known places in high southern latitudes, and showed that they were almost all pure fiction: he considered his work to be, therefore, of no authority, and denied that it had been overlooked; it had been examined by cartographers and writers, and set aside as unreliable. Mr. Enderby expressed similar opinions, from personal knowledge of Morrell, and Mr. F. Galton also exposed Morrell's inaccuracy with regard to the interior of South-west Africa. Captain Sherard Osborn differed in opinion from Captain Hamilton regarding the formation of the Antarctic icy barrier, and believed it to be the seaward edge of an enormous continental glacier. Admiral Ommaney also took part in the discussion. The meeting was then adjourned to March 28.

Anthropological Society, March 15.—Dr. Charnock, V.P. in the chair. Mr. William Stephens Haywood, Long Wittenham, near Abingdon, Berks; and Mr. P. Henderson, her Majesty's Vice-Consul at Benghazi, North Africa, and No. 1 Stafford Place, Buckingham Gate, were elected Fellows. Dr. Daniel Earl Burdett was elected a local secretary for Belleville, Ontario, Canada. The following paper, by Dr. Isidore Kopernicky and Dr. J. Barnard Davis, F.R.S., was read: "On the strange peculiarities observed by a religious sect of Moscovites, called Scoptsi." This curious Christian sect of a well-defined race was fully described in the paper by Dr. Barnard Davis from data supplied him by Dr. Kopernicky of Bucharest, and it was accompanied by an anatomical preparation which clearly demonstrated the character and amount of mutilation practised by the Scoptsi. That practice is based upon the twelfth verse of the nineteenth chapter of St. Matthew, and it has been carried out with such resolution and to so large an extent, that the Russian Government has been compelled to interfere and to punish with extreme severity all members proved to belong to that community. Hence, the Scoptsi are forced to conduct their worship and to carry out their peculiar rites in the most secret manner: nevertheless, they contrive to amass great wealth, and as a consequence they possess considerable influence in districts in which they reside. Accident alone brought under the notice of Dr. Kopernicky the case of the individual whose body furnished the preparation laid before the society. The paper, after entering at length into the modes of conducting the religious worship of the Scoptsi, their estimated numbers, their physical characteristics and other details, viewed the subject in its psychical aspect. Dr. Kopernicky was of opinion that this aberration in Christianity could not be explained otherwise than by the psychological peculiarity of the race of Moscovites in which it prevails. He endorsed the well-known views of the Rev. Dunbar Heath upon the difference which exists between the Semitic and "Aryan" races in their appreciation of the doctrines of Christianity, and held it to be an anthropological fact that the ideas and religious creeds, sound or absurd, moral or immoral, which are produced, or which develope themselves among a certain race, depend greatly upon the character of the psychological sentiments natural to that race. That was the reason why Christianity was so readily accepted, and has taken such root among the Aryan peoples, and why, on the contrary, the Koran has had most success and most persistence among the Semites. An animated discussion ensued, in which the Rev. Dunbar Heath, Mr. Moncure Conway, Mr. Ralston, Dr. Spencer Cobbold, and others, took part.

Institution of Civil Engineers, February 22.—The following papers were read:—"On the New Mhow-ke-Mullee Viaduct, Great Indian Peninsula Railway," by Mr. A. R. Terry; "On the Pennair Bridge, Madras Railway," by Mr. C. W. Stoney.

March 1.—"The Wolf-Rock Lighthouse." By James N. Douglass.

March 8.—"Description of the Line and Works of the San Paolo Railway in the Empire of Brazil." By D. M. Fox.

March 22.—"On the conditions and the limits which govern the proportions of Rotary Fans." By R. Briggs, of Philadelphia.

DUBLIN

Royal Irish Academy, March 16.—The Rev. John H. Jellett, M.A., was elected president, and the following gentlemen were elected council and officers for the current year:—Dr. W. K. Sullivan, Secretary of Academy; Dr. H. Hennessy, Dr. W. Stokes, Dr. A. Searle Hart, Dr. James Apjohn, Rev. Humphrey Lloyd, D.D., Rev. S. Haughton, M.D., Rev. J. A. Galbraith, Dr. MacDonnell, Dr. E. Perceval Wright, Mr. R. S. Ball; John T. Gilbert, Librarian; William H. Hardinge, Treasurer; Dr. John Kells Ingram, Secretary of Council; Sir W. R. Wilde, Secretary of Foreign Correspondence; Rev. George Longfield, D.D., Dr. Samuel Ferguson, Dr. W. J. O'Donnavan, Dr. Alexander G. Richey, Colonel Meadows Taylor, John R. Garstin. Heinrich Ewald, of Göttingen, was elected an honorary member in the department of Polite Literature. The following grants of money were voted:—20*l.* to Dr. John Barker, in aid of his experiments on "Microscopic Illumination." 15*l.* to Mr. E. Reynolds, to enable him to carry out his researches on the "Spectrum Analysis of Chlorine," &c. 15*l.* to Mr. N. Furlong, to enable him to carry out his experiments on the "Innervation of the Heart." Professor Hennessy read a note on "Two Streams flowing from the same source in opposite directions." The president nominated Henry Hennessy, F.R.S., William Stokes, M.D., Sir William R. Wilde, M.D., and Samuel Ferguson, LL.D., vice-presidents for the current year. The annual report was read and adopted, and then the Academy adjourned.

GLASGOW

Natural History Society, February 22.—Mr. David Robertson, F.G.S., vice-president, in the chair. Mr. Thomas Chapman exhibited specimens of *Venilia Macularia* which he had captured in June last in the Pass of Leny, Perthshire, and the Rev. James E. Somerville stated that he had taken the species in some numbers in Argyleshire, both at Loch Awe and Oban. The secretary exhibited a small collection of star-fishes, which had been forwarded from Girvan by Mr. Thomas Anderson, corresponding member.—Mr. Duncan McLellan exhibited monstrosities of the common ash and hawthorn from the Queen's Park; the former showing the twigs flattened like horns of a reindeer, the latter having its branches tortuous like a cork-screw. Both specimens presented a very unusual appearance.—Mr. Alexander Donaldson exhibited an example of malformation in the bill of a rook, regarding which Mr. Gray observed that it possessed additional interest from the fact of its showing only a partial abrasion at the base of the bill, and that it had been arrested probably in consequence of the malformation. Drawings of other malformations were exhibited by Mr. Gray. Mr. John Gilmour exhibited an unusually dark specimen of the hooded crow (*Corvus cornix*), which had the light space on the breast and shoulders very much clouded, giving the bird the appearance of a variety of the carrion crow (*Corvus corone*). Dr. Stirton exhibited specimens of *Adelanthus Carringtoni*—a Jungermannia new to science, which he had found on Ben Lawers, and other places. This moss had formerly been confounded with *Alicularia compressa*, from which, however, it differs not only in the colour and areolation of the leaves, but also in their mode of attachment to the stem. It approaches much more closely *Alicularia declusa* from Campbell's Island in the South Pacific; and as this last has been proved by Dr. Carrington to be an *Adelanthus*, it has been thought proper to refer this moss also to the same subgenus. The Rev. James E. Somerville than read a paper on *Danais chrysippus* and its food plant, *Asclepias gigantea*, with illustrative specimens from Upper Egypt. The author of this paper gave a very interesting account of this butterfly from personal observations made during a three months' residence in Egypt, and also of the plants on which it is known to feed. He likewise described the peculiar properties of the *Calotropis procera* or *Asclepias gigantea* of Linnæus—a plant better known as the apples of Sodom—a beautiful series of which, in its various stages of growth, was exhibited by Mr. Somerville in illustration of his remarks.

BOSTON

Boston Natural History Society, February 2.—Dr. B. Joy Jeffries states that, as at different times during the past three years he had had occasion to call the attention of the society to the physiology of accommodation in man and other animals, including birds, he would ask to be allowed to make a few remarks on a special part of the eye which is interested in, and may be employed in, accommodation. He illustrated his remarks by a series of pictures and diagrams representing sections of the human eye and a number of different animals, made through the ciliary muscle and the adjacent parts of the sclerotic, cornea and iris. From dissections made by many anatomists, and the special studies of several physiologists, it resulted that the space in the eye hitherto known as the canal of Fontana, who first described it in 1778, is now proved not to be a canal with walls, but rather a triangular space between the ciliary muscle, iris, and sclerotic or cornea, filled by a sort of mesh-work attaching the iris to the last-named membrane. This mesh-work is cut off from the aqueous humour. It constitutes the ligamentum pectinatum iridis, and is quite distinct from the circular venous sinus in the sclerotic just outside of it, which it has apparently sometimes been mistaken for it. Dr. Jeffries discussed the question as to whether it took part in the accommodation of the eye, if not in man where it seemingly could not, in the lower animals where its size increases with the decrease of the ciliary muscle. He remarked that our present knowledge of it is due to the recent researches of Drs. Iwanoff and Rollett.

Section of Microscopy, January 12.—Mr. Stodder referred to a communication of Mr. R. C. Greenleaf, on a specimen of *Aulacodiscus oreganus* Bail., prepared by Mr. Samuels, which in the process of mounting separated into two plates; one being the outer, and the other the inner plate of one valve. A few days since a similar thing happened to Mr. Samuels when mounting another specimen of the same species. The diatom separated into two pieces, the inner and outer plates of one valve as Mr. Samuels supposed. But a careful inspection of the specimen which was exhibited to the section, indicated an entirely different origin. One disc was a perfect *A. oreganus*, with all the characters of that species, having ten rays, and "feet." The other was more hyaline, the umbilicus less distinct, the granules and "feet" imperfectly developed, and having eleven rays and "feet." Mr. Stodder's explanation of the appearances—if Mr. Samuels was not mistaken as to the facts—is that the one disc is the parent, and the other a valve of a new frustule, which was forming in the process of self-division, the growth of which was stopped before it had come to maturity. Ehrenberg and some other naturalists have made the number of rays in such forms a specific character; Bailey and others have rejected this principle of classification, but here for the first time we have positive evidence that a form with eleven rays has been derived directly from one of ten rays. Such a change of characters in one order of plants being authentically established, it is a reasonable inference that all other orders may be liable to similar changes, and therefore great caution should be used in allowing specific value to unimportant characters.

January 26.—*Section of Entomology.*—Mr. E. Burgess in the chair. Twelve persons were present. Mr. F. G. Sanborn exhibited a drawing of the larva of *Callosamia promethea*, made by the late Mr. C. A. Shurteff, together with the specimen after it had spun its cocoon. Dr. H. Hagen read a criticism of the views of Dr. Packard concerning the *Neuroptera*, as given in his recently completed "Guide," and explained that in the manuscript of his own "Synopsis of North American Neuroptera" he had, in accordance with the views of the most prominent entomologists for twenty-eight years, distinctly separated the Pseudoneuroptera and Neuroptera as two different parts of the work. Dr. Hagen also remarked that Mr. Fritz Müller had sent to him some white ants from Itahahy, St. Catharina, Brazil, with the following remarks:—"These nests of white ants are more or less regular cylinders, one span high and two or three inches thick. By horizontal floors they are divided into twelve or fifteen compartments or chambers. The outer surface bulges out so that one can make out the number of chambers by the enlargements of the cylinder. A pillar goes through all the compartments; close to this, or in it, runs an oblique passage from each chamber to the next. Sometimes all these passages together form a somewhat regular winding stair through all the compartments. For the impregnated female these passages are too narrow, and she can therefore not leave her chamber. There are, both in the outer wall and in the horizontal divisions, passages too small to admit the passing of the winged ants; but neither in the outside wall nor in the chambers is there any opening to the outside in nests which have not been injured. In the outside wall the passages run from top to bottom. In the divisions, from circumference to centre without reaching this latter. In the flat compartments they are not to be detected from the outside; in the circumference they appear as flattened ridges. In drying, the outer side of the passages falls off, and then they are to be seen as deep hollows with inflated borders. In undisturbed nests the only entrance seems to be on the upper surface some inches under ground. The nest is not directly connected with the earth, but is surrounded by about a finger's breadth of free space. The nest can, therefore, as soon as the upper end is freed from earth, be easily taken out of the ground. I have never found in one of these nests more than one impregnated female. Besides the winged ants, the eggs, and the larvæ, there are found two kinds of labourers; of these, one kind is distinguished by a truncated nose. Not in the nest, but in the same piece of land, are found, in planting corn, single white ants with disproportionately large heads and long mandibles." The winged ants were stated by Dr. Hagen to belong to *Termes striatus*, or perhaps to *T. similis*; the imago is in too bad a condition for accurate determination. The soldier with truncated nose was figured by him as *T. similis*; the soldier with long mandibles as *T. cingulatus*. No description of white ants' nests like this has ever been given before.—Mr. S. H. Scudder remarked that in a recent examination of the external genital armature of our diurnal *Lepidoptera*, he had noticed the extraordinary fact that in the males of the North-American species of the genus *Nisoniades*, these organs were asymmetrical. The asymmetry is confined to the lower lateral plates, which are unusually developed in this genus, and shows itself in the diverse length of the lower process and in the size, and the entireness or the excision of the lateral flap. The only species in the genus, as generally accepted, which does not come under this rule, is *N. Catullus*, but the structural features of all the appendages of the body of this species show that it is wrongly placed in this relation. Mr. Scudder also stated that the butterfly described by Dr. Harris in his State Report as *Eudamus Bathyllus*,—a name invariably accepted by subsequent writers—was not the species originally described and figured by Abbot and Smith under the same specific name; he therefore proposed to call Harris's species *Eudamus Pylades*. Mr. Sprague referred to an instance related by a friend not versed in entomology, where "flies" were seen, through a hole in the ice in midwinter, to ascend in large numbers from the bottom of a stream to the surface and take flight. Mr. B. P. Mann stated that he had taken a specimen of *Carabus Chamissonis* Fisch., in Labrador. Mr. F. G. Samborn remarked that he had taken ten or twelve specimens of the same species in August, on the sides of Mount Washington, N.H., at a height of from four to five thousand feet above the sea. He also reported the capture in Andover, Mass., on Christmas Day, 1869, of *Capnia* and *Tæniopteryx*, moving actively upon the ice; of several *Staphylinidæ* of the genera *Lathobium*, *Stenus*, *Philonthus* and *Lithocharis*, together with *Photinus corruscus* and larvæ of *Telephorus*, and some undetermined Coleopterous and Geometrideous larvæ, also a species of *Salda* (Hemipterous), and of *Diptera*, *Hydrophorus pirata* Loew, and *Sepsis sp.*, which were struggling in water of about one-eighth inch in depth, covering the surface of the ice in meadows. A great number of *Arachnidæ*, mostly of small size, were noticed under the same circumstances, and appeared to represent many species. He was in pursuit of the aberrant forms, *Boreus* and *Chionea*, but several hours of careful search failed to reveal any specimens of either.

PARIS

Academy of Sciences, March 21.—The following papers relating to various departments of physics were read: A note on the variations of the calorific capacity of water towards the maximum of density, by M. Hirn; on the angle of adjustment of a liquid with a solid wall, by M. Moutier; a description of a vertical galvanometer with a balance, suitable for use before large audiences, by M. Bourbouze.—The chemical papers were rather numerous, and included a note on the analysis and uses of the rock known in the Ardennes under the name of *gaize*, or *pierre-morte*, by MM. H. Sainte-Claire Deville and J. Desnoyers, upon which M. Elie de Beaumont made some remarks.—A note by M. Descloiseaux upon some crystallised derivatives of the coal hydrocarbons; a memoir on the action of sulphuret of carbon and carburetted gases upon wood charcoal, by M. Sidot; a note on cobalt and manganese and their alloys with copper, by M. A. Valenciennes; a note on a new method of preparing hydrobromic acid, by MM. Champion and Pellet; a note on the properties of iodic acid, by M. A. Ditte; one on the hydrogenated derivatives of sulphuret of carbon, by M. A. Girard; a note on the vitality of beer-yeast, by M. Melsens; an important note by M. J. Raulin on the chemical conditions of the life of the lower organisms; a paper on tribromhydrin, by M. L. Henry; and a note on the isomeric xylenes and cumenes in the coal-oils, by M. Rommier.—M. Rosenstiehl also presented a paper on the nature of the motor force which produces the phenomena of endosmose; and M. E. Martin an electro-chemical investigation of ozone.—M. Blanqui forwarded a letter describing an instrument for solving spherical triangles without the aid of tables of logarithms; and M. Bowen a continuation of his communication relating to the distance of the sun, of which the titles only are given.—M. Chasles made known a theorem relating to the theory of surfaces which had been communicated to him by Mr. Spottiswoode.—M. Coumbary's notice of the fall of an aerolite in Barbary (given in our last number) was communicated by M. Le Verrier, who also presented some observations on storms in Norway during the year 1869, by M. Mohn of Christiania.—With the exception of a few medical miscellaneous notes, three botanical papers complete the list of communications at this meeting: these were the continuations of M. Trecul's and M. Chatin's valuable researches upon the tracheæ of ferns, and the causes of the dehiscence of anthers (the latter completed), and a notice of a remarkable case of subdivision of the top of a palm-tree, by M. Ramon de la Sagra.

DIARY

THURSDAY, MARCH 31.

ROYAL SOCIETY, at 8.30.—On the relation between the Sun's Altitude and the chemical intensity of total daylight in a cloudless sky: Prof. Roscoe and Dr. Thorpe.—On the acids contained in Crab-oil: Mr. W. J. Wonfor.

SOCIETY OF ANTIQUARIES, at 8.30.—On the Crypt of the Chapter-house at Westminster: H. Harrod, F.S.A.

ROYAL INSTITUTION, at 3.—Chemistry of Vegetable Products: Prof. Odling.

LONDON INSTITUTION, at 7.30.—Geology: Dr. Cobbold.

THE SOCIETY OF ARTS CONFERENCE

THE Society of Arts is entitled to the thanks of the community for the service it performs in holding from time to time conferences for the discussion of public questions of immediate interest. Technical education, street tramways, the sewage question, and the Channel-spanning problem, have all been recently discussed in this way. Last Thursday another national movement, of greater importance than even any of those we have named, was brought under discussion at one of these useful gatherings, namely, the Relation of the State to Science,—a movement that could not have a more natural or more influential supporter than the Society whose special province it is to advance the practical application of science to the needs of our daily life.

The Conference was opened by a paper by Colonel Strange, "On the proposed inquiry, by a Royal Commission, into the Relation of the State to Science." The part which deals with the scope of the intended inquiry we reproduce in another column: we published some time ago a narrative of events.

It is easy to see that in the paper which formed the subject for debate, the writer aimed at giving to the discussion a practical direction, calculated to assist those interested, including the Government, in determining what objects should claim the attention of the Royal Commission which will probably soon be issued. The Conference, though not numerously attended, included many of our most eminent men of science, and the speakers were all of that class. Professor Williamson, of University College, and Dr. Miller, of King's College, addressed themselves chiefly to the educational side of the question, and insisted on the rights of independent teaching of which they are the recognised champions—rights which Colonel Strange in his paper mentions prominently as demanding examination. Professor Williamson forcibly deprecated any cut-and-dried scheme, thus endorsing Colonel Strange's recommendation that the fullest possible inquiry into all existing scientific agencies should be made first and foremost. Dr. Balfour Stewart suggested a very comprehensive classification of scientific work into Observational work, Experimental work not involving time as an essential element, and Experimental work involving time as an essential element. Of these, he stated that the first and last require the permanence and continuity of State institutions, and have been much neglected in England, while the second can to a great extent be achieved by individuals labouring independently. No doubt this classification will more or less form the basis of the scientific system of the future.

The Astronomer Royal, speaking with an evident sense of the weight that must attach to his opinions on such a subject, and in a tone that might almost be called official, announced his belief that much good would come of the proposed Royal Commission. He illustrated the confused state of our scientific officialism by a humorous description of the accounts of the Royal Observatory, of which three distinct sets were required, one for the Admiralty, another in a different form for the Treasury, and a third "to reconcile the other two." He considered that the present movement tended to the creation of a salaried Academy, to which he did not seem opposed, though he pointed out that there are some kinds of inquiry which such a body would never have initiated, as for instance the discovery of Neptune, and Mr. Lockyer's solar researches. Dr. Mann, Mr. De la Rue, and the Rev. Arthur Rigg warmly supported the recommendation that the inquiry should be full. Mr. Edwin Chadwick particularly dwelt on the advantage of official concentration in science, in a speech full of practical sagacity. The discussion was summed up most ably by the chairman, Lord Henry Lennox, President of the Society of Arts, who, in responding to a pointed appeal made to him by Mr. Chadwick, told the meeting how, on one occasion, desiring to ask in the House of Commons a question regarding some scientific matter, he found that it affected four different departments, and should therefore elicit a quadruple reply, the horrors of which he evaded by most informally putting the inquiry to the Premier himself. He did not add that his desire for information was gratified.

The proceedings of the Conference were brought to a practical issue by the following resolution :—" That this Conference desires emphatically to affirm the conclusion of the British Association for the Advancement of Science, that a Royal Commission to inquire into the relations of the State to Science is very desirable, and to recommend that the scope of the inquiry be made as wide as possible." This motion obviously conveyed the sense of the meeting with accuracy, and it was carried unanimously. The chairman announced that the resolution and a full report of the conference would be forwarded by the Council of the Society of Arts to the Government.

Armed with so competent and united an expression of opinion, following up that already given by the British Association, the Government will, no doubt, invest the Commission with very full powers. A little consideration, indeed, will show that the wider the scope given to the inquiry, the more easy will it be to conduct it. Nothing would be so difficult as to confine inquiry to selected portions of such a subject, all the parts of which are so intimately connected as to preclude the possibility of entering on one without trespassing on those which surround it. The whole field of science must be submitted to a comprehensive survey, before any project for its effectual cultivation can possibly be devised. The plain assertion made in Colonel Strange's paper, that at present we have not even the nucleus of a scientific system, received the tacit assent of the Conference, no speaker thinking it worth while to do more than incidentally illustrate its truth. Comprehensive confusion needing comprehensive remedies must first undergo comprehensive examination. We agree with those who think it will be difficult for the Commission to construct a new and complete system. A good and durable system must, as Dr. Mann expressed it, be built up by degrees—brick by brick, as it were. This work is administrative, not deliberative, and should therefore properly devolve on the Minister entrusted with the Department of Science. If, with the materials furnished by the Royal Commission to his hand, he cannot work them into shape, the course is simple—change him !

OUR NATIONAL DRINK

Strong Drink and Tobacco Smoke: the Structure, Growth, and Uses of Malt, Hops, Yeast, and Tobacco. With 167 original illustrations, drawn and engraved on steel by Henry P. Prescott, F.L.S. Pp. 71. (London: Macmillan and Co. 1869.)

Burton-on-Trent: its History, its Waters, and its Breweries. By William Molyneux, F.G.S. Pp. 264. (London: Trübner and Co. Burton-on-Trent: Whitechurch.)

WHEN Mr. Gladstone, some years ago, inaugurated a new era, and opened British ports to wine which could not be brought here previously on account of its value being actually less than the duty it was subject to equally with wine of the most costly sort, it was believed by many that a serious blow had been dealt against a branch of home industry—the production of malt liquor—which is probably more peculiar to this country than any other.

The fact that there has always been a host of poetic and jubilant notions associated with the name of wine, as well as the enhanced estimation of a thing not easily obtainable, may have seemed good reasons for anticipating a very general desertion of beer in favour of cheap wine; but when the inaccessibility which lent enchantment to the name of wine was replaced by the sour reality of shilling hock or claret, the halo of imaginative recommendation was soon dispelled; consequently, these beverages have been very generally classed among things to be avoided, and even "Gladstone" sherry is regarded with profound suspicion. Meanwhile, our national drink has maintained its supremacy, and though its prospects were for a time clouded by the advent of cheap wine, it may safely be said that while the beer-drinking class in this country is quite as large as ever, the amount of malt liquor consumed has scarcely been affected by the introduction of cheap wine.

One of the works referred to at the head of this article gives some account of the materials used in the production of beer, and of the operations they are submitted to; the other contains a history of a town which is now famous as one of the chief seats of the brewing trade, together with an account of the topography and geological features of the neighbourhood. There is also a good description of the breweries, and of the enormous extent to which the industry has grown, with much interesting information as to its origin and development.

The beer-consuming propensity of the Briton is not a characteristic exclusively his own. The Germans, Russians, and Belgians, have long been famous for their cerevisial devotion, and even the Frenchman is rapidly acquiring a taste for beer which demands satisfaction in spite of national tradition and fiscal regulations. At the same time, though the general excellence of British beer has so long been notorious throughout Europe, and the later fame of bitter beer has now become familiar in all parts of the world, it is not without a rival in the beer of Bavaria and Austria; and, while the stupendous proportions of British breweries as well as our vast trade in beer may have hitherto justified the belief that this country was without a competitor in the art of brewing, the rapid development of this branch of industry in Germany and Austria within the last few years is well calculated to suggest the question whether we may not before long find that in this art, as in most others, we no longer occupy a position of secure pre-eminence, but have to contend with other nations for a place in the markets of the world, if not in that of our own country.

The beer of Austria is already imported here and sold in London. It is largely consumed in Paris, where it excited quite a *furore* during the Exhibition of 1865. Moreover, the Austrian breweries, though of comparatively recent origin, are on a scale approaching that of our own great beer-producing establishments. Down the whole length of the Lower Danube, beer-brewing has become a settled and lucrative business. On the shores of the Black Sea and even in Constantinople this is also the case. Almost every town of any importance has its brewery, or several of them, where excellent beer is made. The proximity of these countries to grain-producing districts, as well as the extension of agriculture in the plains of Hungary and elsewhere, are all circumstances in favour of the development of this industry, and the opening of a means of transport to India and China by the Suez Canal may well afford an opportunity for future competition with this country in the supply of beer to those large markets which it has hitherto been our exclusive privilege to provide with beer.

Here, then, is a possibility of British beer finding a rival much more formidable than cheap wine is at home, and in this view of the subject it may be interesting to the readers of NATURE to know something more of the peculiarities of German beer. With the exception of Belgium, where inferior kinds of beer have long been made, the chief seat of beer production, until within the last few years, was Bavaria, and the beer made there was celebrated throughout the Continent. This beer is made by a method different from that practised in this country, and the difference consists chiefly in conducting the fermentation at a very low temperature. Under this condition the yeast that is produced does not collect as a scum at the surface of the fermenting wort, as is the case in our system of brewing; but it separates as small clots or flocculi, which fall to the bottom of the liquor, leaving the surface freely exposed to the atmosphere. The beer brewed in this way is less liable to become sour when kept than beer brewed by the method of frothing fermentation, and this is one of the special characteristics of Bavarian beer. Liebig, who has devoted much attention to the subject, explains this difference as resulting from the facility afforded by sedimentary fermentation for atmospheric oxidation of the soluble gluten, or that constituent of beer wort from which yeast is produced by oxidation. In frothing fermentation this action of the atmosphere is prevented by the layer of yeast collecting at the surface of the liquor. The formation of yeast then takes place by abstraction of oxygen from sugar, and consequently, since beer wort contains more soluble gluten than is requisite for converting the sugar into alcohol, the proportion of sugar to gluten is still further reduced in that way; so that after fermentation has ceased, some of the gluten still remains unaltered in the beer, and, by a subsequent slow fermentation, is capable of determining the conversion of alcohol into acetic acid. In sedimentary fermentation, on the contrary, the unimpeded action of atmospheric air has the effect of separating the whole of the gluten from the wort by converting it into yeast without any decomposition of sugar, otherwise than into alcohol and carbonic acid.

The brewing of beer on this system has latterly extended beyond Bavaria, and it is now extensively practised in Austria and the Rhine district, where the frequent occurrence of basalt and other porous volcanic rocks presents great facilities for making brewing vaults and çellars, in which a low temperature can be maintained. The various details of the art of brewing have also been carefully studied by chemists with Government support, and the rapid progress of this industry in Germany serves well to illustrate the great advantages resulting from the application of scientific skill to practical subjects. There are not a few of our own industrial arts that would be, in like manner, benefited by a better appreciation of the aid which science is capable of rendering them; not a few that are sorely in need of this aid to enable them to keep abreast of the progress made in other countries.

BENJAMIN H. PAUL

OUR BOOK SHELF

Handbuch der Allgemeinen Himmelsbeschreibung. Von Hermann J. Klein. Das Sonnensystem. (Braunschweig, 1869.)

THIS work professes to combine a full account of the most recent physical discoveries in astronomy, with an exact statement of all those points which are commonly met with in handbooks of the science. The present volume, as will be gathered from the title, deals only with the solar system. Certainly it cannot be said to bear out in full the promise of the author. We are particularly struck by the almost entire absence of reference to the labours of English spectroscopists within the bounds of the solar system. Mr. Huggins's researches on cometic spectra are briefly referred to; but his observations on the spectra of the planets are passed over in silence, while place is given to the comparatively less valuable researches of the Padre Secchi on the same subject. We should be far from desiring to undervalue the researches of the eminent Italian astronomer; but no one who is acquainted with the circumstances under which Mr. Huggins and Father Secchi have respectively observed the planetary spectra, could think (we imagine) of comparing the Italian with the English series of observations. A similar remark applies to the solar researches of Father Secchi, which have not been made with sufficient dispersive power to be fairly comparable with the researches of Mr. Lockyer. Yet the labours of the last-named observer are passed over unnoticed, not only in the body of the work, but in an appendix, wherein the author treats specially of recent solar observations. In a note, a brief and inexact account is given of Mr. Lockyer's discovery that the bright lines of the prominence spectra can be seen when the sun is not eclipsed. After this, it is surprising to find that a full account is given of Professor Tyndall's ingenious theory of comets.

The treatise is one, however, we can on the whole recommend. The arrangement of the chapters on the planets is particularly clear and satisfactory. It is noteworthy that the author, with praiseworthy exactness, gives the secular variations of the planetary elements to the term involving the square of the time.

We were inclined to take exception at the manner in which Professor Adams's labours on the planet Neptune are left to the very end of the chapter on the planet; and we still think that their proper place would have been immediately after the account of Galle's detection of Neptune. This, however, is perhaps a small matter; and the statement of the relative claims of Adams and Leverrier is in pleasing contrast with the unjust account which some continental astronomers have not scrupled to give of the matter. Not only does Herr Klein recognise the claims of Adams, but he assigns the just and sufficient reason for putting the two astronomers on the same level, that "Leverrier can no more deserve credit because Neptune was actually discovered before the end of September 1846, than Adams can deserve blame because Challis, up to that very time, though he had indeed found Neptune, had not yet recognised the planet."

R. A. PROCTOR

St. Pierre's Dictionary of Botany.—*Nouveau Dictionnaire de Botanique.* Par E. Germain de Saint Pierre, avec 1,640 figures. Pp. 1,388. (Paris: J. B. Baillière et fils, 1870. London: Williams and Norgate.)

WHEN it is recollected that this bulky volume is the product of a single mind, the industry, no less than the encyclopædic knowledge of its author, strikes the reader with astonishment. Whether it is desirable in the interests of science that a publication of this kind should be the work of one man is another question. The system pursued in the compilation of cyclopædias, of relegating each separate article of importance to the man who has paid special attention to that particular subject, has its advantages, and what is lost in unity is gained in exactness and thoroughness. In these days of subdivision of scientific labour, even a man of M. Germain de St. Pierre's vast erudition cannot be the highest authority in every branch of his science, and accordingly we find the articles of very unequal interest and value. Thus, under the head "Herborisation" occurs a list of plants gathered in the environs of Paris by Cornuti, in 1635, valuable, no doubt, in its way, but altogether out of place in a botanical dictionary. On the other hand, so many interesting observations have lately been made on the physiology of climbing plants by Mr. Darwin and others, that we turned with interest to this volume to acquaint ourselves with the newest researches on the subject. The heading "Liane" does not appear at all, while under "Grimpant" there are just a dozen lines, and no reference to any other article. Dissertations on the relative advantages of living in Paris and in the country like that under "Laboratoire du Botanique" might have been altogether spared. Other objections might readily be made to the plan of the work. A short description of the leading characters of each natural order is useful, but the utility would have been increased by inserting the Latin names of the orders, with a reference from them to the French names, as from *Ranunculaceæ* to "*Renonculacées*," or from *Umbelliferæ* to "*Ombellifères*." The selection of a few genera and even species for description does not commend itself in the same manner, and the selection must necessarily be arbitrary and partial. Nevertheless, with these defects, we have in the work before us a most useful and valuable cyclopædia, containing an immense mass of information on every branch of botany, which cannot fail to be almost a necessary book of reference alike to the man of science and the student. On those subjects in particular in which M. St. Pierre is an acknowledged authority second to none, the work is especially valuable. The illustrations are copious and admirable.

A. W. B.

THE second fasciculus of the twelfth volume of the *Atti della Societa Italiana delle Scienze Naturali*, which has lately reached us, contains only two zoological papers. The most important of these is a systematic catalogue of the testaceous mollusca of the neighbourhood of Spezia and of its gulf, by Dr. C. T. Canefri, which will be of value to the student of geographical distribution. The other includes the first century of South American Coleoptera, by Prof. P. Strobel, with descriptions of numerous new species by Dr. E. Steinheil.

THE ABUSE OF WATER

THOSE who have travelled in remote districts, even at home, cannot fail to have experienced at some time or other a keen sense of the fact that water is one of the most peremptory necessities of life, one which Nature generally supplies so freely and bountifully that habitual familiarity with the gift sometimes tends to lessen its appreciation. Moreover, the utility of water in various ways as a source of power, a means of communication, or a material of manufacturing industry, has led to its application for a multitude of purposes besides the daily wants of life, and in many cases, unfortunately, this has been done in a way that has been attended with very serious consequences as regards the condition of natural sources of water supply.

To take, for instance, the case of our largest river whence the inhabitants of London chiefly derive their supply of water. It became apparent some 20 years ago that the condition of the water, resulting from a variety of polluting influences, was so bad, that the river within the boundary of the metropolis was no longer a fit source of water-supply for domestic use. The commissioners appointed at that time to inquire into and report on the subject, stated as the result of their inquiry that they doubted whether the existence of organic contamination from town drainage was then perceptible in the water of the Thames above the reach of the tidal flow, or that it amounted to a sensible evil, although, as the main drain of a large and populous district, the Thames was at all seasons polluted by surface drainage, and by the sewage of several considerable towns, there being then a population of more than three-quarters of a million on the banks of the river above Kingston. They supported this conclusion by referring to the probability that the large dilution of the sewage with the well-aërated water of the river was attended with such an effect as to cause the disappearance of impurities and their conversion into harmless products of decomposition. But, at the same time, they added that, since the contamination of the water by sewage could not fail to become considerable and offensive with the increase of population and the more thorough and general drainage of towns, it appeared to them only a question of time when the sense of this violation of the purity of the river should decide the public mind to the entire abandonment of the Thames as a source of water supply, unless, indeed, artificial means of purification should, in the meantime, be devised and applied.

Since the date of this report the application of the system of water-carriage removal of excrementitious material from dwellings has been extended in the towns situated in the upper valley of the Thames, and consequently the discharge of such contaminating material into the river, as sewage, has become more direct and more abundant. Hence we find that on several subsequent occasions the foregoing view of this subject has been strongly urged by other authorities, with the addition of warnings that the evil, merely apprehended before, had actually come into existence. Thus in 1858 the first report of the Royal Commissioners on the sewage of towns represented the increased pollution of rivers as an evil of national importance urgently demanding remedial measures, notwithstanding the natural agencies at work to effect the purification of flowing water. Moreover, the influence of water, thus polluted, as a source of disease, was earnestly dwelt upon. Their second report, in 1861, stated that the still increasing pollution of rivers had become so great and general that, besides being in some instances a nuisance and rendering the water utterly unfit for drinking, it was a general source of serious danger of infection for persons consuming even water that presented no appreciable sign of such pollution. Again, in 1866 and 1867 the reports of the Rivers Commission, dealing chiefly with the Thames basin above Hampton and that of the Lea, illustrated very forcibly the abominable effects of the discharge of sewage into these rivers, which are the chief source of metropolitan water supply. Referring to the spontaneous purification of flowing water by atmospheric oxidation—alleged by some to be adequate to render polluted water free from any objectionable character—these reports state that, though the process tends to purification, it is no sufficient guarantee for the water being purged of injurious sewage taint;—that, though the water supplied to London usually contains but a very limited amount of organic impurity, even that fact is, under existing circumstances, no satisfactory ground of assurance that the metropolitan supply of water is wholesome, or that the London drinker of water may not be drinking with it some remnant of the filth of other towns.

The report just issued by the Rivers Pollution Commission reveals the existence of a still more frightful state of rivers in the manufacturing district of Lancashire, where the pollution of the water has reached such an extent that, as compared with the Thames at London Bridge, the rivers are in several instances mere open sewers. That such should be the case is not indeed surprising, when it is considered that in this locality there is an enormous demand for water for all kinds of industrial purposes; that the water generally becomes fouled by such use, and, moreover, that the population has, in some parts, increased fourfold during the last seventy years. This latter circumstance has a much greater influence as a cause of pollution than has been supposed; but the effect of the use of water for manufacturing purposes alone has been, in the words of the Commissioners' Report, "to absorb the whole of the stream, which is the outlet of the drainage of the country, and to apply it to manufacturing purposes solely, so as to throw out of sight altogether the right of the dweller on the bank of a stream to the use of the water of that stream, and, gradually, to assume that the extent of the evil, or the magnitude of the profits which arise from the *abuse* of water in various processes of manufacture, is sufficient justification of the course followed up to the present time."

The Lancashire rivers present a peculiar form of pollution, resulting from the discharge of manufacturing refuse into them. Among the materials thus introduced into river water is arsenic, which is largely used in the calico-printing works. The foul water running from one company's works was found to contain as much as ·042 lb. of arsenous acid in 100,000 lb. Several of the rivers in the Mersey and Ribble basins are thus becoming contaminated with arsenic; and though it appears that the arsenic is, in some respects, gradually got rid of and deposited in the mud, this probably is not always the case. Arsenic is also contributed by aniline colour works and woollen manufactories. In the latter case, its source is ultimately the iron pyrites now so largely used for making sulphuric acid. Taking the quantity of pyrites imported for this purpose to be 400,000 tons a year, and the amount of arsenic it contains at a moderate average, we thus import 1,600 tons of arsenic, of which, there is reason to believe, a large proportion ultimately finds its way into our rivers and streams. In its course there it is sometimes met with in soap, as well as washing soda, and in the soda-ash used for making them. In this way it is met with in London sewage at Barking to the extent of ·004 parts in 100,000.

The Commissioners do not take an alarmist view of this wide distribution of arsenic, for since they find it in appreciable quantity in the rain falling in London, they consider it would also be met with in the case of most large towns as derived from coal smoke; but they suggest that care should be exercised in alkali works to prevent its unnecessary introduction into manufactured products, and they consider that might be easily done.

As regards that pollution of rivers which is due to admixture of human excretal refuse with their water, it has long been maintained by the local authorities of many parts of Lancashire that the evil was less in that district than elsewhere, in consequence of the system adopted there for dealing with such refuse not affording such facility for its discharge into rivers as the water carriage system. On this ground the introduction of the water system of sewerage has been strenuously opposed. The report of the Commission, however, dispels this illusion by evidence which is conclusive in proving that the use of the old form of closets with ash pits, earth closets, &c., affords no protection to rivers. From a long series of analyses of sewage from towns where such closets and middens are used, it appears that, as compared with the sewage from towns where water-closets are used, the composition of both are remarkably similar. Besides the nuisance and other inconveniences of the dry closet system, it appears that the pollution of rivers is but very slightly prevented by it. On the other hand, while the advantage gained by that system consists merely in the retention of a small proportion of the excreta in a state to be available for agriculture, the treatment to which that portion is subjected renders its value as manure very small. Moreover, this is usually effected only at the expense of great risk to public health, and at a cost which is on the average double the money return obtained. The Commissioners, therefore, come to the conclusion that the retention of solid excreta in middens is not attended with any considerable diminution in the strength of the sewage, though the volume is somewhat reduced. On that ground they consider it hopeless to anticipate any substantial reduction of sewage pollution of rivers by dealing only with the solid residue of excreta. At the same time they point out the fact that the discharge of excretal refuse into rivers is not a necessary part of the water-closet system.

As to the influence of the dry closet system on health, the Commissioners refer to the returns of the Registrar-General, and to other evidence, as showing that typhoid fever, scarlatina, diarrhœa, and other epidemic diseases, commit fearful ravages amongst the populations exposed to the pestiferous influences it exercises, and they express the opinion that to it may be attributed much of the responsibility for the high death-rate of South Lancashire towns. They have, however, been unable to obtain conclusive evidence of this owing to the incompleteness of the health statistics. They express astonishment at the frequent inability of Health Boards to inform them of the death-rate in their districts, still less to give information as to particular parts of them.

It is a very general opinion of medical men that the presence of an extremely minute amount of organic impurity may, under certain obscure conditions, render water unwholesome, and capable of causing or propagating disease, especially if that impurity be of animal origin. Sewage is the source from which such impurity is most likely to originate in a specially dangerous form, and it appears the amount capable of causing injury may be so small as to have no influence on the outward appearance of the water. To the smell, sight, and taste all may seem innocuous, and yet there may be present an infinitesimal portion of substance rivalling in potency the most virulent poison.

That water subject to such contamination is thereby rendered unfit for human use, and repugnant to every sense of decency, can, it is believed, require no arguments to be admitted. That the use of such water is, moreover, dangerous and unwholesome, would seem to be suggested by a knowledge of the changes which excretal refuse naturally undergoes, and of the circumstances attending those changes. The medical officers of Her Majesty's Privy Council, after specially studying numerous instances of the outbreak of typhoid fever and cholera, have almost invariably found that the prevalence of these and other epidemic diseases was accompanied by the use of water that had been polluted with drainage from cesspools or sewers. But at the same time it has been impossible to detect or demonstrate, by chemical analysis, the presence in the water of anything to which a fatal influence or the production of disease can be ascribed. This fact, however, does not in any degree, afford a ground for regarding the water as free from suspicion. Such reasoning would apply with equal force to sewage itself, for chemical analysis does not indicate the presence in it of anything specially noxious.

It has indeed often been alleged that if sewage be mixed with twenty times its volume of river water, the organic matter which it contains will be oxidised completely while the river is flowing a dozen miles or so. Considering the importance of the subject, it is surprising that this assertion, though confidently made in many instances, should hitherto have rested upon no more solid foundation than mere opinion. But at last the test of positive inquiry has been applied by the Rivers Pollution Commissioners. The composition of the water of the Irwell, the Mersey, and the Darwen at various points in the course of these rivers has been ascertained with due regard to complications introduced by the influx of unpolluted affluents. The results have shown that when the temperature is not above 64° F., a flow of from 11 to 13 miles produces but little effect upon the organic material dissolved in the water. Examination of the gases dissolved in water containing an admixture of sewage led to the same result. Lastly, experiments devised to augment the effect of atmospheric oxidation on such water, so as to represent a flow of from 96 to 192 miles in a river at the rate of 1 mile an hour, showed that the reduction of organic carbon in the water amounted to only 6·4 and 25· per cent., that of organic nitrogen to 28·4 and 33·3 per cent., though the temperature was 68° F. Thus whether we examine the organic pollution of water at different points of a river, or the rate of disappearance of the organic material of sewage mixed with water and agitated in contact with air, or the rate at which dissolved oxygen disappears in water polluted with 5 per cent. of sewage, we are in each case led to the inevitable conclusion that the oxidation is very slow—so slow in fact that it is safe to infer there is no river in the United Kingdom long enough to effect the complete transformation of sewage in that way.

These results are further confirmed by evidence as to the state of the rivers in the Mersey and Ribble basins; they are consistent with the opinions of chemists, and they are opposed only by dogmatic assertions destitute of proof.

To illustrate the extent to which the polluted state of Lancashire rivers is a disadvantage to manufacturers, the Commissioners state that thirty-nine of the firms who are carrying on different branches of trade in the basins of the Mersey and Ribble, estimate the benefit they would derive if the river water were fit for their use at no less than 10,157*l.* a year, while one calico-printing firm estimates the gain to them at 3,000*l.* a year. The number of manufacturers who have given these estimates form only a small fraction of the total number in the district.

MAGNETIC AND SUN SPOT PHENOMENA FOR FEBRUARY, 1870.

(*As recorded at the Kew Observatory.*)

ON February 1st about 5 p.m. there occurred a very considerable disturbance of the three magnetic elements, which lasted until about 2 o'clock in the early morning of the next day. The tendency of this disturbance was to diminish the declination and the horizontal force, while on the other hand the vertical force was increased during the first half of the disturbance and diminished during the second. The oscillations of the declination were very large. The disturbance was accompanied with an aurora, which was widely observed, and also with earth currents affecting the telegraphic wires. From the appearance of the traces one is inclined to associate the aurora and earth currents with the oscillations of declination rather than with those of the other elements.

On February 11, a little after 6 p.m., another disturbance took place, which continued more or less for thirty hours. As in the previous case the oscillations of the declination were most marked, but these were not so excessive as for the previous disturbance. An aurora was visible at 8 50 p.m. of February 11, and one was said also to have been observed on February 12.

The following is the record of sun-spots derived from the pictures taken :—

February 5	... 4	small groups	2 large ones
,, 6	... 5	,,	1 rather large, 1 very large

THE EXISTENCE OF MAN IN THE TERTIARY EPOCH

IN the *Bibliothèque Universelle et Revue Suisse* for the 15th February, M. Favre, in an article on the above subject, remarks that for some years the discovery of traces left by man of the pre-historic age on the earth have multiplied with a rapidity only explicable on the supposition that the population inhabiting a certain region of the globe was formerly abundant, and that numerous observers have recently applied themselves to the subject with extraordinary energy and zeal. He takes up the question whether the age of stone does or does not extend back to the tertiary period, and he thinks it will prove interesting to give a *résumé* of the various observations tending to show that man inhabited the earth at an epoch anterior to the great extension of the glaciers southwards, and during the tertiary epoch. On *à priori* grounds no substantial reasons can be advanced against the existence of man at the latter period. The temperate zone was then somewhat warmer than at present, and the temperature of Greeenland and Spitzbergen sufficiently agreeable to be adapted to the development of terrestrial mammals. But it is difficult to represent the duration of the period that elapsed between the end of the tertiary deposits and the termination of the glacial epoch. The portion of the quaternary period characterised by the enormous extension of the glaciers was very protracted, and many ages must have elapsed before the glaciers of the Alps were so large as to be able to transport erratic boulders to the height of 1352 metres on the Jura (near Soleure), and the glacier of the Rhone approximated the Rhine, or perhaps even reached it by passing across the cantons of Valais, of Vaud, of Freibourg, of Berne, of Soleure, and of Aargau. The form of the earth's surface must have presented to the eye of such old world inhabitants a very different aspect from that exhibited at present, and if they already existed in the middle tertiary period, they would have been contemporary with the upheaval of the Alps, and with an almost entirely distinct flora and fauna. Under these circumstances man would have to be included amongst the creatures who have survived two geological periods. M. Favre then proceeds to review the evidence that has at present been collected, embracing the following points :—First, the observations of M. Desnoyers in 1863 made at Saint-Prest near Chartres, but previously (1848) known to M. Boisvillette, and (1860) to MM. Langel and Lartel. Here, in a pliocene formation, were found the bones of the *Elephas meridionalis*, *Hippopotamus major*, *Equus arnensis*, *Cervus carnulorum*, and two other species of *Cervus*, *Bos*, *Trojonotherium Cuvieri* (a kind of large beaver), striated in such a manner as to convince M. Desnoyers that the markings were the effects of the handiwork of man. This conclusion has, however, been contested by Sir C. Lyell; but in 1867 arrow or lance-head flint instruments were found in this spot by M. l'Abbé Bourgeois, one of which appeared to have been subjected to the action of fire, though this might have resulted from exposure to forests burning by the action of lightning. Soon afterwards M. Delaunay discovered markings of an analogous nature to the former, on the bone of a Halitherium at Pouancé (Maine et Loire) in a miocene formation containing the bones of Dinotherium. About the same time M. Bourgeois found similar flints in a still older formation (the calcareous strata of Beauce) at Thênay, and at Billy near Selles-sur-Cher. Some differences of opinion exist as to whether these flints are really worked by the hand of man; but the majority of those who have seen them, and are competent to judge, is decidedly in favour of that view. Nevertheless, M. Fraas observes that he has himself seen a lamina of silex become detached from a mass by the action of the sun's rays alone in Egypt; Livingstone and Dr. Wetzstein seem to have observed similar phenomena; and a point that now demands intelligent observation is the greater or less similarity such fragments detached by natural causes bear to the flint instruments or the masses from which they have been detached. He refers also to two fragments of the jaw of a *Rhinoceros pleuroceros* found in the lacustrian chalk of Limaque, and which appear to have been grooved by man, which, however, he admits to be doubtful; and to the observations of Whitney in California, which tend to show the existence of man anterior to the glacial epoch and to the period of the mastodon and elephant, at an epoch since which vertical erosion of the surface has taken place to the extent of two or three thousand feet of hard and crystallisable rocks. Finally he refers to the observations of M. Issel in Piedmont.

MODIFICATIONS IN THE CONSTRUCTIONS OF THE NEST OF THE SWALLOW

IN the tenth number of the *Comptes Rendus* for the present year, is a paper by M. Pouchet, on the Modifications of the Nests constructed by the common Swallow, (*Hirundo urbica* Linnæus,) in which he remarks that it is evident the mode of life of certain animals, far from being persistent and invariable, undergoes modifications under different terrestrial conditions, and that, in many instances, their habits are different from what they were in former ages. Spallanzani indeed remarks in one of his remarkable memoirs on the swallows, that the shape and structure of the nests of birds are interesting features in their history, and that each species constructs its habitation on a plan peculiar to itself, which never changes, and is continued from one generation to another. And this opinion is shared by many naturalists; observations, however, when sufficiently close and attentively made, show that it is erroneous. We do not indeed see any modifications of those of their habits which are associated with their biology, so that the arboreal species seek to form for themselves a subterranean nest, or rear their young ones in dwellings adherent to the coigns of our houses, but it nevertheless is ascertained that in a succession of years, each learns to improve the construction of his residence. Certain birds work up only the products of our own handiwork, and would necessarily employ natural substances if these were deficient. Thus, as may be seen in the museum of Rouen, the Loriot of Europe sometimes forms its nest with thread ends under the branches of trees, which cannot possibly be the natural method. For several centuries the common swallow has disported itself in our crowded cities, and with its friendly masonry attached itself to our houses. The chimney swallow, still more familiar and audacious, often builds in the smoky shafts of our domiciles, or even in the noisiest factories, undisturbed by the din or the fires or the movement around them. Such habits must form a strong contrast with those of their predecessors in times long gone by. When we ourselves wandered untutored savages in the prehistoric times, or when still later we constructed lacustrine towns, or megalithic monuments, the habits of the birds can scarcely have been identical with those of to-day, for such human edifices afforded little security or shade. They must then have built amongst rocks. Nearly the same remarks apply to the storks, which have not remained stationary, but have preferred to their less commodious dwellings those offered to them by man. These changes in the industry or the manners of birds are perhaps even more rapid than we might at first sight suppose; and M. Pouchet's observations have demonstrated to him that notable improvements have been adopted by swallows in their modification during the first half of the present century. Having directed a number to be collected for the purpose of having drawings made from them, M. Pouchet was astonished to find that they did not resemble those he had collected some forty years ago, and which were still preserved in the museum of Rouen. The present generation of swallows have notably improved on the architecture of their forefathers, amongst those still building in the arches and against the pillars of the churches. Some, however, still adhere to the old methods, or such nests may possibly have been old ones which have undergone reconstruction. In the streets, on the other hand, all the nests appeared to be constructed on the new method. And now for the differences observed. The old nests show, and all ancient writers as Vieillot, Montbrillard, Rennie, Deglaud, &c., describe the nest of the house-swallow as globular, or as forming a segment of a spheroid with a very small rounded opening, scarcely permitting the ingress and egress of the couple that inhabit it. The new nests, on the contrary, have the form of the quarter of a hollow semi-oval (le quart d'un demi-ovoide creux), with very elongated poles, and the three sectional surfaces of which adhere to the walls of edifices throughout their whole extent, with the exception of the upper one, where the orifice of the nest is situated; and this is no longer a round hole, but a very long transverse fissure formed below by an excavation of the border of the section, and above by the wall of the building to which the nest is attached. This opening has a length of nine or ten centimetres and a height of two centims. M. Pouchet considers this new form affords more room for the inmates and especially for the young which are not so crowded, whilst they can put out their heads for a mouthful of fresh air, and their presence does not interfere with the entrance and exit of the parents. Lastly, the new form protects the inhabitants of the nest better than the old one, from rain, cold, and foreign enemies.

THE ROTUNDITY OF THE EARTH

A RECENT number of the *Field* contains an account of a very amusing investigation which has been recently conducted on the Bedford Level to settle the question whether the earth is a globe or not! It appears that a Mr. Hampden threw out a challenge by which he offered to pay 500*l.* to anyone who would prove the rotundity, which challenge has been taken up by Mr. A. R. Wallace, who has lodged a similar sum with the Editor of the *Field*. To test this point, six miles of the Bedford Level were used, three signals, each 13 feet 4 inches above the water level, being put up three miles apart. Mr. Wallace asserted that if he were correct the central signal would appear elevated about 5 feet above the line joining the other two; Mr. Hampden holding, of course, that they would all be in the same straight line. It is needless to say what the result was, but we now come to a part of the story which is not so amusing, and here we quote from the *Field*:—

Both Mr. Hampden and Mr. Carpenter assented to the details of this experiment in our presence as conclusive, although we regret to say that Mr. Carpenter alleged his opinion was founded upon theory alone, and that it had never, as far as he knew, been tried. Now, the fact really is, that in a little treatise published by "Parallax," and which we have now in our possession, with Mr. Carpenter's name on the title-page, in his own handwriting, an experiment similar in its nature is described as having been made on the very same piece of water as that on which we were then occupied, with a result exactly the reverse of that which recently occurred. Mr. Carpenter was, in fact, engaged to decide a disputed question of which he and his principal professed to be practically ignorant, although it was in print on the authority of the head of their sect that it had already been tried in the same locality; *and this must have been then known to Mr. Carpenter, and has since been admitted by him in our presence.* The good faith and perfect fairness of Mr. Carpenter were not, therefore, quite of the nature we then believed them to be, and we have no hesitation in affirming that he was a most improper person to be selected to act as referee in such a matter. The deception was, to say the least of it, "unscientific;" yet Mr. Carpenter and his master, "Parallax," both profess to be ardent in the cause of science; and that it has recoiled upon their heads can cause no regret to anyone who values the truth.

Although the diagrams of what was seen by the telescopes used at both ends, and acknowledged to be correct by Mr. Carpenter and Mr. Hampden, show the central signal more than 5 feet above the line of the two extremes, these gentlemen coolly claim the victory, and threaten to bring an action against the Editor of the *Field* (who was appointed umpire by Mr. Hampden himself) for fraudulently deciding against them.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

On Prof. Tyndall's Exposition of Helmholtz's Theory of Musical Consonance

IN NATURE for March 3 you published a letter of mine, in which I stated that the exposition of Helmholtz's theory of musical consonance given in Prof. Tyndall's lectures on Sound was both "radically different from the original, and erroneous." I supported my assertion by a series of arguments which, both to myself and to other competently informed persons, appeared conclusive.

Prof. Tyndall has taken no notice, public or private, of my letter, although he has since its publication written in your columns on another subject.

Your readers, as well as myself, are surely justified in calling on Prof. Tyndall either to rebut my argument or admit my conclusion.

Trinity College, Cambridge, March 29 SEDLEY TAYLOR

[Prof. Tyndall's Lectures on Sound have been translated into German, and the following is a verbatim copy of the "Vorwort des Herausgeber":—

"Die Vorlesungen welche Herr Tyndall als Nachfolger der grossen Naturforscher Davy und Faraday in dem Wintermonaten vor den gebildesten Kreisen Londons in der Royal Institution über die verschiedenen Theile der Physik zuhalten pflegt, haben in England allzeitige Anerkennung gefunden. Herr Tyndall besitzt in ungewöhnlichem Grade die Gabe, durch die glückliche Vereinigung einer eben so klaren wie eleganten Darstellung, mit vortrefflich ersonnenen und schlagenden Versuchen selbst die schwierigeren Lehren der Physik dem gebildeten Publikum zugänglich zu machen. Eine Herausgabe seiner Vorlesungen in deutscher Bearbeitung dürfte desshalb auch bei uns nicht wenig zur Verbreitung physikalischer Kenntnisse in weiteren Kreisen beitragen. Die Unterzeichneten haben daher, wie schon früher die Vorlesungen über die Wärme, so auch jetzt die vorliegenden Vorträge über den Schall unter ihrer besonderen Aufsicht übersetzen lassen, und die Druckbogen einer genauen Durchsicht unterzogen, damit auch die deutsche Bearbeitung den englischen Werken ihres Freundes Tyndall nach Form und Inhalt möglichst entspräche.—H. HELMHOLTZ, G. WIEDEMANN."

Prof. Tyndall's work, his account of Helmholtz's Theory of Dissonance included, having passed through the hands of Helmholtz himself, not only without protest or correction, but with the foregoing expression of opinion, it does not seem likely that any serious damage has been done.]

Apparent Size of Celestial Objects

ABOUT fifteen years ago I was looking at Venus through a 40-inch telescope, Venus then being very near the Moon and of a crescent form, the line across the middle or widest part of the crescent being about one-tenth of the planet's diameter. It occurred to me to be a good opportunity to examine how far there was any reality in the estimate we form of the apparent size of celestial objects. Venus through the telescope, with a magnifying power (speaking from memory) of 135, looked about the size of an old guinea, *i.e.*, of a crescent cut off from that coin. The Moon, to my naked eye, appeared the size of a dessert plate. Having fixed their apparent dimensions in my mind, I adjusted the telescope so that with one eye I could see Venus through the telescope, and with the other the Moon without the telescope, and cause the images to overlap. I was greatly surprised to find that Venus instead of being about one-sixth of the diameter of the Moon was rather more than double its diameter, so that when the adjustment was made to bring the upper edge of the Moon coincident with the upper point of the crescent of Venus, the opposite edge of the Moon fell short of the middle of the crescent, a very palpable demonstration of the fallacy of guesses at size, when there are no means of comparison.

On another occasion a lady was looking at Jupiter through my telescope, and having first put on a power of 60 I changed it for one of 140. To my question, what difference she observed in the size of the planet, she answered, I see no difference in size, but a good deal in brightness. Here the area of the one image was more than five times that of the other.

The fallacy of guesses at size without objects of comparison is most strikingly shown in the ordinary expression of an ignorant observer looking at objects by day through a spy-glass. If you ask, as I have often done, a person unacquainted with optics whether he recognises any difference in size between an object, say a horse or a cow, seen with or without a telescope, he will always answer No, but it (the telescope) brings it much nearer. This, of course, is really an admission of increased magnitude, but the observer is unconscious of it; a horse to him is as big as a horse, no larger or smaller, whatever be the distance.

The assistance which may be derived from the degree of convergence of the optic axes alluded to by your correspondent "T. R." may be something when we know what the object is, or when it is moved to and fro, but if the object be unfamiliar, and there be no standard of comparison, I doubt whether any fair guess could be made.

Suppose all objects had never been seen but at one and the same distance, then an observer looking at a given object without any external standard of comparison, would probably make a fair guess at its size, for the picture on his retina would have a definite size, and his mind would estimate it by relation to other pictures of known objects which he had seen at other times; but as we see all the objects with which we are familiar at all degrees of distance, we have no standard of comparison for an image on the retina.

The common phantasmagoria effect where a figure appears to advance or recede from us though it really does not change its position, but its size is one of the many illusions produced by representing things as they are seen under certain circumstances which have become habitual, and habit interprets the vision. So if one lie on his back in a field, and throwing the head back, look at distant trees or houses, they will appear to be in the zenith, because when we ordinarily look at the zenith the head is thrown back.

Is the apparent size of the Sun or Moon, as expressed in common parlance, anything more than a reference to some standard which we have early adopted, and which, not having any means of rectifying, we assume. To me the Moon at an altitude of 45° is about 6 inches in diameter; when near the horizon, she is about a foot. If I look through a telescope of small magnifying power (say 10 or 12 diameters), so as to leave a fair margin in the field, the Moon is still 6 inches in diameter, though her visible area has really increased a hundred-fold.

Can we go further than to say, as has often been said, that all magnitude is relative, and that nothing is great or small except by comparison? W. R. GROVE.

An After Dinner Experiment

SUPPOSE in the experiment of an ellipsoid or spheroid, referred to in my last letter, rolling between two parallel horizontal planes, we were to scratch on the rolling body the two equal similar and opposite closed curves (the *polhods* so-called), traced upon it by the successive axes of instantaneous solution; and suppose, further, that we were to cut away the two extreme segments marked off by those tracings, retaining only the barrel or middle portion, and were then to make this barrel roll under the action of friction upon its bounding curved edges between the two fixed planes as before, or, more generally, imagine a body of any form whatever bounded by and rolling under the action of friction upon these two edges between two parallel fixed planes; it is easy to see that, provided the centre of gravity and direction of the principal axes be not displaced, the law of the motion will depend only on the relative values of the principal moments of inertia of the body so rolling, in comparison with the relative values of the axes of the ellipsoid or spheroid to which the *polhods* or rolling edges appertain; and consequently, that, when a certain condition is satisfied between these two sets of ratios, the motion will be similar in all respects to that of a free body about its centre of gravity.

That condition (as shown in my memoir in the Philosophical Transactions) is, that the nine-membered determinant formed by the principal moments of inertia of the rolling body, the inverse squares and the inverse fourth powers of the axes of the ellipsoid or spheroid shall be equal to zero—a condition manifestly satisfied in the case of the spheroid, provided that two out of the three principal moments of inertia of the rolling solid are equal to one another.

My friend Mr. Froude, the well-known hydraulic engineer, with his wonted sagacity, lately drew my attention to the familiar experiment of making a wine-glass spin round and round on a table or table-cloth upon its base in a circle without slipping, believing that this phenomenon must have some connection with the motion referred to in my preceding letter to NATURE: an intuitive anticipation perfectly well founded on fact; for we need only to prevent the initial tendency of the centre of gravity to rise by pressing with a second fixed plane (say a rough plate or book-cover) on the top of the wine-glass, and we shall have an excellent representation of the free motion about their centre of gravity of that class of solids which have, so to say, a natural momental axis, *i.e.* (in the language of the schools) two of their principal moments of inertia equal. For greater brevity let me call solids of this class uniaxal solids. I suppose that the centre of gravity of the glass is midway between the top and bottom, and that the periphery of the base and of the rims are circles of equal radius. These circles will then correspond to *polhods* of a spheroid, conditioned by the angular magnitude and dip of the spinning glass; to determine from which two elements the ratio of the axes of the originally supposed but now superseded representative spheroid is a simple problem in conic sections; this being ascertained, the proportional values of the moments of inertia of the represented solid may be immediately inferred. The wine-glass itself belonging to the class of uniaxal bodies, the condition that ought to connect its moments of inertia with the axis of the representative spheroid (in order that the motion may proceed *pari passu* with that of a free body) is necessarily satisfied.

The conclusion which I draw from what precedes is briefly this—that a wine-glass equally wide at top and bottom, and with its centre of gravity midway down, spinning round upon its base and rim in an inclined position between two rough but level fixed horizontal surfaces, yields, so long as its *vis-viva* remains sensibly unaffected by disturbing causes, a perfect representation, both in space and time, of the motion of a free uniaxal solid, as *e.g.* a probate or oblate spheroid, or a square or equilateral prism or pyramid about its centre of gravity, and conversely that every possible free motion about its centre of gravity of every such solid admits of being so represented.

To revert for an instant to the general question of the represensentative rolling ellipsoid, I think it must be admitted that the addition of the time element to the theory and the substitution of a second fixed plane in lieu of a fixed centre, considerably enhance the value and give an unexpected roundness and completeness to Poinsot's image of the free motion of rotation of a rigid body, of which so much and not altogether undeservedly has been made. From an idea or shadow Poinsot's representation has now become a corporeal fact and reality, as if, so to say, Ixion's cloud, in the moment of fruition, had substantified into a living Juno. I heard the late Professor Donkin, of revered and ever-to-be-cherished memory, state that when as a referee of the Royal Society he first took in hand my paper on rotation, he did so with a conviction that all had already been said that could be said on the subject, and that it was a closed question; but that when he laid down the memoir he saw reason to change his opinion. I owe my thanks to M. Radau and the editors of the Annals of the Ecole Normale Supérieure for having been at the pains to disentomb the little-known conclusions therein contained from their honourable place of sepulture in the Philosophical Transactions. K House, Woolwich Common, April 2

The Principle of the Conservation of Force and Mr. Mill's System of Logic

WILL you permit me briefly to point out, what has not, as far as I am aware, been yet noticed—the very important modifications of the logical theory of induction resulting from the consideration in reference thereto of the physical theory of the correlation of forces?

As I believe the subject is now more ripe for discussion than it was when, some dozen years ago, I first began to work out the bearings of the higher results of physical research on the general theory of causation, logical, and metaphysical; the following questions which, in the course of a correspondence on this subject, I submitted to Mr. Mill so long ago as 1863, may, perhaps, contain suggestions of thought not unwelcome to some students of NATURE.

"How then," I wrote, "do our new views of force affect the established theory of causation? Now I would rather, if you will allow me, submit the whole subject interrogatively to you, than give dogmatically my own thoughts. And, more particularly, allow me to submit to you these two questions—1st, Whether the physical theory of transformation (and identity) does not necessitate all such logical changes of expression, at least, as may be implied in the abolition of the conceptions of "permanent causes," and of "kinds," as real and absolute existences? And, 2ndly, whether—"if, as I have endeavoured to show, the inductive facts on which are based the principles of conservation and correlation lead to such a more general principle as may be thus expressed, *every existence has a determined and determining co-existence*,—whether, I say, "we are not justified in enunciating such a principle as the complement of that fundamental axiom of our present logic, 'every effect has a cause'?"

I believe I am at liberty to say that, though affirmative answers to these questions would necessitate very important changes in the "system of logic, inductive and ratiocinative," Mr. Mill, as to the first, admitted the necessity of certain changes of expression, at least, and generously encouraged me in the prosecution of the researches indicated by the second question.

Of the results of these researches I shall here only say that, as the axiom, "every effect has a cause," is the foundation of a logic which must be distinguished as a *logic of sequence*, the new axiom above stated may be shown to be the basis of a *logic of co-existence*, of which *Geometry* appears as an example. But as to this, as to the conception of force implied in this idea of co-existence, and as to the bearing of this new conception of force on the speculations with regard to space of a fourth dimension, perhaps I may have another opportunity of addressing you.

Athenæum Club, March 30

Dust and Germs of Life

PROF. TYNDALL'S exceedingly interesting article in No. 20 of NATURE seems to me to leave unexplained a fact very familiar to naturalists. It is well known that collections of natural history, say a Herbarium or an Entomological cabinet, will, if left undisturbed for a number of years, and unpoisoned, become infested with animal life, chiefly Acari and larvæ of Coleoptera; and that the surest way of preventing such attacks is thorough ventilation. Now if the floating matter in the air settles so readily after only a few days' stillness, as Prof. Tyndall's experiments seem to indicate, and does not even enter into an uncorked flask, it is out of the question that it can penetrate through the keyholes or chinks of our cabinets. Setting aside the theory of spontaneous generation, we are then forced to the conclusion that this life must arise from germs already existing in the specimens when they are preserved, or in the very limited amount of atmosphere originally confined in the cabinet. Is either of these explanations tenable? A strong argument against the former alternative seems presented by the fact that, as far as I am aware, the same species of Acarus infests plants in a Herbarium brought from the most widely diverse localities, an inland meadow or the seashore, the plains of England or the Alps of Switzerland. Can any of your physiological readers throw light on this subject? F. L. S.

Catkins of the Hazel

WHILE looking at some hazel bushes to-day, I noticed that where the red tuft of stigmas was protruded, the male catkins adjacent on the same twig were immature; while, on the other hand the stigmas had fallen, and the fruit was already swelling, where the scales of the male flowers were open to show the stamens.

A week or two back (in another locality) I could not find a single female catkin which had not lost its stigmas; while nearly all the male catkins had opened, and many had shed their pollen.

Is this always the case with the hazel? If so, it would be a striking illustration of Darwin's aphorism, "Nature abhors perpetual self-fertilisation."

I ought to add, that my observations are not confirmed by the illustrations in the books to which I have access, namely, Balfour's "Class Book," Lindley's "School Botany," and Lemaout and Decaisnes' "Traité de Botanique." In all these, a female catkin with its tuft of stigmas is represented on the same twig as a bunch of fully developed male catkins.

Will some one of greater experience inform me if I am in error as to the above facts? MARCUS M. HARTOG

University College, London, March 24

ANCIENT BRITISH LONG BARROWS

II.

THE chambered long barrows of North Wilts, Somerset, and Gloucestershire differ, as a rule, but slightly in external form from the simple or unchambered long barrows of South Wilts and Dorset. They are, however, generally of somewhat smaller dimensions, being from about 120 to 200 feet in length and from 30 to 60 feet in breadth. The side ditches characteristic of the unchambered barrows are seldom to be met with, but the margin of the grave-mound is, or rather was, usually defined by a low wall, built of loose tile-shaped fragments of oolitic stone. In some cases, as at West Kennet (see fig. 1), there is good evidence that the mound was originally surrounded by a series of obelisks of sarsen stone, the intervals being filled up with the usual dry walling just described. Sometimes, too, large monoliths or triliths are found at the broad end of the tumulus. As regards orientation, or position in reference to the points of the compass, the direction of east and west commonly observed in the simple barrows prevails in four out of five cases with the chambered barrows; and as in the former class of monument the interments were at the eastern end, which is also the higher and broader, so likewise do we find that the stone chambers or cists occupy the same position in the chambered barrows.

In internal structure the chambered barrows exhibit many varieties, but three principal types are recognised by Dr. Thurnam, viz.—(1) those in which the chamber opens into a central passage or covered way; (2) those with chambers opening externally; (3) those containing cists instead of chambers. The essential distinction between a chamber and a cist is, that the former is entered by a lateral aperture, whilst a cist can only be opened by removing the covering stone from above. The views and plan in figs. 4 and 5 of the chamber and gallery of the great tumulus at West Kennet already alluded to will show the reader at a glance the nature of the simpler specimens of the first and most characteristic type of structure. It is only necessary to add that the West Kennet chamber was covered by three very large blocks of sarsen stone, and that its dimensions were as follows: length 8 feet, breadth 9 feet, height 8 feet. Some of the barrows of the first type—as, for example, those of Stoney Littleton and Uley—are of much more complicated internal structure than that of West Kennet; but they all possess in some form or other the central gallery or avenue, ingeniously supposed by Nilsson to be the homologue of the passages to the caverns which probably served as the first dwelling-places of man.

It must not be supposed that chambered barrows are confined to North Wilts, Somerset, and Gloucestershire; but those in distant counties appear to differ from those of the districts above referred to in certain respects, and especially in being usually circular in form. The sepulchral stone chamber, universally known under the name of "Wayland's Smithy," though situated in Berkshire, is close to the confines of North Wilts, and was originally covered by a true long barrow. Dr. Thurnam surmises that the barrow was removed, or at least the chamber disclosed, at an early date, as he finds that the name "Welandes Smiththan" was applied to it so long ago as the middle of the tenth century, a name very unlikely to have been used so long as the barrow was intact.

It might seem at first sight that the presence of megalithic chambers in the tumuli of North Wilts, Somerset, and Gloucestershire is a characteristic which entirely differentiates them from the simple earth mounds of South Wilts, and that we should be warranted in assigning the two classes of monuments to different peoples, or at all events to different stages in the history of the same people. Every one familiar with the surface geology of the two districts will, however, at once admit the validity of Sir Richard Hoare's statement, that the absence of the stone structures in the South Wiltshire long barrows is simply due to the want of the necessary material. Referring in connection with this subject to the South Wiltshire Downs, Dr. Thurnam writes:—"Scattered blocks of silicious grit or sarsen stone are indeed found here and there on the surface, but they are neither numerous nor large enough for this purpose. In North Wiltshire and the adjacent part of Berkshire the case is different, and sarsen stones of large dimensions and in great numbers are found in the hollows of the higher chalk downs. From these were derived the immense stones of the circles and avenues of Avebury; and as most geologists and antiquaries believe, those out of which the great trilithons, and mortised uprights and imposts of Stonehenge itself, in South Wilts, were formed."

FIG. 1.—LONG BARROW AT WEST KENNET (PERISTALITHS AND WALLING RESTORED)

The implements and pottery of the chambered barrows agree very closely with the specimens derived from the simple earthen tumuli. The infrequency and rude character of these objects, especially when compared with the comparatively abundant and highly-finished weapons and tools yielded by the chambered tumuli of Scandinavia and Brittany, are sufficiently remarkable. Perhaps the fact that our chambered barrows have been so generally searched by treasure-hunters in various ages may serve to some extent to explain the almost entire absence of polished stone implements. Such objects would probably have attracted the attention of persons of that class; the ruder objects, having no value in their eyes, would be left in the tombs. The delicate leaf-shaped arrowheads alluded to in our former article as found in unchambered tumuli also occur, though rarely, in the chambered barrows. Fig. 3 will show that the manufacturers (whoever they may have been) of these weapons were possessed of no mean skill in the fashioning of flint; and it may perhaps be allowable to infer from the rarity and perfection of these objects, as contrasted with others obtained from long barrows, that they were obtained from tribes in a somewhat more advanced stage of civilisation. It is a singular circumstance that all the leaf-shaped arrowheads have

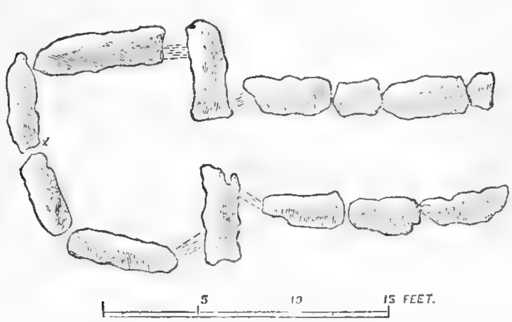

FIG. 2.—PLAN OF CHAMBER AND GALLERY

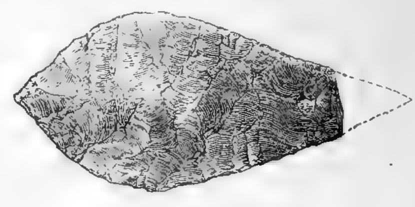

FIG. 3.—FROM FYFIELD LONG BARROW

one or both ends broken off. The breaking of the point of the dead warrior's spear was probably a solemn ceremony, and contrasts agreeably with repulsive funereal practices to which we shall presently refer.

The bones and teeth of animals apparently used for food, are found in considerable numbers. The remains of *Bos longifrons* and *Cervus elaphus* are, however, less frequent than in the unchambered barrows, whilst those of the wild boar are much more abundant.

We have already in our first article alluded to the important evidence which the critical study of the human remains from the long barrows is calculated to afford us, but in our remarks thus far we have purposely refrained from entering into the details of this subject. Although certain of the chambered barrows have afforded numerous skeletons, these monuments have been so frequently disturbed by treasure-seekers in bygone times, that our information as to the mode of interment is not so satisfactory as could be wished. There seems, however, to be little doubt that the bodies were placed round the walls of the chambers in a crouching or squatting posture, a favourite attitude for the dead both among early races and existing savages. The primary interments in the simple unchambered barrows consist either of a single or two separate skeletons, or of a number of bones promiscuously interred. In the latter case the bones are frequently found huddled together in so narrow a compass as to preclude the idea of the corpses having been buried entire. This is most reasonably accounted for by the practice known to prevail among savage races of burying the dead in or near their huts, and subsequently disinterring the bones for the purpose of burying them in the cemetery of the tribe. Canon Greenwell, so well known for his explorations in the Wolds of Yorkshire, thinks that some of the bones from long barrows examined by him indicate the horrible practice of cannibalism. Dr. Thurnam endorses Mr. Greenwell's opinion on this point in the following words: "Altogether I see no difficulty in acceding to the conclusion of Mr. Greenwell, that in the disjointed, cleft, and broken condition of the human bones in many of the long barrows, and especially in those examined by him at Scamridge, near Ebberstone, and near Rudstone, Yorkshire, we have indications of funeral feasts, where slaves, captives, and others were slain and eaten."

In a large proportion of the long barrows of the South-West of England, many of the skulls have been found to be split open apparently by some such weapon as a stone axe. The sharpness of the fracture seems to leave no doubt that the injuries were inflicted during life, or at all events before burial. It is inferred from the frequency of these cleft skulls, and the direction in which they are split, that they are those of victims immolated at the burial of a chief. Sometimes one skull is found uninjured while all the others are injured. In the light of what has come down to us from classical writers of the customs of Western Europeans at the beginning of our era, we see no reason to doubt Dr. Thurnam's conclusions on this point, although we should have liked to have more precise information of the relative number of cleft and uninjured skulls in particular barrows.

The question how far the human remains, more especially the skulls, enable us to determine the race characters of the people or peoples who lie buried in the tumuli of Britain, has been discussed with great care and at considerable length in two papers by Dr. Thurnam, published in the Memoirs of the Anthropological Society for the years 1864 and 1870. In the first of these papers the conclusions, based on the examination of a very considerable number of skulls and limb bones, were maintained that the people whose remains are found in the long barrows were a short, long-

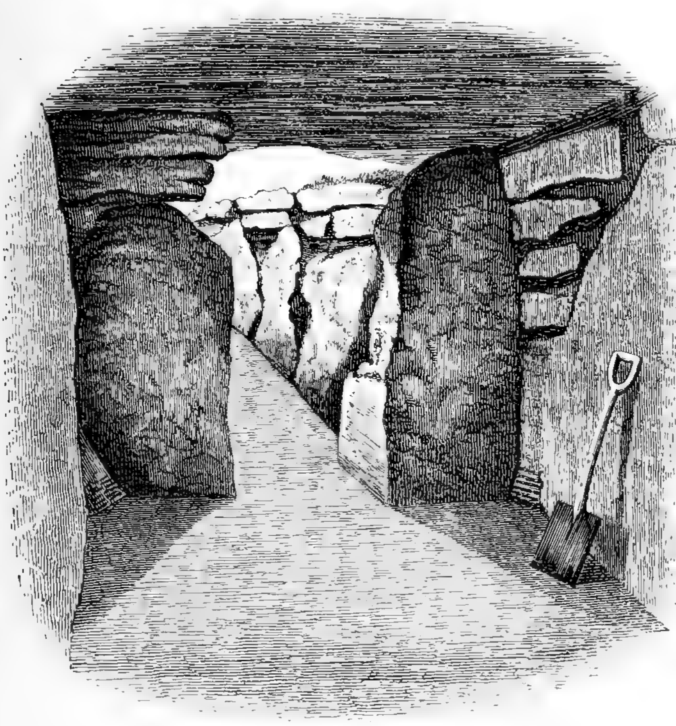

FIG. 4.—VIEW IN THE CHAMBER, LOOKING THROUGH THE ENTRANCE

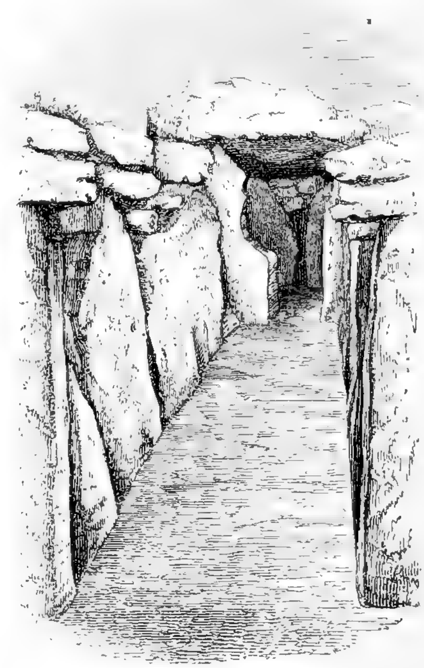

FIG. 5.—GALLERY LOOKING TOWARDS THE CHAMBER

headed race, with small features, whilst those from the round barrow were a tall, short- or round-headed race, with larger and more prominent faces. There was nothing new in this statement that the skulls of the ancient Britons of the later or Bronze age were usually of rounded form ; the chief novelty was the fact deduced by Dr. Thurnam from his explorations in the primeval long barrows, that the skulls from that form of tumulus are of extreme length, such as now prevails only in far distant lands, as for example in India, Africa, and Australia.

Dr. Thurnam's general conclusions as to the skull-forms from the barrows, were concisely expressed by him in the formula—"long barrows, long skulls: round barrows, round skulls." This coincidence between the form of the barrow and the shape of the skulls which it contained, appeared to be so strange to some minds that they hesitated to give full weight to the statistics brought forward in support of it. The unfavourable reception which Dr. Thurnam's conclusions met with in certain quarters, however disagreeable to him at the time, can now only be a subject of congratulation, as it no doubt served as a spur to further investigation, the results of which are most conclusive. In the paper published in the Anthropological Memoirs of 1870, Dr. Thurnam was enabled to discuss the character of as many as sixty-seven skulls from the two classes of long barrows, no fewer than twenty-seven of them being from simple barrows, although the first described skull from that class of tumulus was obtained so recently as 1863. The results of the measurements of these sixty-seven skulls, as contrasted with those derived from seventy skulls from the round barrows, may readily be made evident to those of our readers who are least acquainted with the technicalities of craniology. Skulls are now usually classed according to the form of the brain case, as "long," "short," and "intermediate," the limits of each class being accurately defined. Of these sixty-seven skulls from long barrows, then, it is found that eighty-two per cent. are technically long, and eighteen per cent. intermediate; not one technically short or round. On the other hand, of the seventy round barrow skulls, eighty-three per cent. are short, and seventeen per cent. intermediate ; not one long. Bearing in mind that the archæological evidence has satisfactorily established the superior antiquity of the long as compared with the round barrows, the conclusions here arrived at, based as they are upon a wide induction of instances derived from one district and one class of monuments, are a clear gain to science, and are not for one moment to be compared with such hypotheses as that of a primitive short-headed population, founded by Retzius upon the examination of isolated crania from various parts of Europe.

The question of the relation of the men of the long barrows to the existing people is one of great difficulty. It might seem natural to infer that the skulls recognised by some excellent observers, such as Dr. Beddoe, as Keltic skulls, are the modern representatives of the ancient long heads. They seem to us, however, to differ in many essential particulars, especially in the important element of height. Dr. Thurnam appears to have been impressed with certain historical evidence favourable to the notion of the Iberian origin of the long barrow people, and he has accordingly carefully studied the large series of Basque skulls in the museum of the Anthropological Society of Paris. The results of the comparison between the two classes of skulls do not, however, seem to go far towards supporting the Iberian theory. We are inclined to think that Dr. Thurnam should have turned to the north rather than to the south of Europe for the representatives of the primitive long-headed population of Britain. He readily allows that certain skulls obtained from ancient cemeteries (grave-rows) in northern Germany closely resemble those of the long barrow folk, but he seems to have been deterred from following up the clue by the fact that these grave-row skulls are of the iron period, and probably of post-Roman date. Since the date of Dr. Thurnam's paper, however, skulls of the same long and high form have been found in Rheinhessen, in graves assigned by the eminent archæologist Lindenschmidt to a date 500 years before Christ. Similar skulls have also been discovered in Bohemia with weapons of stone and bronze.

We have devoted so much space to the archæological and craniological portion of Dr. Thurnam's paper, that we are unable to notice in detail the admirable way in which the physical facts observed are reviewed in the light of historical evidence. It must suffice to say that the men of the long barrows are identified with those "described by Cæsar under the name of *Interiores Britanni*, as forming the aboriginal population," whilst those of the round barrows are inferred to be the Belgæ, who, according to Cæsar's account, passed over to Britain from the Continent, in immediately pre-Roman times, for the purpose of plunder and making war.

NOTES

We are glad to be able to state that energetic steps are now being taken in the matter of the Expedition to view the approaching Eclipse of the Sun. We believe that Mr. Lassell, the President of the Royal Astronomical Society, will call attention to the subject at the meeting of the society to-morrow evening.

Mr. Lockyer, in his third lecture on the Sun, delivered at the Royal Institution on Saturday last, showed an interesting experiment with a candle, which gives a good general idea of the solar phenomena as observed by his new method. As round the sun Mr. Lockyer can spectroscopically detect an ordinarily invisible hydrogen envelope which is rendered evident by bright lines only as contrasted with the nearly continuous spectrum given by the white light of the surface of the sun, so also there is an ordinarily unnoticed envelope (of sodium vapour) round a common candle flame which gives a bright line spectrum as contrasted with the continuous spectrum of the flame itself. Mr. Lockyer also showed that some of the phenomena he has seen when watching a solar storm may be reproduced by disturbing a candle flame.

We have heard so much recently of the long-delayed determination of Cambridge University to apply itself in earnest to the cultivation of Natural Science, that the information contained in the following paragraph must be a blow to those of its friends who hoped to see that it was entering on a new course :—"The Syndicate appointed to consider the means of raising the necessary funds for establishing a Professor and Demonstrator of Experimental Physics, and for providing buildings and apparatus required for that department of science, and other wants of the University, have made a report to the Senate, in which they state that they have addressed a communication to the several colleges of the University, to inquire whether they would be willing, under proper safeguards for the due appropriation of any moneys which might be entrusted to the University, to make contributions from their corporate funds for the above-mentioned objects. The answers of the several colleges, except that of King's, which has not yet been received, have been fully considered by the Syndicate. They indicated such a want of concurrence in any proposal to raise contributions from the corporate funds of colleges, by any kind of direct taxation, that the Syndicate felt obliged to abandon the notion of obtaining the necessary funds from this source, and accordingly to limit the number of objects which they should recommend the Senate to accomplish. They confined their attention, therefore, to the means of raising sufficient funds only for carrying out the recommendations of the Physical Science Syndicate in their report dated Feb. 27, 1869. These were to provide the stipends of a Professor of Experimental Physics, of a Demonstrator and an attendant, requiring altogether a sum of 660*l.* per annum; also to provide a capital sum of 5,000*l.* for a new building, and 1,300*l.* for apparatus. The Syndicate are of opinion that these sums may be raised from the ordinary sources of revenue of the University, and that a small addition (viz., 2*s.* a head) to the amount of the annual capitation tax will suffice for the purpose. They think, also, that there are circumstances connected with the fixing the amount of the capitation tax by the Grace of May 31, 1866, which in themselves justify some increase, and they mention the increased payments of late required for the town improvements. They think that the buildings may be erected from the existing building funds, and apparatus purchased by money belonging to the chest, and now invested." Was ever a more lame and impotent conclusion? It makes us seriously think whether the time has not come when the State should exercise more control over the enormous revenues of these old colleges, which seem determined to go on in the old track.

AN important zoological discovery has just been made in Australia. Mr. Gerard Krefft, the energetic curator and secretary of the Australian Museum, Sydney, has sent to the Zoological Society of London an account of a new and very singular freshwater fish recently discovered in Queensland, which united the external form of *Lepidosiren* with other characters belonging to the extinct Ganoid fishes of the genus *Dipterus* and its allies, and seems to form a connecting link between the *Dipnoi* and the *Ganoidei*. Mr. Krefft proposes to call this fish *Ceratodus forsteri*, after Mr. William Forster its discoverer. His paper on this subject will be read at the next scientific meeting of the Zoological Society on the 28th inst.

IN calling attention to a paper read before the Society of Arts on Thursday last, an abstract of which will be found in another column, we cannot avoid contrasting with the fact that our Legislature is now for the first time directing its attention to the question whether the State ought to recognise Science, the support which the French Government is at the present moment actually giving to scientific researches of the highest importance. In the Budget for 1870 there is a grant of 60,000 fr. for the meteorological observatory at Montsouris; one of 12,000 fr. for the publication of Delaunay's Lunar Tables (to be the first of five similar annual grants); one of 100,000 fr. (to be followed by one of 300,000 fr. in 1871), for the Ecole pratique des hautes études; one of 500,000 fr. for technical instruction; and one of 60,000 fr. for the observatory at Marseilles; while primary instruction finds its true level in a supplementary grant of 1,112,000 fr. for the necessary expenses during 1869 and 1870. In contrast with this, it is doubtful whether the grant of 4,000*l.* voted by Parliament some years ago for a botanical museum at the Glasnevin Gardens, Dublin, may not actually be withdrawn.

WE hear from Edinburgh that there is much excitement amongst the supporters of the Lady Medical Students, on account of the Professor of Chemistry refusing to accord one of the Hope Scholarships to Miss Edith Pechey, who is studying medicine at the university in that town, and who, by the number of marks gained, is entitled to a junior scholarship. The case is stated thus. Many years ago a Dr. Hope, amidst great opposition, opened a chemistry class for ladies. The movement was then so unpopular that he admitted these students through a window, as they were not allowed to pass through the gateway of the college. At his death all the fees he had obtained from this class, amounting to about 1,000*l.*, he left to found the Hope Scholarships. These scholarships consist of four, two senior and two junior. The rule is as follows:—"The class honours are determined by means of written examinations held during the session. The four students who have received the highest marks are entitled to have the Hope Scholarships to the laboratory of the University." This passage from the university calendar certainly gives us the idea that *any* student who has passed the written examinations is entitled, if a sufficient number of marks be obtained, to the benefit of it. Dr. Crum-Brown proposes to give Miss Pechey one of the bronze medals, but declines to give her the junior Hope Scholarship she has obtained, and which entitles her to six months' free admittance to the laboratory. Out of 234 men and six women, Miss Pechey comes third: the two men above her were last year's students, so that of this year's students Miss Pechey stands pre-eminently first. As she is a matriculated, registered, medical student, her supporters contend that she can legally claim the honours due to her. We believe, however, that the matter is to be put before counsel, so that a legal opinion may be obtained on the subject. We are informed, also, that Miss Sophia Jex-Blake's name has come out in the first-class honours list in chemistry; so the lady doctors may fairly be congratulated on the results of their first session in Edinburgh.

THE Senate of the University of London has appointed to the new office of Assistant-Registrar Professor T. A. Hirst, Ph.D., F.R.S., Professor of Mathematics in University College, London, and one of the permanent secretaries to the British Association.

THE new building of the University of London, in Burlington Gardens, will be opened by the Queen in person on Wednesday, May 11. Her Majesty, accompanied by the Prince and Princess of Wales and the Princess Louise, will be received at the entrance of the building by the Chancellor (Lord Granville), the Vice-Chancellor (Mr. Grote), the member for the university (the Chancellor of the Exchequer), and the Chairman of Convocation (Dr. Storrar), and be conducted to the Senate Room, from whence Her Majesty will pass to the larger rooms in the building, and finally to the large theatre, where an address will be presented. The Queen will then declare the building opened, and leave by the principal entrance. As many visitors as can conveniently be accommodated in different portions of the building will be invited, including the Premier, some of the Secretaries of State, the Lord President of the Council, representatives from the sister universities, the learned bodies and affiliated colleges, with the examining staff of the university.

THE chair of Natural History in the Royal Agricultural College, Cirencester, lately vacant by Prof. Thistleton-Dyer's removal to Dublin, has been filled by the appointment of Dr. W. R. M'Nab, of Edinburgh.

THE University of St. Andrews has conferred the honorary degree of LL.D. on Mr. J. T. Boswell-Syme, well known as the editor of the last edition of "Sowerby's English Botany," and the author of many valuable contributions to botanical science.

THE origin of the minute discs termed red blood-corpuscles, which float in our circulating fluid in such countless millions, communicating to it its rich opaque hue, is still a matter of question amongst physiologists, though most are inclined to believe that they proceed from the nuclei of the white corpuscles. But even supposing this to be the case, the question immediately arises, whence come the white corpuscles? and the reply is, from the lymphatic glands, and those large organs which for want of a better term are called ductless glands, of which the spleen, the thymus, and thyroid glands are examples; this reply being grounded on the fact that large numbers of white corpuscles are found distributed in the interior of the glands, whilst the blood returning from them contains more such corpuscles than the blood running towards them. Still the mode of origin of the white corpuscles in these glands and elsewhere is unknown. A recent investigation by Dr. Klein, of Vienna, appears to furnish some clue to the discovery of this point, for he has demonstrated that a process of division of white corpuscles may, under favourable conditions, be observed to occur, a statement which, if corroborated by further researches, will prove of much importance both in physiology and pathology. In the blood of the water-newt, he remarks, three kinds of colourless cells may be distinguished, though their differences are not very strongly marked. In one of these forms the clump of protoplasm, of which the corpuscle is formed, assumes an hour-glass form, and with the performance of the liveliest movements in each half, ultimately divides into two, in each of which a nuclear structure is visible. In a second kind the protoplasm forms a flat transparent disc, from the border of which a projection containing a distinct nucleus forms and gradually becomes detached. In a third form a kind of pinching off occurs of a minute portion from the general mass. The primary corpuscles may divide twice or thrice.

Les Mondes for March 31st contains a translation of Prof. Tyndall's article in NATURE for the 17th of the same month, on Floating Matters and Beams of Light.

MESSRS. W. & A. K. JOHNSTON are preparing a series of Botanical Diagrams for Schools and Colleges, uniform with their "Illustrations of Natural Philosophy," 50 in. by 42 in. A good series of diagrams is very much wanted by botanical lecturers; the parts should be on a larger scale than in the late Prof. Henslow's diagrams published under the authority of the Government School of Science and Art, and the series more complete than that issued by the Christian Knowledge Society, which is very good as far as it goes, and remarkably cheap.

THE Marlborough College Natural History Society has published its report for the half-year ending Christmas 1869, from which we gather, that beyond all question a real taste for science is taking firm root at Marlborough, though here and there, in the various papers, we get all too glowing descriptions, instead of the sober evidence of the keen eye of the observer. Here, for instance, is a description of the cuttle fish:—"And while I enumerate the greatest oddities to be seen in the 'motley crew' of fishes, shall I forget thee, O cuttle, that lookest so innocent and harmless, till some white-waistcoated visitor takes thee up condescendingly, when with one mighty effort thou contractest thy muscles, and in an instant sendest a mighty stream of thy own peculiar ink over that erst virgin waistcoat? Oh, the inimitable look of pity and contempt then depicted on the faces of the natives! If by thy squirts and fliks, O cuttle, thou hast made an enemy, thou hast made one that will never molest thy inky tribe again. It is interesting to know that these murky creatures are provided with backbones which have the peculiar quality of ink-erasing."

THERE is in the West Riding a Geological and Polytechnic Society, which publishes an annual report of proceedings. In that for 1869 an account is given of the meeting held at Wakefield, together with a number of papers on the history, antiquities, and mineral products of the county. The author of "On the Rocks of the neighbourhood of Pontefract," shows that there is coal enough along the line of the Lancashire and Yorkshire Railway, to yield nearly ten million tons a year for 489 years: and that the prospect of getting further supplies below the Magnesian Limestone and the New Red Sandstone is very promising. The Rev. Scott F. Surtees contributes an argumentative paper to prove that the memorable battle between Harold of England and Harold of Norway was fought, not at Stamford Brig, but at Pontefract, and that the memory thereof is preserved by the name Ponte-fract—broken bridge. Other papers contain notices of the extinct fauna of Yorkshire, of flint implements, and of certain singular ancient pits in the neighbourhood of Ripon.

A PARAGRAPH appears in a recent number of the San Francisco *Bulletin*, stating that deer, antelope, bear, and elk constitute the large game of California. Deer are found in great abundance, and many hundreds are killed yearly on Tamalipas. The deep gulches, woods, and covers of Marin County afford excellent sport to the deer hunter. Elk do not range nearer than the Oregon line, but a few are still met with on the banks of the Sacramento and San Joaquin rivers, where in former years they were so abundant. The brown and black bear are also hunted in Marin County, and along various parts of the coast range. White and grey geese are found in all the bay counties, on the lakes, and up the rivers in abundance. Duck are shot in the same localities, of which the most valued is the mallard, which remains and breeds in the country. Then come the redhead, springtail pigeon, wood duck, blue and green winged teal, broadbill, spoonbill, sawbill, whistler, butterball, fantail, or Dutchman, and Cadwell's. Quail abound in the surrounding counties. In the immediate neighbourhood of the city quail are scarce, being trapped and slaughtered for the markets so earnestly, that here they are now almost exterminated. Rabbits are also found in the quail grounds. The English or jack snipe are shot in the freshwater marshes on the San Joaquin and Sacramento rivers, in the Amador, Gilroy, and Santa Clara valleys. Of the bay snipe there is an abundant variety, such as curlew, willet, whitewings, plover, yellowlegs, robin, doewitch, ringneck, and sandpiper. The grouse, one of the finest game birds, frequents Mendocino and the upper counties of the State; several attempts have been made to stock the lower counties with these birds, but with little success. Trout abound in all the rivers running into the bay, and are taken with both bait and fly, but principally the former.

REMARKABLE SPECTRA OF COMPOUNDS OF ZIRCONIA AND URANIUM

THOUGH the spectra of different salts of bases which show well-marked absorption bands often differ in detail, yet they generally resemble one another so much that there is no difficulty in recognising each element. Judging from facts hitherto known, it was more probable that spectra of the new type described in my former paper* were due to a new element than that they were merely due to a combination of zirconium with uranium, and that there seemed to be no reason for suspecting a few special compounds of uranium would give spectra with bands unlike all others. Uranic salts, when in a state of moderately fine powder, give a spectrum not only showing absorption-bands, but also those which depend on fluorescence, and are characteristic of light reflected from the powder.† These two kinds of bands can be easily distinguished by means of a plate of deep blue cobalt glass, which proves that the abnormal bands seen in the spectra of the compounds of zirconia with the oxides of uranium are due to genuine absorption and not to fluorescence.

In studying the spectra of crystalline blow-pipe beads, it seemed desirable to examine those made with carbonate of soda, with or without a little borax. Though beads of carbonate of soda crystallise on cooling, so as to be only partially translucent, yet with strong direct sunlight well-marked spectra may be seen. For example, in the oxidising flame uranic oxide is easily dissolved by carbonate of soda alone, and when quickly cooled an orange-coloured bead is obtained, probably containing uranate of soda in a vitreous condition. It gives a single well-marked absorption-band in the green, with so small a quantity of the oxide, that in a bead $\frac{1}{8}$ inch in diameter $\frac{1}{2000}$ grain shows the spectrum to the best advantage, and even $\frac{1}{10000}$ grain can be easily detected. In examining the various products from jargons in order to study the supposed new earth in a state of purity, a small quantity of a dark-coloured substance was obtained, apparently zirconia, containing some oxide which communicated a green tint to a glassy, borax blowpipe-bead, but yet not sufficiently

* Proceedings of R. S. vol. xvii. p. 511.
† See Stokes's paper, Phil. Trans. 1852, p. 463 and 1853, p. 392.

distinct to show that it was due to uranous oxide. Though the presence of zirconia prevented solution by pure carbonate of soda, the addition of a little borax enabled me to prove that uranic oxide is really present in some jargons. Such then being the case, it seemed desirable to ascertain whether the oxides of uranium would give rise to any special spectra when present along with zirconia in crystalline blowpipe-beads. To my astonishment I found that the spectra were precisely the same as those obtained in the case of what I had thought to be an approximately pure new earth.* Hence the very abnormal spectra, which seemed sufficient to establish the existence of a new earth, are really due to compounds of zirconia with the oxides of uranium, which have such a powerful action on light, that an almost inappreciable amount is sufficient to produce the spectra to great perfection—in fact so small an amount, that the total quantity which misled me was only a few thousandths of a grain; and its presence might easily have remained unsuspected, if I had not discovered the carbonate of soda test just named. In the case of transparent blowpipe-beads of borax with microcosmic salt, it is requisite to have as much as about $\frac{1}{50}$ grain of uranous oxide to show faintly the characteristic absorption-bands, whereas, when present along with zirconia in the crystalline beads, $\frac{1}{30000}$ grain gives an equally well-marked spectrum; and $\frac{1}{2000}$ grain shows it far better than a larger quantity, which makes the beads too opaque. These very minute quantities were obtained by the repeated division of a small known weight, either before or after fusion with borax. This spectrum also differs very considerably from the spectra of the usual salts or blowpipe-beads of uranous oxide. On comparing them side by side, the only common peculiarity is the fact of there being numerous absorption-bands distributed over a large part of the spectrum; but they do not correspond in either number or position. On the contrary, they differ almost as much as possible; and the darker bands in the spectrum of this zirconia compound occur where the transmitted light is the brightest in other cases. One of the most striking peculiarities of the spectrum of some jargons is, that when light passes in a direction perpendicular to the principal axis of the crystal, and the spectrum is divided by means of a double-image prism into two spectra, having the light polarised in opposite planes, though some of the absorption-bands are of equal intensity in both images, yet others are comparatively absent, some in one and some in the other; whereas, in the case of other dichroic crystals, all the absorption-bands are usually more distinct in one image, and fainter, or even comparatively absent, in the other. The general character of the spectrum was entirely unlike that of all the known compounds of uranic oxide. Instead of the moderately broad absorption-bands in the blue end, ignited jargons give a most unusually large number of narrow black lines, extending from the red end, so that nearly all occur in that part of the spectrum which is entirely free from bands in all previously known compounds of uranic oxide. Besides uranium, and several of the more common earths and oxides, I have detected in some zircons erbium, didymium, yttria, and another substance which exists in such small quantity that I have not yet been able to ascertain whether or no it is the suspected new earth. These accidental constituents do not indeed occur in sufficient quantity to be of importance, except as modifying the physical and optical properties, the didymium giving the usual characteristic absorption-bands (zircons from Sveneroe, Norway), and the manganese, the same spectrum as that of garnets (zircons from an unknown locality in Siberia†). The oxide of uranium is so easily reduced at a high temperature to the state of protoxide in a borax-bead, with excess of boric acid, and is so readily peroxidised at a dull-red heat, when crystallised along with borate of zirconia, that there seemed good reason to refer the change in the spectra to temperature rather than to the state of oxidisation, until after it was found that they were due to uranium. By gently flaming the crystalline bead, the spectrum is entirely altered, and presents five well-marked absorption-bands, all of which occur at the red end, where no trace of bands exists in the case of ordinary uranic salts. I have not found any other element besides zirconia which causes uranium to give similar abnormal spectra, at all events in similar conditions. A few have special characters, but the majority exert little or no influence. Even when the blowpipe-beads are crystalline, they show only the usual spectra of the oxides of uranium. Moreover no such great change in the character of the spectra of other elements which give absorption-bands is to be seen when they are combined with zirconia. So far as my present experience goes, it seems as if such very abnormal spectra were met with only in the case of these remarkable compounds of zirconia with the oxides of uranium. These facts now put us in a position to explain why certain zircons give three different spectra. Some jargons (usually those of a green tint) contain a little uranium so combined that the characteristic spectrum is only faintly visible, whereas, after ignition, the intensity of the absorption bands is permanently increased often to a very great extent, and this more powerful action on light is accompanied by an increase in hardness and in specific gravity, sometimes as much as from 4·20 to 4·60. These changes are approximately proportional to the amount of uranic oxide in the various specimens, as shown by comparing the spectra of the blowpipe-beads. On the whole, since this abnormal type of spectrum is so characteristic of combination with zirconia, it appears probable that the effect of a high temperature is to cause the uranic oxide to combine more specially with the zirconia, as though the greater part existed naturally as a silicate, but after ignition as a zirconiate. We may also apply the same explanation in the case of zircons, more or less strongly coloured by other oxides, which become almost colourless when heated; and this unexplained peculiarity of zircons may depend on the fact of zirconia being able to play the part of both a base and an acid, which as compared with silica has an affinity for bases varying according to the temperature. The brown-red zircon from Ceylon, named at page 514 of my former paper, gives a spectrum precisely like that of the borax blowpipe-beads crystallised after treatment in the deoxidising flame. No doubt it contains uranous oxide. These facts thus clearly show that the various spectra which seemed to indicate the presence of a new element existing in three different physical conditions, are in reality only characteristic of the two oxides of uranium combined with zirconia, or not in combination. Perhaps some may think that my having been thus led astray shows that little or no reliance can be placed on the method of investigation employed, but I contend that the mistake was due to its being such an unexpectedly delicate test for uranium; moreover, the error was ultimately corrected by a further development of the same method. As far as the interests of science are concerned, there is no need to regret the general result. We have lost what appeared to be good evidence of a new earth, but have gained an almost entirely new system of blowpipe testing, which enables us to detect such a minute quantity of some substances as could not be recognised by the ordinary means.

H. C. SORBY

* Figs. 1 and 2 of my former paper.
† For both of these I am indebted to my kind friend Mr. David Forbes.

THE RELATION OF THE STATE TO SCIENCE

WE have referred in another column to Lieut.-Colonel Strange's valuable paper, read before the Society of Arts. The following is a report of the more important part of it. After giving a sketch of the history of the movement in favour of a recognition by the Government, of the necessity of defining the relations which should subsist between the State and scientific education throughout the country, commencing with the meeting of the British Association at Norwich in 1868, Colonel Strange proceeds to state the points which he thinks should be especially kept in view in the proposed inquiry. These are:—

1. The scope which the inquiry should include.
2. Some of the probable results of the inquiry.
3. The constitution of the Commission itself.

1. *The Scope of the Inquiry.*—The first thing to do will certainly be to take stock of what is now done by the State for advancing science. A reference to the parliamentary votes shows a considerable expenditure on science, in some form or other. The British Museum receives upwards of 100,000*l.* a year, the South Kensington Museum 92,000*l.*, and the Science and Art Schools 74,000*l.*, but in these cases a large proportion goes to art, not wholly to science.* The Royal Observatories of Greenwich, Edinburgh, and the Cape of Good Hope, the Royal School of Mines, the Ordnance Survey, the Hydrographic Department of the Admiralty, are all scientific branches of the admi-

* The total amount voted in the Estimates, for 1869-70, to maintain the "Science and Art Department of the United Kingdom" was 225,253*l.*

nistration, supported by the State at considerable cost. Enormous sums of money have been spent on special inquiries of a scientific character, such as those on armour-plate structures, ordnance, ammunition, small arms, explosive agents, and projectiles. The Parliamentary votes show also 10,000*l.* a year as given for meteorological observations. We also find a large number of small sums, forming, however, a considerable aggregate amount, given in aid of the funds of various colleges, universities, and museums; in some instances towards the salaries of specified professors, in others towards general purposes. The Royal Gardens of Kew receives 22,075*l.*; the Botanical Gardens of Dublin and Edinburgh receive respectively 1,931*l.* and 1,893*l.*; 20,900*l.* is spent on geological, and 92,790*l.* on the Hydrographic Department and naval surveys, besides very large sums on other miscellaneous objects.* Some of the institutions above named issue reports, from which the results of the expenditure on them may be inferred. In other cases this is not done. The wording of the votes seldom conveys any useful information on the subject whatever, and sometimes conveys incorrect information. The grant of 1,000*l.* a year distributed by the Royal Society is an example of such inaccuracy. This is said, in the words of the vote, to be given to the Royal Society "to enable the society to carry on certain experiments for public objects," whereas, instead of being given, as here stated, to the Royal Society, or for public objects, it is given to the community at large, and a committee of the Royal Society undertakes gratuitously the very laborious task—which does not even receive nominal acknowledgment—of distributing it with the strictest economy and impartiality, to such persons, whether belonging to the Royal Society or not, as may prove their ability to make good use of the aid they solicit in prosecuting scientific research.

Now, the results supposed to be obtained by the large expenditure recorded in the estimates may be thus enumerated:—(1). The maintenance of the efficiency of the public services in matters of a scientific nature. (2.) The teaching of science, directly, as by payment of professors, or indirectly, as by the maintenance of museums, botanical gardens, and the like. And (3), direct or indirect scientific progress, whether observational or experimental. What is wanted is, a clear statement of the degree in which these several results are attained in each particular case. With this information before us, we shall be in a position to arrive at trustworthy conclusions as to whether the money brings in each case an adequate return; whether the inadequacy of the return is due to defective organisation or to abuse; and whether, therefore, a more satisfactory result may not be obtainable in each case by a process of remodelling, without increased expenditure. We shall also ascertain, probably, that the whole expenditure in some particular case is needless, and is at present absolutely wasted. We shall learn, too, no doubt, that there is much divided, and probably much utterly undefined, responsibility in many of the cases in which large sums of public money are spent. Another fact, already patent, will be brought out prominently, namely, the entire absence of any pervading system by which the expenditure on scientific objects is regulated. Finally, it will clearly appear that the expenditure is very partially distributed, some branches of science receiving a very large amount of assistance from the public purse, whilst others, of equal importance to the community, receive none at all. This taking stock of our present scientific arrangements, it can hardly be doubted, is an absolute necessity to the success of the proposed inquiry.

Much of the information above adverted to will bear more or less on the question of "the higher scientific education." But in indicating the scope of the inquiry in this direction, it is very desirable that a clear conception should be formed of the meaning of this phrase. My own conception of it is this. Public opinion has decided that science should form part of the general education given at large and public schools, and at the universities. Such scientific education should comprise the elements of scientific knowledge, and the results of scientific labour, so far as these results are generally accepted as settled. Teaching of this kind forms, in my opinion, a portion of the great educational question which has been for some time occupying public attention, and which is now in a fair way of being put on a satisfactory footing. To impose on the Royal Commission the consideration of such teaching would be doing the same work twice over, and adding, therefore, unnecessarily to their already most laborious inquiry. But beyond the scientific teaching of schools and universities, there is much to be done in order to train advanced students to become investigators and observers, and this I conceive to be the object intended to be described by the phrase "higher scientific education."

It is maintained by very high authorities that it is beneficial intellectually to the investigator himself to have to teach, on account of the mental discipline and the habit of precise thought which it imposes on him. At present, unquestionably many of our best investigators are teachers also, and in all Continental scientific systems the two functions are combined. Two conditions seem important. First, that an investigator should not be required to impart the mere rudiments of scientific knowledge, but that his students should be far advanced before they come under his tuition; they should, in fact, be men who had already gained some distinction at the universities or elsewhere, and who had resolved on following science as a profession. The second condition is that the labour of teaching should engross only a moderate portion of the time of the investigator, leaving him ample leisure and spare energy for original research. At present, this latter condition is precisely reversed in the cases of most of our professors engaged in investigation, and we accordingly only reap the benefits of a mere residuum of their highest faculties.

Another matter connected with scientific teaching is considered by persons engaged in that important occupation to require attention, namely, the possible effect on independent educational institutions of rival State schools of science. The apprehended interference with such interests may perhaps be obviated by restricting State aid to the "higher" teaching which I have attempted to define, leaving the preparation of students for such higher teaching to the universities and other institutions of an independent character. But before any rules on this subject can be laid down, it is obviously necessary that the exact amount and kind of action now taken by the State in respect of teaching, and the effect of that teaching, both on scientific progress and on independent interests, should be ascertained with the utmost care.

It is also desirable that the Commission should collect the fullest possible information regarding all foreign scientific systems, down to the latest period. I by no means consider that any of these systems in particular is so perfect as to justify our creating a servile imitation of it. But it is only the part of wisdom, before organising our own scientific administration, to examine carefully the results attained abroad by nations whose experience in such matters is now very extensive. This examination will suggest many arrangements that we may safely adopt, and, no doubt, some that we should do well to reject. Not even the nucleus of a scientific system at present exists in England, and we are therefore the more free to shape, on the best available models, the organisation which a full inquiry will undoubtedly show to be necessary.

A great mass of facts connected with both scientific teaching and scientific investigations having been thus accumulated, the next step will be to digest and analyse them. The result of this most important process will be to show—first, what is redundant; secondly, what is imperfect; and thirdly, what is altogether wanting. It will indicate cases in which separation is desirable, as, for instance, cases where the concurrent cultivation of two or more branches of science, not naturally allied, tends to impede the growth of each. Cases will also occur in which combination would be beneficial. But one of the most important results of the analysis will be the bringing to light the scattered character of our scientific efforts; almost every department of the State having charge of some scientific institution—the Admiralty of one, the War Office of another, the Board of Trade of a third, and so on, a dispersion which is absolutely prohibitive of harmonious system, of progressive improvement, of efficient superintendence, of economy in expenditure, and of definite responsibility.

The final process will be to reduce to order the chaos of which I have merely attempted a broad indication. This will probably consist in a total re-arrangement of the internal organisation and the official distribution of our scientific institutions, with a view to concentrated superintendence and responsibility. It will also involve a revision of scientific staffs and salaries, with all the attendant questions of patronage, promotions, distinctions, privileges, and pensions.

2. *Some of the Probable Results of the Inquiry.*—The first of these will be the accumulation of a vast amount of facts and opinions, collected from every available source, and from the most competent authorities, regarding an extensive variety of

* The amounts above given are quoted from the Civil Service Estimates or 1869-70, those for the present year not having yet been published.

subjects of which we are at present in a state of comparative ignorance. If the inquiry produced no other immediate fruits than these, it would have performed a priceless service. Another result will be that we shall see for the first time what are the principles which should determine the action of the State for the advancement of science. At present there exists the most violent conflict of opinion on this subject, from those who hold that State intervention in science is unjustifiable and disadvantageous, to those who desire such intervention to be universal. Between these extremes there lies the middle and more reasonable section of thinkers, who recognise in the State simply a machinery for doing, on the part of the community, whatever is generally advantageous to the great mass of the people, but which transcends the power of individuals to perform. To discriminate fairly between the branches of scientific exertion which should devolve on the State and those which should be left to private energy, is one of the most valuable results that can be expected from the inquiry.

We may hope, as another most important result, that a central ministerial administration of scientific affairs will be shown to be necessary. In all other civilised countries a Minister of State is charged with this duty. It seems absolutely impossible to organise or maintain in an efficient state anything like a harmonious scientific system, without a dominant authority presiding over the whole. There are already indications of a coming Minister of Public Instruction, to administer the proposed national system of primary education; it can hardly be doubted that he should also have charge of whatever relates to State intervention in science.

The creation of such new scientific institutions as may be proved to be necessary, is another result that may be looked for. Though I have long been of opinion that the want exists, I do not think that the time has yet arrived to indicate how it should be supplied. The inquiry will develope clearer and more consistent estimates of the extent of the want, and of the best mode of meeting it, than, in the absence of full information regarding existing institutions, anyone can now hope to form. The cost of new scientific institutions alarms many persons who have only superficially examined such questions, but it will be probably found that increased expenditure in some directions may be met by retrenchment in others, and that no great change in the aggregate outlay on science will have to be made. On the other hand, we may feel sure that no outlay whatever will be recommended by a Royal Commission, unless it be incontrovertibly proved that such outlay will be beneficial to the nation.

Eventually, the responsibility of sanctioning increased expenditure for scientific purposes must rest with Parliament, by whom any proposals of that kind will be most scrupulously examined.

3. *The Constitution of the Commission.*—This is of vital importance. If its constitution be not such as to command, not only the confidence of the public generally, but also that of men of science, it cannot hope for success. The necessary elements in such a body seem to be administrative capacity, impartiality, and varied scientific knowledge. The first two elements will be secured by the nomination of persons versed in public affairs, and of high and independent station; the last by the due representation of the main branches of scientific activity. Probably four scientific members will suffice, to represent respectively, (1) Mathematics, including Astronomy; (2) Chemistry; (3) Physics; and (4) Natural History. To give a decided preponderance to either one of these great subdivisions will create strong and well-founded dissatisfaction. However lamentable the fact, it is certain that men engaged in one branch of science are very apt to underrate the importance of all others. The decision of a physiologist on an astronomical inquiry, or that of a mathematician on a matter connected with biology will be received with jealousy, a jealousy not by any means in most cases destitute of reasonable foundation. The subjects which will come before the Commission will be so difficult and so various, that four of the ablest men of science in their different departments will not be found more than will be necessary to give weight to the conclusions at which the Commission may arrive, and they should be men admittedly representative of their respective departments.

In the remarks which I have ventured to make, I have not dwelt on the importance to a civilised nation of progress in scientific knowledge. I have felt that I might safely take this for granted in addressing the Society of Arts, a society whose efforts have been during so long a period devoted to the promotion of such progress, and who do not require to be told that our commerce, our arts, our national supremacy on land and at sea, and our everyday conveniences are, more or less, dependent on our application of the laws of nature and the properties of matter. Whether or not an exhaustive inquiry into the state of science in England is imperatively needed, and what should be the scope of that inquiry, are the questions which, I believe, we have to-day met to discuss. It appears to me that the time for such an inquiry is opportune.

At no period of our history has there been so great a readiness to place administrative power in the hands of the Government. Public opinion acts now so energetically and effectually in the legislature, that the old jealousy of Government interference has been almost entirely dispelled. The tendency of the day is rather to impose fresh duties on the Government than to restrict its action. Men's minds, at the present time, view without apprehension, and examine with more impartiality and a higher discrimination than at any former period, proposals for radical changes. The nation has, moreover, been roused from the apathy with which it used to regard the ignorance of the masses, and is prepared for measures to redress the evil which, even ten years ago, would not have been listened to. It cannot be doubted that an equal readiness will be shown to examine with calmness and candour well-considered proposals to place on a proper footing a department of the State's duties which has never as yet undergone a strict and methodical examination. The nation requires primary education, and will enforce it upon those whom it is to benefit; it insists on the teaching of science in schools and universities; will it not approve of measures without which that teaching must be comparatively fruitless—measures calculated to attain the ends to which teaching is but a means—a more perfect knowledge of nature, and more absolute sway over her forces and her laws?

SCIENTIFIC SERIALS

THE *Student and Intellectual Observer*, New Series, No. 2, for April, contains an article entitled "Animals as Fellow-Boarders," being a translation of Von Beneden's valuable paper on *Commensalisme*, read before the Belgian Academy, describing the habits of creatures who may be said to board together, but whose association is distinct from that of victim and parasite. They are of two kinds, Free Fellow-Boarders, such as the tiny pea-crab, which lives in mussel-shells; and the Fixed Fellow-Boarders, like the barnacles which cover the skin of whales.

THE *Journal of Botany, British and Foreign*, New Series, No. 2 (double number for March and April) contains the following original articles: On two new British *Hepaticæ*, by Dr. Carrington; a fifth decade of new Chinese plants, by Dr. Hance; on *Rosa sepium*, by Mr. J. G. Baker; Addenda to the "Cybele Hibernica," by Mr. Ralph Tate; notes on Ray's "Hortus Siccus," by Dr. H. Trimen, with other shorter papers; also reports of recent additions to our moss and lichen flora, by Dr. Braithwaite and Rev. J. M. Crombie; a continuation of Mr. Baker's Review of the genus *Narcissus* from the *Gardener's Chronicle*, with other extracts and translations, reviews of new publications, proceedings of societies, &c., &c.

THE *Revue des Cours Scientifiques* for March 26 contains report of a Lecture by M. Paul Bert, on Sympathetic Nervous Actions, an article by Alph. Favre on the Existence of Man in the Tertiary Epoch, and a notice of Prof. Harkness's Spectroscopic Observations. The number for April 2nd is almost entirely filled by a translation of Prof. Tait's lecture before the University of Edinburgh, on the characters of a true science; and report of a lecture by M. Lorain at the Hospital Saint Antoine at Paris, on Scientific Medicine.

IN the *Deutsches Archiv für Klinisches Medicin* (xiii. and xvii. Heft. 1, received March 12), Liebermeister, of Basle, describes a very ingenious apparatus, constructed under his superintendence, for determining quantitative variations in the production of carbonic acid by man, and gives several examples of the results obtained. Amongst other conclusions he shows that the increase of carbonic acid in reading and singing is only to a small extent attributable to increased exertion consequent on fuller ventilation of the lungs, but is essentially due to the increased muscular energy exerted in the performance of those acts.

REICHERT and Dubois Reymond's *Archiv für Anatomie und Physiologie*, Heft. vi., 1869, is almost entirely occupied with a valuable contribution by Dr. Gustav Fritsch, assistant in the anatomical museum at Berlin, on the comparative anatomy of the hearts of amphibia, illustrated by four plates and many drawings.

THE *American Naturalist* for March contains several interesting articles. The longest is by Mr. E. G. Squier, "On the Primeval Monuments of Peru compared with those in other parts of the world." He describes a class of stone structures in Peru belonging to what is regarded as the earliest monumental period, coincident in style and character with the cromlechs, dolmens, and "sun" or "Druidical" circles of Scandinavia, the British Islands, France, and Northern and Central Asia. Considerable aboriginal Peruvian tribes once lived in houses built on piles, or on floats in the shallow waters of the Andean lake. The remnants of such a tribe still live in this manner, and bear the name of Antis; they spoke and still speak a language differing equally from the Aymara and Quichua, called Puquina. Early chroniclers speak of them as extremely savage, and calling themselves, not men, but *Uros*. Whole towns of them, it is said, lived on floats of *tortora* or reeds, which they moved from place to place according to their convenience or necessities.—Prof. Joseph Leidy contributes remarks on some curious sponges; and Mr. W. W. Bailey a sketch of the Truckee and Humboldt valleys between the Sierra Nevada and the Rocky Mountains.

Silliman and Dana's American Journal of Science and Art for March contains the following articles:—Photometric Experiments, Part I., by O. N. Rood. Contributions to the Chemistry of Copper, Part I., by T. Sterry Hunt. Notice of a recent Land-slide on Mount Passaconaway, by G. H. Perkins. On the Silver Mines of Santa Eulalia, Mexico, by J. M. Kimball. Machinery and Processes of the Industrial Arts, and Apparatus of the Exact Sciences by F. A. P. Barnard. On Norite or Labradorite Rock, by T. Sterry Hunt. On the Cause of the colour of the water of Lake Leman, by A. A. Hayes. On the Potassio-Cobaltic Nitrite known as Fischer's Salt, by S. P. Sadtler. Notice of some Fossil Birds from the Cretaceous and Tertiary formations of the United States, by O. C. Marsh. Descriptions of Shells, from the Gulf of California, by A. E. Verrill. Notice of Dr. Gould's Report on the Transatlantic Longitude. Meteors of November, 1869, by Prof. H. A. Newton.

SOCIETIES AND ACADEMIES

LONDON

Ethnological Society, March 22.—Prof. Huxley, F.R.S., president, in the chair. Mr. R. S. Newall was announced as a new member. — A paper was read on current British Mythology and Oral Tradition, by Mr. J. F. Campbell (of Islay). After explaining the sources whence his popular tales of the Western Highlands had been derived, he referred to the traditional character of myths, and expressed an opinion that many genuine British traditions orally preserved in Celtic may probably be old Aryan myths, mingled perhaps with pre-Aryan myths. Popular oral history must be founded on a real event, but minor details gradually drop out, while the most conspicuous incidents approach each other. The author showed how a legend sprouts from a fact which, being at first accurately told, passes into a tradition, while the dates and persons and localities become uncertain. Poetry is a good vehicle for preserving facts, and many current traditions carry with them a rhyme or a proverb to aid the memory. Hence, too, historic events are readily preserved in the ballad form. The president, Dr. Archibald Campbell, and Mr. Bouverie Pusey spoke upon this communication.—Dr. Campbell then read a note by the Rev. R. J. Mapleton on a Cist with Engraved Stones on the Poltallock Estate, Argyleshire.

Zoological Society, March 24.—Dr. E. Hamilton, V.P., in the chair. Mr. P. L. Sclater exhibited a coloured drawing received from Dr. Salvadori, of Turin, of a bird which Dr. Salvadori had proposed to describe as a new genus and species, but which was evidently referable to the singular pigeon recently named by Mr. Gould as *Otidiphaps nobilis*.—Mr. W. B. Tegetmeier exhibited and made remarks on a living specimen of an Axolotl (*Siredon pisciformis*) which had undergone the change into the Salamandroid form recently described by Professor Dumeril, of Paris.—A third letter was read from Mr. W. H. Hudson, containing remarks on the ornithology of the vicinity of Buenos Ayres.—Mr. Osbert Salvin read a paper on the birds of Veragua, based on large collections recently formed by Enrique Arce in that country, and in continuation of a former memoir on the same subject. The present communication contained an account of 214 species not given in the former list, and made altogether 434 species now known to occur in this limited district. Of these additional species several were stated to be new to science and of great interest.—Mr. P. L. Sclater read a notice of two rare species of pheasants from Upper Assam recently added to the society's living collection. These were a Monaul (*Lophophorus sclateri*) and a Tragopan (*Ceriornis blythii*), both lately described as new by Dr. Jerdon. For these specimens, both of which were in fine plumage and of very remarkable beauty, the society was indebted to the liberality of Major Montagu, of the Bengal Staff Corps.—Mr. P. L. Sclater read some further notes on the cuckoos of the genus *Coccyzus*, in continuation of a former paper on the same subject.—A communication was read from Professor J. V. Barboza du Bocage, containing a description of a new species of pelican from Angola, proposed to be called *P. sharpii*.—A communication was read from Dr. J. C. Cox, giving descriptions of eight new species of shells from Australia and the Solomon Islands.—A communication was read from Mr. Jonathan Couch, of Polperro, describing a new species of *Aplysia* or sea-hare, which had recently occurred on the coast of Cornwall, and which he proposed to call *A. melanopus*.

Chemical Society, March 17.—Prof. Williamson, F.R.S., president, in the chair. The following gentlemen were elected fellows: D. Brown, A. Muirhead, T. L. Patterson, D. Penny, S. T. Smith. The first paper read was on artificial alizarine, by W. H. Perkins, F.R.S. The lecturer commenced by sketching the history of the researches which had finally led to the artificial production of alizarine. This colouring matter was first obtained by Robiquet and Colin from madder root, and investigated by Schunk, who assigned to it the formula $C_{14} H_{10} O_4$; it will subsequently be seen how very near this formula comes to the truth. Strecker and other chemists had reasons to write $C_{10}H_6O_3$ as the composition of alizarine, relating it to the compound $C_{10}H_5Cl\,O_3$ which Laurent had produced from naphtaline, and which Strecker regarded as chloralizarine. A few years since Graebe, when investigating a hydrocarbon known as quinone, $C_6H_4O_2$, found it to be a benzol in which two atoms of hydrogen were replaced by the group $[O-O]''$. A derivative of this body, the chloranil, $C_6Cl_4\,[O_2]''$ yields hydric chloranilate on successive treatment with caustic potash and hydric chloride. This reaction induced Graebe to view the chloride of Laurent's chloroxynaphtalic acid as the dichlorinated quinone of naphtaline,—

$C_{10}H_8$	$C_{10}H_4Cl_2\,[O_2]''$
Naphtaline.	Chloride of chloroxynaphtalic acid or Dichlornaphtoquinone.

and indeed when this naphtaline derivative is acted upon successively by potash and hydric chloride, it furnishes chloroxynaphtalic acid. After it had thus been shown that chloroxynaphtalic acid, Strecker's chloralizarine, was a quinone acid, Graebe and Liebermann thought it probable that alizarine might also be the quinone acid of some hydrocarbon, and it was now only necessary to know this hydrocarbon. On reducing a specimen of natural alizarine, a substance of the composition $C_{14}H_{10}$ was obtained; but this is the formula of anthracene of coal tar, and indeed the substance obtained by the reduction of alizarine possessed all the properties of anthracene. This fact led Graebe and Liebermann to assume alizarine to be the quinone acid of anthracene,—

$C_{14}H_{10}$	$C_{14}H_8\,(O_2)''$	$C_{14}H_6 \left\{ \begin{array}{l} (O_2)'' \\ HO \\ HO \end{array} \right.$
Anthracene	Quinone of anthracene or Anthraquinone.	Anthraquinonic acid or Alizarine.

Having obtained anthracene from alizarine, it now remained to produce alizarine from anthracene. For this purpose it was first required to have the quinone of anthracene. Graebe and Liebermann found the desired substance in the oxygenated compound, $C_{14}H_8O_2$, which had been obtained by Laurent from anthracene. They heated this anthraquinone with bromine, acted upon the dibromanthraquinone thus gained with potash, and decomposed the potash salt thus obtained by hydric chloride. The product of these successive reactions was alizarine. But to turn this beautiful discovery to practical account, it was necessary to replace the bromine required in the process by some cheaper re-agent. A good substitute has been found in sulphuric acid.

When anthraquinone is heated with oil of vitriol, disulphoanthraquinonic acid is formed, and this decomposed by caustic potash yields the potassium salt of alizarine, from which hydric chloride liberates the alizarine. Artificial alizarine is entirely identical with the colouring matter obtained from the madder root. Both of these products crystallise in needles which are usually curved, especially when small. They dissolve in caustic alkalis, forming violet solutions of the same tint. When applied to mordanted fabrics, they produce exactly the same colours, bearing the treatment with soap equally, and resisting in the same degree the influence of light. Their alkaline solutions show identical absoption bands in the spectrum. Both yield phtalic acid when treated with hydric nitrate. As a substitute for madder, artificial alizarine has been objected to, on the ground that pure alizarine alone will not produce the madder colours, other colouring matter being required. But Schunk says that, after a long course of experiments, he has been led to the conclusion that the final result of dyeing with madder is simply the combination of alizarine with the mordants employed; and he recommends extraction from madder prints as the easiest method of preparing pure alizarine on a small scale. Artificial alizarine, as sent to the dyer and printer, is not exactly pure alizarine, and generally produces, with alumina mordants, a somewhat redder shade than madder. This is due to some impurities whose nature is, as yet, not known. A good deal has been said about the supply of anthracene. It must be remembered, however, that tar-distillers have as yet but little experience in separating this substance. Mr. Perkin's investigations on this matter have led him to believe that coal-tar contains considerable quantities of this hydro-carbon. No doubt, the kind of coal used, as well as the temperature employed in the gas-works, influences the quality of the tar as a source of anthracene; but upon these points no definite information has yet been obtained. Mr. Perkin illustrated his interesting lecture by exhibiting samples of fabrics dyed and printed with artificial alizarine, and also by projecting the spectra of some alizarine solutions upon a screen. By producing alizarine from anthracene, Graebe and Liebermann have given the first instance of the artificial formation of a vegetable colouring matter. The way by which the beautiful discovery has been arrived at proves decisively, as the president pointed out, the high importance of studying the molecular arrangements of chemical compounds.

Entomological Society, March 21.—Mr. H. W. Bates, vice-president, in the chair. The first part of the "Transactions" for the present year was placed on the table. The attention of the meeting was devoted exclusively to *Lepidoptera*. Specimens were exhibited by Messrs. Howard, W. J. Vaughan, Bond, Frederick Smith, and Stainton. An interesting discussion on dimorphic forms of the larva and imago was participated in by Messrs. Albert Müller, A. G. Butler, Pascoe, J. Jenner Weir, Stainton, McLachlan, and the chairman. The paper read was by Mr. W. F. Kirby, "Notes on the butterflies described by Linnæus."

BRIGHTON

Brighton and Sussex Natural History Society, March 10.—The president, Mr. T. H. Hennah, in the chair. A report from the committee was received, urging the advisability of forming a microscopical section. On the motion of Mr. Hazlewood, seconded by Mr. Wonfor, it was resolved that the report of the committee be received, entered on the minutes, and approved, the effect of which is to establish a microscopical section, and instead of one meeting on the second Thursday in each month, to have a second meeting for strictly microscopical objects on the fourth Thursday in each month.—A paper by Mr. Clifton Ward, F.G.S., "A sketch of the Geological History of England, so far as it is at present known," was read by Mr. Wonfor, hon. sec., in which, from the earliest dawn of the Cambrian period down to the present day, the changes produced by depression, deposition, elevation, denudation, &c., together with an account of the various types of animal and vegetable life during each period, were graphically described, and the amount of land above water in England at each period was represented by a series of fifteen charts.—It was announced that the Bryological Flora of the county of Sussex would soon be ready for distribution, the Society having determined to publish it at once, instead of waiting for the issue of the annual report in September.

EDINBURGH

Royal Physical Society, February 23rd.—Mr. C. W. Peach, president, in the chair. The following papers were read:—

1. Note on the Klipspringer Antelope (*Oreotragus saltatrix*). By Mr. D. R. Kannemeyer. A skin of this antelope was exhibited, and its various peculiarities pointed out and described—the long, wiry, and close hair with which it was covered, and the remarkable structure of its strong limbs and feet. Major Harris, in his work on the wild animals of South Africa, described it as having jagged edges to its hoofs; there was really a long, narrow depression or oval-shaped hollow on each of the divisions of the hoof. These peculiarities were admirably suited to the habits of the animal, which lived on the tops of high mountains, and was remarkable for the speed, agility, and sureness of foot with which it could leap from rock to rock up and down the face of inaccessible precipices; and also for the great distance of its leaps, and the small surface of some projecting ledge or pinnacle of rock upon which it could suddenly arrest its course, even when in full career. Mr. Kannemeyer described the various enemies the animal had to defend itself from—the eagle, the panther, and man—and referred to the manner in which it was hunted by the colonists, and his own experience in stalking it.

2. On the Deposits of Clay in the Neighbourhood of Stirling. By Rev. James Brodie, A.M., Monimail.

3. Specimens of Polyzoa, &c., from the Faroe Islands, were exhibited and described by Mr. C. W. Peach, A.L.S., &c. The author stated that the specimens were from Stromoe, one of the Faroe Islands, and not gathered by himself, but were given to him by a person who had been there. They consisted of sixteen species of Polyzoa, four of Mollusca, three of Hydrozoa, two Sponges, three Annelide cases, with Foraminifera and Diatomacea. A portion of one of the shells shows the marks of rasping by limpets when feeding on the leathery disks of Hydrozoa. He remarked on this as a curious instance of vegetable-eating animals being able to put up with such tough and hard fare when out of their native home, and thus accommodating themselves to their changed circumstances. He considered that the specimens were not got in deep water, nor far from land, as not a single really deep-sea form occurred amongst them. All of the species are to be got in our own seas, and with two exceptions (at present northern forms from Shetland and Wick, N.B.) have been collected by the author from Land's End to John o' Groats.

4. Dr. J. A. Smith exhibited a head of a red deer, the property of Mr. T. O. Horne, which was killed in the end of January near Kingussie, Inverness-shire. Instead of the usual well-developed brow and bez-antler which marked the red deer, this animal had on the right side two small and very short antlers springing close to the root of the horn, and on the left side a very small brow-antler, and then a large second antler springing from near the root of the horn, and running nearly parallel to the beam. It measured about a foot in length. The beam of the same horn measured one foot ten inches long, terminating in a couple of forked antlers above. The other horn was rather shorter, and also terminated in two antlers. The variety was probably due to some local injury sustained by the deer when the horns were beginning to sprout, the soft horn of the left side having apparently been split in two. Dr. Smith stated he was indebted to Mr. Muirhead, Queen Street, for recently sending him a specimen of the *Ballan Wrasse*, measuring 18½in. in length, taken in the Firth of Forth, where it is by no means common; also, a very large specimen of the Lump-sucker or Hen-padle, *Cyclopterus lumpus*. The fish was full of roe; it measured 20½in. in length by a foot in depth, and weighed 10lb. 13oz. He also noticed the very large male salmon taken on the 11th February. Mr. Anderson informed him it weighed a little over 56lb., and measured 4ft. 2in. in length by 2ft. 7in. in greatest girth. The salmon was taken along with several others at Mr. Anderson's fishing station, near Stirling.

PARIS

Academy of Sciences, March 28.—M. Darroux communicated a paper on Equations, with partial derivations of the second order, and M. Tisseraud a note on a point in the differential calculus.—A memoir was read by M. J. Jamin, on the employment of the electric current in calorimetry, in which the author described a method of applying the heat produced by an electric current to the determination of the specific heat of various bodies.—M. Jamin also communicated, on his own behalf and that of M. Amaury, a memoir on the specific heat of water between zero (32° F.) and 100° C. (212° F.) The authors showed that the specific heat of water undergoes no particular alteration about 39·6° Fahr., and that from upwards it increases with the temperature.—M. A. Trécul presented the sixth portion of his memoir on the position of the tracheæ in ferns, in which he described the ramification of the petioles in various plants of that group, including several species of *Asplenium*, *Aspidium*, and *Polypodium*. — A note was read on the organs and phenomena of fecundation in the genus *Lemanea*, by M. Sirodot. The *Lemaneæ*, although among the highest of the fresh-water Algæ, were described by M. Rabenherst in 1868 as producing "spores germinating without fecundation." The author described what he regards as antheridia in two species (*L. catenata* and *L. fluviatilis*), and indicated the mode of fecundation as observed by him. — M. Ducharter communicated an abstract of two Greek papers by M. Koressios, in which the author expressed the opinion that the disease now ravaging the vines in France attacks them from the roots, and recommended a certain mode of treatment.—M. Leymerie presented, through M. Elie de Beaumont, some observations on the conclusions lately put forward by M. Magnau, with regard to the lower cretaceous formation of the Pyrenees. He maintained that there is no evidence of the existence of the Albian stage in the Pyrenees, and also objects to the admission of the Muschelkalk as existing in the Zechstein in the departments of the Tarn and Aveyron. The same author addressed a note on the fragmentary state of the higher summits of the Pyrenees, in which he maintained that the broken state of the rocks forming these summits must be due to the effects of the force exerted during their elevation, and concluded therefrom that the summits of these and other mountains cannot have lost much of their original heights by subaerial action. M. Elie de Beaumont made some remarks on the permanence of artificial earthworks, as confirmatory of the author's views.—Papers on medical subjects were also read.

PHILADELPHIA

American Philosophical Society, February 4.—Pliny E. Chase presented tables of rainfall, and described them. The most interesting deductions were, as far as related to Philadelphia, that the spring and summer will be alike, and the autumn and winter alike. The tables are for 45 years up to date, from observations at the Pennsylvania Hospital. Dr. Brinton made observations on the zealous and long-continued studies of the language of the Choctaw Indians, made by the missionary Mr. Byington, who died a year ago. Dr. Brinton has a list of over 75 works, including the Bible, printed in Choctaw. Mr. Byington's Choctaw Grammar has been revised four times, and at his death he had progressed with his fifth revision. The MS. of this work was in Dr. Brinton's hands, and was presented to the Society for publication.

February 18.—Prof. Cope read a paper intitled, "Fourth contribution to the Fauna of the Miocene period in the United States." He exhibited the periotic bones of a large whale from the miocene of North Carolina, which had been discovered by Prof. W. C. Kerr, State Geologist. The part of the skeleton found consisted of the left side of the cranium to the temporal fossa, mandible, and many vertebræ, ribs, &c. It was found 30 feet below the surface in the bank of a stream. It represented a type near the true *Balænæ*, but partaking of the characters of the *Balænopteræ*. One peculiarity was the enormous thickening of the supraorbital process of the frontal, which was 17 inches deep. This individual was 17 inches deep. Vertebræ of two other individuals were found in other places, and a complete vertebral column of the same extended across a stream 20 miles distant from Kerr's specimen. Vertebræ taken from the last, referred it to the same species. This specimen was 50 or 60 feet long, and extended across the stream in such a way as to serve as a foot-crossing when the water was very low. The species was named *Mesoteras kerrianus*. Prof. Cope mentioned the discovery of the genus *Sus* for the first time in the United States, in the neighbourhood of Squankum, N.J. He said it agreed with the occurrence of the dugong noticed by himself and the rhinoceros by Marsh in giving an Asiatic character to that extinct Fauna. The hog he called *Sus vagrans*, and said it was as large as the common *S. scrofa*. He called attention to the abundance of the species of the *Pythonomorpha* in the United States, and described two new species from New Jersey, viz., *Mosasaurus fulciatus* and *M. varthrus*. The first with round curtra and an additional rib on the asquadratum, the second with depressed ceutra, and a quadrate bone more like that of *M. dekayi* than *M. depressus*. He said he knew 27 species of *Mosasauroids*. In the last work on the subject, only three species were described.

DIARY

THURSDAY, April 7.

Royal Society, at 8.30.—On supra-annual Cycles of Temperature in the Earth's Surface Crust: Prof. Piazzi Smyth.—Researches in Animal Electricity: Dr. C. B. Radcliffe.
Society of Antiquaries, at 8.30.
Linnean Society, at 8.—On new species of Annelids, &c.: Dr. Baird —On Algæ from the North-Atlantic Ocean: Dr. Dickie.
Royal Institution, at 3.—Chemistry of Vegetable Products: Prof. Odling.
Chemical Society, at 8.—On the Analysis of Deep-sea Water: Dr. John Hunter.—On the refraction equivalents of the aromatic Hydrocarbons and their derivatives: Dr. J. H. Gladstone.—On an acid Feed-water from the Coal-fields of Shellarton, N.S., and the results of its use: Prof. How.
London Institution, at 7.30.—Geology: Dr. Cobbold.

FRIDAY, April 8.

Royal Institution, at 8.—Pedigree of the Horse: Prof. Huxley.
Royal Astronomical Society, at 8.
Quekett Microscopical Society, at 8.

SATURDAY, April 9.

Royal Institution, at 3.—The Sun: J. Norman Lockyer, F.R.S.

MONDAY, April 11.

London Institution, at 4.—Chemistry: Prof. Bloxam.
Royal Geographical Society, at 8.30.
Royal Institute of British Architects, at 8.

TUESDAY, April 12.

Ethnological Society, at 8.—On the Danish Elements in the population of Cleveland: Rev. J. C. Atkinson.—On the Ancient Tribal System of Ireland: H. M. Westropp.—On the Brain in the Study of Ethnology: Dr. Donovan.
Photographic Society, at 8.
Institution of Civil Engineers, at 8.—Dressing of Lead Ores.—Maintenance and Renewal of Railway Rolling Stock: Mr. R. Price Williams.

WEDNESDAY, April 13.

Royal Geological Society, at 8.—On the Fossil Remains of Mammals found in China: Prof. Owen, F.R.S., F.G.S., &c. — Further Discovery of the Fossil Elephants of Malta: Dr. A. A. Caruana. Communicated by Dr. A. Leith Adams, F.G.S. – Brief preliminary Notes on a large Coal-measure Reptile from the Low Main Coal Shale: T. P. Barkas, F.G.S.
Royal Microscopical Society, at 8.

THURSDAY, April 14.

Mathematical Society, at 8.—On the Mechanical Description of a Nodal Bicircular Quartic: Prof. Cayley.

BOOKS RECEIVED

English.—Birds of Marlborough: E. F. Im Thurn (Marlborough, Perkins; London, Simpkin and Marshall).

Foreign.—Die Alterthümer unserer heidnischen Vorzeit, vols. i. and ii. (Mayence, V. V. Zabern).—Journal für Ornithologie, Jan. 1870.—Om Vegetationsforholdene ved Sognefjorden: A. Blytt (Christiania, J. Dahl).—Lichenes Daniæ, eller Danmarks Laver: J. G. Deichmann Branth og E. Rostrup (Copenhagen, Gads). — Undersogelser over Christiniafjordens Dybvandsfauna: G. O. Sars (Christiania, Dahl).—Zeitschrift für Parasitenkunde, vol. ii. pt. i. (Jena, Mauke).—Naturwissenshaftliche Reisen im tropischen Amerika: Dr. Wagner (Stuttgart, Cotta).—Archivio per la Zoologia l'Anatomia e la Fisiologia, Series ii. vol. i. (Turin, Loescher).—Reisen im Archipel der Philippinen: Dr. Semper, Æolidien (Wiesbaden, Kreidel).—Through Williams and Norgate.

CONTENTS

Errata.—In No. 21, page 539, first column, line 21 from bottom: for "Perth," read "Pesth."—In No. 22, page 557, first column, line 3 from bottom: for "Sir Sidney Smith," read "Mr. Sidney Smith."

Printed by R. CLAY, SONS, & TAYLOR, at 7 and 8, Bread Street Hill, in the City of London, and published by MACMILLAN & Co. at the Office, 63, Bleecker Street, New York.—THURSDAY, April 7, 1870.

THURSDAY, APRIL 14, 1870

THE TOTAL SOLAR ECLIPSE OF DECEMBER NEXT

ON Friday last, Mr. Lassell, the president, brought before the Royal Astronomical Society the subject of the total solar eclipse of December next, with a view to eliciting information as to the steps necessary for observing it. A most interesting discussion ensued, in which the Astronomer Royal, the president, Messrs. De la Rue, Stone, and Huggins, Admiral Ommaney, Colonel Strange, and Lieutenant Browne, R.A., took part. The line of totality passes near the following places :—Odemira, in Portugal, Cadiz, Estepona (about twenty miles north of Gibraltar), Oran, on the Algerine coast, Syracuse, and the region including Mount Etna in Sicily.

The duration of totality will be a little over two minutes of time. It is proposed that an endeavour shall be made to equip two expeditions to observe the phenomena of the eclipse at two of these points, in order that, should adverse weather occur at one station, results may be, perhaps, obtained at the other. It is thought probable that the station of Oran, in Algeria, will be occupied by a French party of astronomers. The choice for English observers seems to be between Cadiz, Gibraltar, and Syracuse. Both Admiral Ommaney and Lieut. Browne, R.A., spoke from personal experience favourably of the climate of Gibraltar at that time of the year. The speakers were unanimous in considering that both parties ought to be equipped for the following main objects:—(1) Photography; (2) Spectrometry; (3) Polarisation. Other objects of subsidiary importance, as Photometry and Meteorology, would also receive due attention. An approximate estimate of personal and instrumental force gives from 20 to 25 skilled observers, and about 10 telescopes of from 4 to 6 inches aperture, as the complement necessary for *each* of the two expeditions.

The first step which the Council propose to take is to invite, by circular and other means, those prepared to volunteer for this service to send in their names at once, specifying the particular class of observation which the observer desires to be engaged in. The number of actually available telescopes and instruments will also be ascertained.

When this preliminary information has been acquired, the Council of the Royal Astronomical Society, which has resolved itself into a committee for the purpose, will then consider whether they should apply to Government for such assistance as may enable them to utilise, with the utmost advantage, their own resources. Pending the collection of this information, it would be premature to attempt any estimate of the public assistance which may be required to guarantee the success of this enterprise. But it is not too early to lay before our readers some idea of its character and importance.

The systematic examination of the solar surface is emphatically a modern study, which has, even during the last twelve months, advanced with enormous strides. Until recently these researches were limited to the ocular inspection and photographic representation of features rendered visible at ordinary times by our improved telescopic power, and to similar modes of examining certain other features developed during eclipses. Subsequently, with the wonderful aid afforded by the spectroscope, a new class of phenomena was brought under examination, but only momentarily, on the rare occasions of total solar eclipses. Only last year M. Janssen and Mr. Lockyer, labouring independently, showed that many of the spectroscopic observations, for securing which an eclipse had been believed to be indispensable, could be made without the aid of that phenomenon,—a discovery second, in dignity and value, to none that this age has achieved. But these very methods have opened out inquiries and doubts which again require for their solution the peculiar circumstances attending total obscuration of the sun's disc.

For instance, the corona which has been seen at times to extend to a distance beyond the sun greater even than the sun's diameter, has been very generally stated to indicate a solar atmosphere, a conclusion not entirely borne out, however, by the spectroscopic method of investigation; and Dr. Frankland and Mr. Lockyer have stated their opinion that the *whole* of the corona can hardly be solar—this opinion being based partly on their approximate determination of the pressure in these regions. This question was manfully attacked during the eclipse observed last year in America, but the results, which will be found most carefully detailed in the report printed by the American Government, were not conclusive.

Again, it has been shown that the solar chromosphere is not entirely seen by the new method of observation; away from the sun its light is ordinarily so feeble that it cannot be detected through our brighter atmosphere, but during eclipses it is seen; and in this matter the American astronomers did admirable work, which, however, requires strengthening, for many still hold that the radiance depicted on the photographic plates immediately round the moon in the photographs, is not the chromosphere, as stated by Dr. Gould and others, although there are very many arguments which can be brought forward in favour of their idea that it is that envelope. Other points might easily be brought forward to show the extreme and, in fact, special importance of eclipse observations at the present time.

If researches such as these yielded no fruits beyond the satisfaction of our craving desire to know more of the structure and constitution of the sun, they would still be prosecuted with ardour. But the knowledge they are calculated to advance has a much wider range and a more tangible character than the gratification of philosophical curiosity. Sabine, Lamont, and Wolf many years ago detected the contemporaneity of magnetic disturbances and the maximum outbreak of spots on the sun's surface. More recently De la Rue, Stewart, and Loewy have established a relation between the sun spot maxima and the configuration of the planets Venus and Jupiter. Systematic observations have been carried on at the Kew Observatory continuously for nine years for the express purpose of throwing light on the apparent connection of the sun spots with magnetic and planetary phenomena. During this period upwards of nine thousand photographic pictures of the solar disc have been taken. These researches, and those of Carrington, extending over many years, have shown that though the spots, if observed from day to day and month to month, appear to break out capriciously both in point of size and position, yet when observed perseveringly for a series of years, a recurrence of phenomena, so far at least as the total area covered by spots is concerned, becomes evident. The period required to complete this cycle is variously estimated, a little over eleven years being that most generally accepted. On Thursday last, a remarkable paper by Prof. Piazzi Smyth, Director of the Royal Observatory, Edinburgh, was read at the Royal Society, in which the results given by thermometers, buried at different depths in the earth and observed for upwards of thirty years, were tabulated and discussed. The main deduction from these observations was that the temperature of the earth, divested of the effects of transient atmospheric changes, seemed subject to a secular law. This secular variation in the earth's temperature may of course be due to secular changes going on deep in the structure of the globe itself; but it may be ascribed also, and with a far higher degree of probability, to changes in the heat-supplying power of the sun.

There is one extremely important fact connected with these changes, namely, that one of them is accomplished in $11\frac{1}{10}$ years; that is, exactly in the sun spot periods as determined by Wolf, and identical, or nearly so, with the period obtained from the Kew observations.

But the spots are only one of the known evidences of changeful activity going on in the great central luminary. The form, disposition, and dimensions of the prominences, and the distribution of the chromosphere, are visibly undergoing constant alteration. May these phenomena not also have their period of recurrence? And may not they, equally with the spot outbreaks, stand in some relation to what formerly used to be considered purely terrestrial phenomena, namely, magnetism, electricity, humidity, temperature, and rainfall? To carry the hypothesis one step further: if there is a physical relation between the solar changes and meteorological occurrences, and if the solar changes are subject to laws which cause them to recur in regular series, have we not in this secular arrangement a clue by means of which climatic variations may be studied with greatly increased effect? Is not, in short, the systematic study of solar phenomena extremely important from a meteorological point of view?

If this hypothesis, which is one daily gaining strength, be but probably sound, the careful observation of the physical phenomena of solar eclipses becomes an urgent necessity, as calculated not only to afford more just and more noble views of the constitution of the universe, but to confer on mankind the same power with respect to climatal vicissitudes, which we already possess with respect to astronomical phenomena, the power of confident prediction, which will never be ours until we have a firm grasp of the secular laws by which those vicissitudes are governed.

If these views be generally accepted, as we know they will be by those acquainted with the subject, we need not fear that anything which the knowledge and devotion of our astronomical physicists, or the power of the Government, can supply, will be wanting to effect the due observation of the Solar Eclipse of December in a manner creditable to our age and our country.

A.

ON THE BASIS OF CHEMICAL NOTATION

CHEMISTS are so much in the habit of employing what are called chemical symbols, that they are liable occasionally to forget the realities symbolised; while persons interested in the realities of chemistry, but not themselves chemists, are apt to call in question the propriety of employing any such symbols at all,—looking upon the entire system of chemical expression as an arbitrary one, having its chief warrant from authority, and not only throwing an unwarrantable gloss upon the facts, but frequently overshadowing them. That the accepted system of chemical notation is, indeed, to some extent arbitrary, and that it does throw more or less gloss upon the facts, may be admitted at once as indisputable; but nevertheless its relation to the facts is so simple and direct, and its utility as a means of illustrating and classifying the facts is so remarkable, that its justification ought not to prove a seriously difficult labour.

It being the especial business of chemists to consider every material object in relation to the kind of matter of which it is composed, they have gradually become acquainted with about sixty different kinds of matter that are unalterable in their kind by way of subtraction. The entire matter of a piece of iron, for instance, may cease to exist as iron, and, by an accretion of other matter, appear in the form of rust. But, though alterable in this way by the addition of other matter than iron to it, it is experimentally unalterable by the subtraction of other matter than iron from it. Now the sixty or more different kinds of matter having this property of unalterability by subtraction, though never declared to be in their essence elementary, are always tacitly assumed to be so; and chemical changes are accordingly interpreted in a definite way which, on this particular assumption, would appear to be the only legitimately possible way, but which, irrespective of this particular assumption, can only be regarded as one of several more or less probable ways.

Making the assumption, however, with eyes shut or open, as the case may be, chemists are able to learn, by analysis, the respective weights of the different elementary substances constituting a given weight of any compound substance. The results of the analyses are, of course, expressible in various modes; the most obvious, and, so to speak, impersonal mode, being the centesimal one—the setting forth of so many parts by weights of the respective constituents in 100 parts by weight of the particular compound. But in the case of several different compounds having one or more common constituent, the relationship of composition subsisting between the different compounds is much better brought out by taking some common constituent as a constant, and the other constituents as variable in relation thereto, rather than by taking all the constituents alike as variable.

Now, among the sixty or so elements, hydrogen is characterised by this peculiarity, that in nearly all the compounds of which it is a constituent, it exists in a smaller proportion by weight than any other constituent, while in absolutely all its compounds it exists in a smaller proportion by weight than some other constituent; so that in the compounds which it forms with but one other kind of elementary matter, its proportion by weight is always less than that of the other elementary matter with which it is combined. Even in that particular hydrogen compound, namely, marsh-gas, in which the amount of constituent hydrogen is largest, its proportion reaches only to 25 per cent., while among the many thousands of hydrogen compounds known to chemists, the following, and certain of their immediate congeners and isomers, are almost the only ones containing hydrogen to the extent of 11 per cent. and upwards :—

	Per-centage of constituent hydrogen.
Marsh-gas	25·0
Higher paraffins	14 to 20·0
Ammonia	17·6
Methylamine	16·1
Higher alcohol bases	14 to 15·5
Olefiant gas and homologues	14·3
Higher alcohols	13 to 14·0
Wood-spirit	12·5
Water	11·1

From the circumstances, then, of hydrogen forming so small a proportion by weight of the compounds it helps to constitute, its proportion may conveniently be taken as unity, and the composition by weight of the above tabulated hydrogen compounds be preferably expressed as follows :—

	Parts by weight.		
Marsh-gas	1 hydrogen	to	3·0 carbon
Ethyl hydride	1	,,	4·0 carbon
Ammonia	1	,,	4·7 nitrogen
Methylamine	1	,,	5·2 nitrogen + carbon
Ethylamine	1	,,	5·4 nitrogen + carbon
Olefiant gas	1	,,	6·0 carbon
Alcohol	1	,,	6·6 oxygen + carbon
Wood-spirit	1	,,	7·0 oxygen + carbon
Water	1	,,	8·0 oxygen

Now, while hydrogen is thus the least weighty, it is usually also the most mobile constituent of its several compounds. Accordingly, by acting on its several compounds with various reagents, it is possible to effect a removal of more or less hydrogen from them, often in the form of free hydrogen gas, more often in the form of some familiar hydrogen compound, such as water or muriatic acid. For instance, if muriatic acid itself, formic acid, ortho-phosphoric acid, and acetic acid, be each of them acted upon with either metallic sodium or caustic soda, taking care to keep the acid in excess, new compounds are produced, the composition of which in relation to that of the original acids may be expressed as follows :—

Muriatic acid and sodium chloride.

1 hydrogen + 35·5 chlorine
23 sodium + 0 hydrogen + 35·5 chlorine

Formic acid and sodium formiate.

1 hydrogen + 6 carbon + 16 oxygen
11·5 sodium + $\frac{1}{2}$ hydrogen + 6 carbon + 16 oxygen

Phosphoric acid and sodium phosphate.

1 hydrogen + 10·3 phosphorus + 21·3 oxygen
7·6 sodium + $\frac{2}{3}$ hydrogen + 10·3 phosphorus + 21·3 oxygen

Acetic acid and sodium acetate.

1 hydrogen + 6 carbon + 8 oxygen
5·7 sodium + $\frac{3}{4}$ hydrogen + 6 carbon + 8 oxygen

It is observable that the new compounds differ in composition from the original acids by a consecutively decreasing gain of sodium, and by a corresponding loss of the whole, of one-half, of one-third, and of one-fourth the original hydrogen respectively; and there is this additional point for consideration, that while in the case of formic acid and acetic acid it is not possible to obtain a compound differing from the original acid by a removal of one-third of its hydrogen, in the case of phosphoric acid it is not possible to obtain a compound differing from the original acid by a removal of one-half or one-fourth of its hydrogen. But, by further treatment of phosphoric acid with caustic soda, another compound may be obtained, differing in composition from the original acid by a removal of two-thirds, instead of one-third, the original hydrogen; while, by treatment of acetic acid with chlorine, a series of new compounds may be obtained, differing in composition from the original acid by a removal of one-fourth, and two-fourths, and three-fourths successively of the original hydrogen. Anyhow, the tendency of the hydrogen of formic acid is manifestly to break into halves, that of the hydrogen of phosphoric acid to break into thirds, and that of the hydrogen of acetic acid to break into quarters.

Now, assuming the reacting units of the four acids to contain each but a single proportion, or one part by weight of hydrogen, there seems no reason why this hydrogen should in each case break up in a specifically different manner; and, in other cases, in yet different manners, as into sixths, eighths, twelfths, and so on. But assuming the re-acting unit of formic acid to contain two proportions, that of phosphoric acid to contain three proportions, and that of acetic acid to contain four proportions of hydrogen, the reason of the different mode of breaking up becomes perfectly obvious, as shown in the following comparison with respect to composition of the original acids and their produced sodium salts; whereby it appears that a similar exchange of twenty-three parts by weight of sodium for one part by weight of hydrogen is effected in each of the four reactions.

Muriatic acid and sodium chloride.

1 hydrogen + 35·5 chlorine
23 sodium + 0 hydrogen + 35·5 chlorine

Formic acid and sodium formiate.

2 hydrogen + 12 carbon + 32 oxygen
23 sodium + 1 hydrogen + 12 carbon + 32 oxygen

Phosphoric acid and sodium phosphates.

3 hydrogen + 31 phosphorus + 64 oxygen
23 sodium + 2 hydrogen + 31 phosphorus + 64 oxygen
46 sodium + 1 hydrogen + 31 phosphorus + 64 oxygen

Acetic acid and sodium acetate.

4 hydrogen + 24 carbon + 32 oxygen
23 sodium + 3 hydrogen + 24 carbon + 32 oxygen

This, then, is the assumption actually made by chemists, and further warranted by many important considerations. For example, ammonia has the property of forming compounds with the above acids by direct combination or addition; and the respective maximum quantities of the formic, phosphoric, and acetic acids, with which a given weight of ammonia can so combine, do actually yield twice, three times, and four times respectively the particular weight of hydrogen that is yielded by the maximum quantity of muriatic acid with which that same weight of ammonia can combine. Instead, therefore, of regarding the unit weights of all hydrogen compounds as including alike a single proportion of hydrogen, chemists regard them as including 1, 2, 3, 4, ... and x proportions of hydrogen respectively, accordingly as their constituent hydrogen is capable of removal in the ratios $\frac{H}{1}, \frac{H}{2}, \frac{H}{3}, \frac{H}{4}, \ldots$ and $\frac{H}{x}$, respectively. And this position, as to the relative unit weights of different chemical substances, arrived at by the above or by some other method of attack, is the gist of the whole question. Admitted, the rest follows as a matter of course: and it will hardly be arguing in a circle to adduce the simplicity of what follows as a reason for admitting the position on which it is consequent.

The relative unit weights of different hydrogen compounds being determinable in this way, certain relations of quantity subsisting among other common constituents of the different compounds become very quickly apparent, as shown in the following examples:—

Caustic potash.
1 hydrogen + 39 potassium + 16 oxygen

Formic acid.
2 hydrogen + 12 carbon + 32 oxygen

Nitric acid.
1 hydrogen + 14 nitrogen + 48 oxygen

Phosphoric acid.
3 hydrogen + 31 phosphorus + 64 oxygen

It is obvious that in the units of these different compounds, determined with respect to their constituent hydrogen, their constituent oxygen amounts to one, two, three, and four times sixteen parts by weight respectively; and it further appears that, whenever the units of different compounds differ from one another by their amounts of constituent oxygen, the increment or decrement of oxygen is always sixteen parts or some multiple of sixteen parts, as exemplified in the case of mono-potassic succinate, malate, and tartrate, for instance—

Potassium	39 +	hydrogen	5 +	carbon	48 +	oxygen	64
,,	39 +	,,	5 +	,,	48 +	,,	80
,,	39 +	,,	5 +	,,	48 +	,,	96

Thus, from an examination of the above, and of thousands of other instances, it would appear that the proportion by weight of constituent oxygen present in the reacting unit of any chemical substance is invariably sixteen parts, or some multiple of sixteen parts; that when two or more units of chemical substance differ from one another by the weight of their constituent oxygen, the difference always amounts to sixteen parts, or some multiple of sixteen parts; and, in fact, that sixteen parts by weight of oxygen constitute the smallest proportion by weight of oxygen, relatively to one part by weight of hydrogen, that can be introduced into, or educed from, any unit of chemical substance.

Similarly it may be shown that twelve parts by weight of carbon constitute the smallest combining proportion of carbon, relatively to one part by weight of hydrogen, and to sixteen parts by weight of oxygen; and so, not only to carbon and to oxygen, but to every presumed elementary body, there may be assigned a particular number, termed its proportional number, expressing the smallest proportion by weight of the particular body, relatively to one part by weight of hydrogen, that is found to exist in any unit of chemical substance. These relative quantities of the different elements, namely, one part by weight of hydrogen, sixteen parts by weight of oxygen, twelve parts by weight of carbon, fourteen parts by weight of nitrogen, twenty-three parts by weight of sodium (natrium), thirty-nine parts by weight of potassium (kalium), &c., &c., are denoted by the initial letter or letters of the names of the respective elements; so that the following composite expressions for the previously adduced potassium salts,

Succinate	$KH_5C_4O_4$
Malate	$KH_5C_4O_5$
Tartrate	$KH_5C_4O_6$

indicate the unit weights of the several salts to consist of once thirty-nine parts by weight of potassium, of five times one part by weight of hydrogen, of four times twelve parts by weight of carbon, and of four, five, and six times sixteen parts by weight of oxygen respectively.

To say that the relative proportions by weight of the different elements, expressed as above by the initial letters of their respective names, constitute the smallest proportions of them that are existent in and transferable to or from any unit of chemical substance, is tantamount to saying that they constitute indivisible or atomic proportions. Accordingly, the relative weights of these proportions are very commonly spoken of as atomic weights, and the proportions themselves as atomic proportions. Some most distinguished chemists maintain, indeed, that these atomic weights are really the relative weights of distinct physical particles, or atoms. Other chemists, while not denying that this may be so, do not admit that it necessarily must be so, and, when using the word "atom" at all, employ it simply as a convenient synonyme or abbreviation of the phrase "atomic combining proportion."

It is further noteworthy, that the above deduced elementary atomic weights, or smallest relative weights of different elementary matter that are found to exist in a unit of chemical substance, also constitute the relative weights of different elementary matter which are specially comparable with one another in regard to space, to diffusive movement, to heat, and to single and multiple powers of colligation and mutual replacement.

WILLIAM ODLING

THE VOYAGE OF THE NOVARA

Reise der Osterreichischen Frigatte "Novara" um die Erde, in den Jahren 1857-58-59, *unter den Befehlen des Commodore B. von Wüllerstorf-Urbair.* Anthropologische Theil. Bearbeitet von Dr. Fried. Müller. (Vienna. 1868.)

THIS important work scarcely appears to have attracted the attention it deserves, and we propose referring to a few of the more interesting facts it contains.

The object of ethnography, Dr. Müller observes, is not to regard man as an individual, but as a member of a family, and hence to consider him by such light as can be gained from the investigation of his speech, his thoughts, his feelings, and his entire mode of living. He thinks the classification of the different races of man in accordance with the colour of the skin and the characters of the hair, extremely unsatisfactory, though adopted by many of the best anthropologists of modern times, as Linnæus, Blumenbach, Cuvier, Pickering, &c., nor less so the method of Retzius, who attended exclusively to the form of the skull and face. Race and language, or form of speech, on the other hand, he thinks, are associated by the closest and profoundest ties. The persistence of some of the races whose contours have been handed down to us by the artists of the ancient Egyptians and Persians may, he considers, at a low estimate, be placed at 8,000 years, since it is likely that they had endured at least as long previously to their being fixed in stone as they have done since. Everything, he thinks, serves to show the persistence and invariability of race. But if we pass from man regarded from an anthropological to an ethnographical point of view, his unchangeability is no longer perceptible. The form of the land, the climate, the Flora and Fauna by which he is surrounded, all exert a powerful influence upon him. The low grade of mental development on which the Australian stands, may easily be attributed to the singular dearth of useful plants and useful animals by which he is surrounded; and the Polynesian would undoubtedly have advanced to a higher level, if the plants and animals around him had been appropriate objects to stimulate and extend his intellectual faculties. The views here expressed, it will be seen, are curiously in accordance with those expressed by Buckle.

Dr. Müller estimates the total number of inhabitants on the earth at 1,342 millions, an estimate which differs from that of Behm by only five millions. He divides them into the following races:—1. Australian; 2. Japanese; 3. Malays; 4. Ballaks; 5. African Negroes; 6. Central Africans; 7. Hottentots; 8. Caffres; 9. Americans; 10. Northern Asiatics; 11. South Asiatics; 12. High Asiatics; 13. Europeans.

A general view of the ethnology and language of each of these is given, with details of those subdivisions that were encountered by the *Novara* in her voyage. Some of these are excellently drawn up, and contain much original and interesting matter. To take one as a specimen—the Chinese.

These he regards as representing the highest type to which the Mongolian type can attain, and standing to the yellow races in the position that the Greeks of old did, and the Germans, French, and English of the present day, do to the nations of Europe.

The physical features of the country and the characters of the climate are lightly sketched. Their Fauna and Flora are stated to be richer in useful animals and plants than any other region of the earth. Their clothing, dwelling, food, amusements, and arms are then described. The character of the modern Chinese is hit off in a few happy touches. The basis of his character is rest. Hence his condition of stagnation. His knowledge leads always to the same results; the present is still the best, and for the ideal, and the improvement and advance of the future, be it never so golden, he has no aspirations. The ceremonies of marriage and the occupations of daily life are detailed. The children are stated to be well educated, and it is noticeable that in the better families even the girls are taught general literature, music, and painting. Their trade, religion, and, finally, their language, are considered. The same plan is pursued with the other divisions, and the reader is presented with a very entertaining, though highly condensed, account of the principal types of mankind.

OUR BOOK SHELF

Alpine Flowers for English Gardens. By W. Robinson, F.L.S. (London: J. Murray. 1870.)

THE author of "The Parks, Promenades, and Gardens of Paris," presents us here with a work which will be of great value to every lover of gardening. Although the formal and unsightly monstrosities of Loudon's "Landscape and Suburban Gardener" are now happily out of date, there is probably no department of landscape gardening in which a cruder and more artificial taste is still displayed than in the construction of rock-work. Not only is the prevalent style of rockery faulty from an æsthetic point of view, but, as Mr. Robinson shows, it is eminently unfitted for the growth of Alpine plants, which, even when their stems reach only a few inches above the ground, strike their roots feet, and even yards, into the soil with which the crevices in the rock are filled, in order to enable them to withstand the sudden droughts to which they are subject. Messrs. Backhouse, of York, have shown how, by careful attention to the conditions under which plants thrive in their native habitats, many ferns and flowering plants which are usually seen only in greenhouses, can be successfully grown on out-of-door rockeries; and if the directions given by Mr. Robinson are carefully followed, any professional gardener or private gentleman, with the appliances ordinarily found in a moderately-sized garden, will be able to produce results which will astonish his friends and neighbours. The descriptive list of Alpine flowers, with the soil and treatment suited to each, is complete and valuable; some of the illustrations are pretty, others are on too small a scale to be effective.

Systematisches Verzeichniss der in Deutschland lebenden Binnen-Mollusken, zusammengestellt, von Carl Kreglinger. 8vo. (Wiesbaden, 1870.)

A BOOK of 403 pages, and merely a list of the inland (or land and freshwater) Mollusca of Germany, without any description or figure. Nearly one-half of this extensive compilation is taken up with useless synonyms of the species. Among the chaff there is some good grain in the nature of geographical and geological distribution. The author does not seem to be a species-maker; although in some cases he attaches, in my opinion, too much importance to slight and local differences. However, there is unfortunately no court of appeal. He evidently has not consulted all the works which he cites; or he would not have adopted Dr. J. E. Gray's specific name of *striatula* for the *Zonites radiatulus* of Alder, the former having described or rather indicated the species as "*Helix Zonites striatula*," and thus contravened the established rules of nomenclature. Nor do we find any reference to works which were published last year before the date of his preface, for instance, the concluding volume of "British Conchology." Herr Kreglinger enumerates 347 species as inhabiting Germany—a wide range, extending from Schleswig-Holstein to Dalmatia (a distance of between 800 and 900 miles), and comprising every variety of situation and soil, mountain, forest, pasture, woodland, lake, river, marsh, and the sea-coast. Indeed, in the last respect, he has "travelled out of the record" by adding some unquestionably marine species belonging to the genera *Melampus* and *Truncatella.* The number of British inland species is 125. Of *Clausilia* we have 4 only, while Germany boasts of 54; of *Vitrina* and its allies we possess but 1 out of 9, of *Neritina* 1 out of 5, and of *Hydrobia* (or *Paludinella*) 1 out of 18; the genera *Zospeum* and *Lithoglyphus*, which are peculiar to South Germany, and the family of *Melania* are utter strangers to our country. It is to be regretted that the author has without inquiry followed L. Pfeiffer in recognising such genera as *Azeca* and *Ferussacia.* Those few workers, to whom the high price of 20*s.* may not be an object, will be glad to have this *catalogue raisonnée* in their libraries.

J. GWYN JEFFREYS

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Dinornis

I OBSERVE in your interesting paper of Feb. 17th, a statement that the larger varieties of Dinornis had, in all probability, become extinct before the occupation of the Middle Island of New Zealand by the present race of natives. I have observed previous statements to the same effect, supported by the authority of gentlemen whose opinions deserve the highest consideration, and by the assertion that no tradition of the existence of such birds has been found amongst the present representatives of the native race. I have good reason to question the accuracy of the latter assertion, at any rate.

I was myself in New Zealand for nearly seven years, from 1841 to 1848, and I had unusual opportunities of becoming acquainted with the condition of the Middle Island as it then was, having been in the service of the New Zealand Company as a surveyor and explorer in the settlement of Nelson, and subsequently in the other districts now known as Canterbury, Otakou, and Southland. I can state positively that some of the natives then resident in the Motueka and Motupippi districts of the Nelson settlement, at a time when the actual existence of such birds past or present had not been suspected, told us what appeared to us to be foolish stories about large birds which their immediate ancestors had been in the habit of hunting. One of them described to us most vividly the manner in which they beset these birds with dogs, and the mode in which the birds defended themselves by kicking. He stated that the dogs were frequently killed by a single kick, and that men not unfrequently had limbs broken in the same way. Other stories there were of an extravagant character, indicating perhaps a more remote origin—about birds so very large that one of them was said to have pulled down out of a tall tree an unfortunate hunter who had endeavoured to conceal himself there, and had *eaten* him on the spot; and these latter stories, no doubt, induced us to treat the others with less consideration.

I never met a native chief who told me that he had himself seen such a bird alive, and I do not think that any native whom I should have been inclined to trust ever told me even that his *father* had seen such birds, but they did assert expressly that their fathers—by which they would mean immediate ancestors, had so hunted and killed these large birds. I was further assured, at a later period, by a native chief named Teraki, who resided near the mouth of the Taieri River in the Otakou district, that he believed such birds still existed in the interior of the country, and that if I would go with him for a month he thought that he could show them to me. The same man told me curious stories about the existence, in the interior, of a quadruped whose habits he described, and which, if it did really exist at all, must, I think, have been a description of beaver. That fact may possibly tend to discredit his evidence, but I can only say that if it had been possible for me, consistently with my duties at that time, to go with him, I should have been very glad to do so.

The country to which he referred as the interior was the country to the west of the Taieri River, towards the source of that and of the Matou, or Molyneaux. It has, since that time, been fully explored, in consequence of the discovery of gold there, and it does not appear probable that he was correct in supposing that such birds still lived, though there are stories among the early explorers of having seen and heard strange things.

The rarity of these birds was attributed by Teraki and other natives of that district in which they were once abundant to over hunting, and to the fires, which, sweeping across a country covered principally with coarse grasses, had destroyed nests and eggs, and driven the birds themselves into the swamps for refuge, to meet death by suffocation from smoke and water.

Such an explanation appears to me to be probably correct, and the fact that complete skeletons have been found in the Taieri swamp, in a situation to which no existing stream of water could have carried so large a carcase, appears to lend weight to it. I have myself found on the low hills to the south of the river Matou the charred remains of egg-shells and bones of some variety of that genus, but not of the largest. I was instrumental in obtaining the first specimens of bones of such large varieties of the Dinornis as were discovered in the Middle Island. They were procured from a bed of peaty soil beneath the sands at the ancient embouchure of the Waikouaite River near Otakou, on an occasion when extraordinary low tides followed a strong south-east wind. They were forwarded from Waikouaite to Colonel Wakefield, and sent by him to Professor Owen, but there was not among them any complete skeleton, or any complete head.

Halstead WILLIAM DAVISON

The Earthquake at Manilla: its Theoretical Significance

THE first section of my Outline of a Theory of Earthquakes and Volcanic Eruptions,* which appeared in March 1869, concluded with the words, "At the same time we take advantage of this opportunity to refer to the catastrophe which, according to our theory, must occur on the 30th of September or the 1st of October of this year, and to call the attention of the inhabitants of those countries which are more especially exposed to earthquakes—that is to say, equatorial lands, particularly Peru, the East Indies, &c.—to the danger which threatens them." I wrote these words under the immediate impression of the results derived from my strict investigation of the earthquakes from 1848 to 1868—an investigation which awakened in me the firm conviction that the influence of the moon upon earthquakes is an incontestable fact. As these results were then known to me only, the prediction referred to must have surprised those scientific men who may consider themselves authorities on this subject. There was nothing peculiar in this. But the remarkable circumstance was that, although *before* the 1st of October not a single voice was raised against my theory, after that day (which passed in Peru without an earthquake) there appeared in the *Cologne Gazette* an anonymous article laden with the most vehement abuse of myself. I was able to take it quietly, because I knew I was in the right. For I had nowhere mentioned the localities to be visited by the threatened earthquake so exactly, nowhere defined the limits of it so closely, as the public thought fit to assume. In every passage I made use of the *vague* expression, "*Equatorial countries*," adding, by way of example, Peru, Mexico, Equador, the East Indies, &c.; in fact, at present, my theory does not admit of my explaining myself otherwise. People overlooked, or wished to overlook, the fact that in this case stress was laid upon *the time* and not *the place*. In the same way the earthquake in the Rhine country on the 2nd October, and the devastating outbreak of the volcano Puraie in Columbia on the 4th October,† were passed over with the most marvellous silence. I comforted myself, however, with the hope that later intelligence would afford me satisfaction, and I was not mistaken. Early in November a telegram announced that a "severe earthquake" had caused great destruction in Manilla; still no date was added, and for a few days I was only able to say that I supposed this earthquake took place on the 1st October. (See "Sirius," vol. iii. p. 7.) But the *Bulletin Hebdomadaire*, of the 9th January last, brought the following decisive intelligence of extraordinary importance for the earthquake theory:—"We learn from the *Courier* of the Philippine Islands that an earthquake took place at Manilla on the 1st October last. It was about half-past eleven in the morning when the first shocks were felt. Then followed the most frightful oscillations which lasted forty-five or fifty seconds, or, according to other observers, even over a minute. These oscillations were regular measured cadences, and violent, like the rocking of a ship in a storm. According to the indications of the pendulum, they were first in the direction S.E.—N.W., later N.E.—S.W. Many persons became sea-sick. The terror of the inhabitants during these anxious moments was fearful. They thought of the earthquake in the year 1863," &c., &c.

In accordance with the foregoing is the following information in the *Gazette* of the Eastern Seas—"Manilla, Oct. 2: The earth shook during yesterday's earthquake in the most alarming manner, like a ship in a violent storm; walls and beams cracked; all the walls in the rooms showed splits, and the ground was everywhere covered with chalk and mortar. In the garrison town of Manilla itself, the entire façade of the Augustine

* Three sections have appeared up to the present time.

† The newspapers give the following account of the catastrophe:—"Intelligence has been received of a violent eruption of the volcano Puraie in Columbia, accompanied by terrible devastation and loss of human life. Towards three o'clock on the fourth of October, the mountain began with violent eruption to throw up immense masses of ashes and lava. Two or three villages at its foot are said to have been entirely destroyed, with their inhabitants. The water of the River Canoa rose at Popayan a foot above its usual height, and the rapid current thus occasioned brought down lava and the bodies of men and animals from the devastated localities. At eleven o'clock on the morning of the same day the river was almost dried up."

Church is split, but still standing. In the old palace of the Governor, one part of the building fell in. There is hardly a house that has not been more or less seriously injured. The earthquake is said to have been more violent still in the neighbouring places, Balacan and Cavite, where also a lamentable loss of human life took place. Except the first two shocks, with which the earthquake began, the movement of the earth's surface was horizontal, but the *violence was not less than that in the year* 1863. If *the shocks from below* had recurred, Manilla would in all probability have been to-day but a heap of ruins.—3rd October: Yesterday evening, at six o'clock, we had a second earthquake with horizontal movement, and of rather long duration.—4th October: Yesterday evening, at eight o'clock, another earthquake of short duration. The original news from Balacan and Cavite is confirmed: in the first locality nearly all the stone houses fell in; amongst them the church, the town-hall, the parsonage, &c. — 11th October: The shocks were repeated on the two following days—(on the 4th and 5th) so that we have been visited with earthquakes on five consecutive days. Since then there has been quiet. According to the accounts received to-day from the provinces, the earthquake was felt throughout the whole of the Island of Luzon, that is to say, over an extent of country six times larger than Wales. The earthquake is said to have been most destructive in the southern province of Albay." It is evident from all this that we have here no mere ordinary earthquake, but, in point of fact, an event resembling the earthquake of 1863, as expressly observed in the passages cited.

The question will now occur to every thinking man: Is this exact concurrence of prediction with observation only an accident, or the actual expression of a law of nature? Is the circumstance that the catastrophe happened *two hours and a half after the culmination of the Moon*, which took place on that day *in the zenith of Manilla*, only a playful freak of the subterranean goblins, or is it connected with that theory according to which earthquakes occur, under favourable circumstances, at those places situated immediately over the summit of the tidal wave*? He who answers the question without previously examining into the matter, adopts certainly the most convenient method. But such is not the conduct of a friend of truth. I have derived my answer from the investigation mentioned in the commencement of this communication, and believe that what I have published is a sufficient justification for the prediction I have made; at the same time I consider that I may, in reliance upon their professional feeling, venture to demand from the representatives of science that they pass no judgment on my views, without knowing them in their entirety.

Prague RUDOLF FALB, Editor of "Sirius"

* The point of greatest pressure outwards against the earth's crust—such pressure being caused, according to my theory, by the action of the tide of the semi-fluid central mass of the earth—is situated mathematically under the place in the zenith of which the moon is at the time. Local circumstances unfavourable to the occurrence of earthquakes *can*, and in most cases, *will*, modify the observed result, so as to cause it to vary more or less from the mathematical calculation.

Right-Handedness

IF asked what part of the human body seems chiefly affected by advancing civilisation, I would be inclined to reply that it is the right hand.

At first sight the four-handed mammals might be thought to have an advantage; but because four hands are employed both for prehension and locomotion, while in man there is one pair of organs for each, man's two hands are worth more than the ape's four. As man rises from the rudest stages—such as digging roots, hunting, and tending cattle, to arts which are highly mechanical—the right hand becomes a more special and serviceable organ than the left, so that the loss of it to an engraver, a clerk, or an artist, compared to the loss of the left, would be a much more serious affair than it would be to a drover, who could clutch his stick or gesticulate to his dog almost as well with the one hand as the other. Admitting that, physiologically, there is a slight reason for the preference of the right hand, all our tools and fashions lend themselves to encourage its further dexterity. Screws, gimblets, &c., are made to suit the supinating motion of the right hand. Tools of the scissor kind are also made for the right hand, and I have seen a print-cutter's gauge made specially for a left-handed person fetch a very low price when it came to be sold. The slant in writing, the shed of the hair in boys, the manner in which buttons and hooks are placed on clothes, and the system of writing from left to right, all seem related to right-handedness.

In drawing, the pupil is recommended to begin at the uppermost corner on the left hand side, where the ornament is of a small and repeating character, so as to avoid fingering the part already finished. A schoolmaster I knew was able to detect left-handed boys, when they used the pen with the left against orders, by the writing either being straight or sloped the wrong way. Most boys know that it is easier to draw a profile with the face looking towards the left hand; yet on looking over the hieroglyphs in the British Museum the faces will be generally found towards the right. The normal way of writing the hieroglyphs is from right to left, though frequent instances occur of their being written from left to right.

I believe there is a constitutional reason for the preference given to the right hand, but I also believe that habit has strengthened nature's tendency, and that as the touch of the hereditary Hindoo weaver has become proverbially fine, so the aptitude of the right hand over the left is greater, with advancing civilisation, than in a state utterly savage. At that period of a child's life when creeping seems a more natural mode of progression than walking, there is no apparent dexterity in the right hand more than the left, and when man was almost utterly without arts, I can believe his state to have been ambidexter or ambisinister.

The elephant is known to employ one tusk more than another in rooting, &c., and when I asked Sir Samuel Baker which tusk went by the name of the "servant," he informed me that it was the right tusk generally, but the exceptions to the rule were far more numerous than was the phenomenon of left-handedness with human beings.

We have no reliable statistics of the proportion of left-handed persons to right in ancient or in savage nations. If Judges xx. 15, 16, is to have any weight in the matter, the proportion of left-handed in the tribe of Benjamin seems to have been greater than at the present day.

Left-handedness is very mysterious; it seems quite against physiological deductions and the whole tendency of arts and fashion. Prof. Buchanan, of Glasgow, who wrote an able memoir on right-handedness in 1862, thinks that left-handedness may be due to transposition of the viscera, and tells me that his friend Dr. Aitken found such a case. But surely transposition of the viscera must be far rarer than obstinate left-handedness. In cases of left-handed persons which I have examined, the limbs of the left side were proportionally larger, just as those of the right side are in normal cases. I have also found that left-handedness is hereditary. J. S.

The Balance of Nature

PREVIOUSLY to the recent wonderful Spectrum discoveries the sun's energy attracted more attention from *savans*, and many apparently extravagant theories were offered in explanation of this most wonderful of all physical phenomena; it is probable that the few remarks I have to make may appear equally extravagant.

As my intention is to allude more especially to the maintenance of the sun's energy, I will only make a passing observation as to its origin. The two conditions in which we find matter in the solar system are that of orbital motion and central repose; in the latter condition matter exhibits its energy in the form of light and heat; whilst in the former the light and heat are transformed into motion. If the earth was suddenly brought to a condition of rest, its energy, hitherto under the form of motion, would be exhibited as light and heat, and it would in a certain degree be converted into a sun.

If it could be shown that the sun was surrounded by an absolute non-conductor of its forces, it evidently would retain its energy for ever. As there would be no exhaustion, the sensations of light and heat would no longer exist. Now we reasonably believe that all space is filled with a highly elastic fluid or ether—this ether in a state of constant and intense action giving rise to the phenomena of solar light and heat. But if no obstacle existed to check or interfere with this action of the ether, it would, like any other body moving in space, retain its action for ever, without the necessity of a continuously acting agency or cause. If this can be granted, then it follows that the energy of the sun—which may have been necessary in the beginning to give this action to the ether—is no longer exhausted when the ether is once in motion. Hence this active ether is really an absolute preserver or non-conductor of the solar power or force, exhibiting itself as light, heat, &c.

But certain obstacles do exist to check the action of the ether. These are the various bodies which move in space and revolve round the sun, one of which is the earth we inhabit. But the resistance which the earth offers to the motion of the ether is the cause which converts this motion into that which gives the sensation of light, heat, &c., just in the same way that other matter in motion is transformed by resistance into heat and light. A more simple illustration of what I mean would be given by supposing a current of sea-water to give out a phosphorescent light only when an obstacle to its motion is introduced, such as a stone or stick, or when the waves of the ocean give out light by dashing upon a rock or the sea-shore.

From this line of argument it will be concluded that the only causes which exhaust the sun's energy are the several planetary and other bodies, moving in space, upon which the waves of ether dash, thus transforming their energy into the sensational forces of light, heat, &c.; but the area of these resisting bodies is exceedingly small in comparison with the rest of space, in which the ether is acting by its own energy, and without coming in contact with any resisting or exhausting obstacle.

It remains, then, to account only for the amount of the sun's energy which is absorbed or transformed by these planetary and other bodies. Although we may have thus reduced the solution of this mighty problem to a narrower space, yet it is just as difficult to account for the maintenance of the exhausted energy occasioned by a single grain of sand moving in space as by all the planetary and other bodies together.

Seeing that constant exhaustion or transfer of the sun's energy does take place, although in a much less degree than would be the case if it were not confined to the moving bodies in space alone, it remains then to account for its maintenance. The first question we should ask ourselves is this: Is there any evident or known force tending towards the sun as a centre? The immediate reply will be gravitation; and although in the present state of scientific knowledge it may be difficult or impossible to define what gravitation is, yet there cannot be a doubt that it is a force acting on all matter, with a tendency to carry all material bodies direct to the sun. As such force dashes into or upon the sun, it becomes in its turn transformed into light, heat, &c. It is indeed not improbable that future discovery may teach us that gravitation may have its origin from and bear some certain proportion to the resistance presented by the several bodies in space, which are illuminated by the sun's energy; thus establishing the beautiful law of light and heat being transformed into the force of gravitation—gravitation again into light and heat; thus sustaining and maintaining, for all time, the sublime fountain of motion and life, thought, and every sensation and action that organic matter is able to experience. W. L.

Sir W. Thomson and Geological Time

THE strongest statement about the retardation of the earth's motion of rotation by tidal friction, supposing the earth had been for so long a time provided with an ocean, is to be found in the appendix to a sermon preached by Professor Pritchard, F.R.S., then president of the Royal Astronomical Society, before the British Association at Nottingham. He there, in combating Darwin, says, "One million of million years ago, if the solid earth could then have been provided with an ocean, the length of the day would probably have been less than the flash of the hundredth of a second of time!"

I announced to the Literary and Scientific Society of Nottingham that this was an error in calculation, and based on a fallacy in reasoning; and Mr. Pritchard withdrew the result, while maintaining the method, in a letter read to the meeting after a lecture on the subject that I subsequently gave. But I am informed that it has since been republished in its old shape.

There is a still more amazing statement put forward in this appendix by the champion of Anti-Darwinism. Mr. Pritchard says he is familiar with the optical structure of the human eye. He dwells on the wonderful mechanism, and hints at the wonderful chemistry of it; and quotes the well-known passage from Darwin (Ed. 1. p. 188) in which, while he gives up all attempt at showing gradation in the structure of the eye of Vertebrata, recent and fossil, yet he shows that in the Articulata the series is more complete. He quotes this, I say, to show that Darwin undertakes to explain by natural selection the structure of the *human* eye, which is precisely what he declines to do. "Let us attend," he says, "to the process of natural selection by which this marvellous organ is said to have come into being." '"I can see," says Mr. Darwin, "no very great difficulty . . . in believing that natural selection has converted the simple apparatus of an optic nerve into an optical instrument as perfect as is possessed by any member of the great Articulate class," i.e. *as perfect as the human eye.*' Is not this amazing?

Rugby, March 22 J. M. WILSON

The Moon's Diameter

WILL you permit me to say a few words on the interesting question raised by Dr. Ingleby in your last? The sun, moon, and all the heavenly bodies appear set, as it were, in the blue sky when the weather is clear; and as they are rarely visible unless when surrounded by at least a small space of blue sky, it seems to me that they will be naturally judged to be at the same distance from us that the sky is. But what is this distance? What, in other words, is the mean distance from which the blue light diffused or reflected from the air or vapour comes to us? Prof. Tyndall, who has devoted much attention to the causes of this blue appearance, may perhaps be able to tell us. The problem, of course, is rather an indefinite one, but an approximate solution might assist us in determining the question.

As to the heavenly bodies appearing larger when nearer the horizon, I shall leave some one else to settle the angular magnitudes in the case. Mr. Abbott, to whom Dr. Ingleby refers, proves that the fact is not confined to the heavenly bodies, but that portions of the sky seen under the same angle appear at least three times as large when near the horizon as when near the zenith ("Sight and Touch," pp. 136-7). But then, does the blue light come to us from the same mean distance when we look towards the zenith and when we look towards the horizon? or does it come from a much greater distance in the latter case, and thus apparently increase the magnitude of a portion of it whose size remains unchanged? In other words, is the sky seen as a hemisphere, or as a much smaller segment of a spherical surface (the observer being at the centre, not of a sphere, but of a small circle, the plane of which coincides with the horizon)? Most persons who look at a clear sky will, I think, adopt the latter alternative. It will be interesting to know if scientific research bears out natural impression in the case.

Other solutions of the difficulty might undoubtedly be proposed. Association of ideas, which is now the favourite device for helping a lame dog over a style, might be called to the rescue, and with some plausibility. Clouds and birds—everything, in fact, that passes above us—are nearest to us and look largest when most elevated. Elevation is thus associated with comparative nearness, and approach to the horizon with comparative distance. It is, however, simpler, if correct, to maintain that we see the sky as it really is, and that the apparent distances and magnitudes of the heavenly bodies are determined by the fact that they appear to be set in the sky, not placed at a great distance beyond it. W. H. STANLEY MONCK

Trin. Coll. Dublin, April 2

Heat Units

THE science of heat, which is capable of being made and is rapidly becoming one of the most exact of the experimental sciences, seems to labour unnecessarily under an excessive variety of units of measurement. At present there are used—

Units of Mass.	Thermometric Degrees.
Grain,	
Pound,	Centigrade,
Gramme,	Fahrenheit.
Kilogramme.	

Whence, evidently, there result *eight* different thermal units, to all of which the common name "unit of heat" is applied, or, at least, names inadequately distinctive. In the face of this it would really seem that some such suggestion as I here proceed to make must eventually be adopted.

Define, first, as follows:—A *therm* is the quantity of heat necessary to raise the temperature of 1 gramme of water from 0° C to 1° C. Secondly, 1 kilotherm = 10 hectotherms = 1000 therms = ... , thus having kilotherm, hectotherm, &c. suggestively corresponding to kilogramme, hectogramme, &c., in name as well as in nature.

Therms and kilotherms, which would probably alone be required in practice, would thus take the place of "thermal units, centigrade," "gramme-water-units," "kilogramme-units of heat," and others more or less lengthy and inexact at present to be found in writings on Heat and Energy.

College Hall, St. Andrew's, April 4. THOMAS MUIR

The Solar Prominences

It may interest some of your readers to hear that the bright lines of the hydrogen "flames" extending beyond the sun's disc can be seen with much less instrumental aid than has hitherto been considered indispensable. I have succeeded in seeing them quite unmistakably by the following very simple means. I fixed one of Mr. Browning's direct vision spectroscopes (having seven prisms) on a board which also carried a two-inch object-glass belonging to a good field telescope. I mounted the instrument thus arranged (shall I say as an altazimuth) on the back of an ordinary bed-room mirror, and directed it at the sun. The slit was set so as nicely to divide the D line, and a blue glass was generally interposed in front of the slit to sift the light. As the image of the sun traversed the slit at intervals, the flames appeared as bright prolongations of the F line extending beyond the sun's limb. It was also clearly seen at times that these prolongations were narrower than the F line and were not in the centre of it, also that they were frequently detached from the sun's limb, and sometimes they were not straight: appearances depending as is generally supposed on the velocity and pressure of the gas in the flame. The flames were also readily seen in the C line. In observing the solar spectrum I have found coloured glasses in front of the slit very useful to shut out as much as possible of the light from the parts of the spectrum not under observation. By using the spectroscope without its slit and collimating lens, and directing it towards the great nebula in Orion, it shows close together three bright images of the nebula exhibited on a continuous spectrum.

Streatham Hill, April 8. ERNEST CARPMAEL

Modern Geometry and the University of London

The letter entitled "Euclid as a Text-book," which appeared in last week's NATURE, seems to me to call for immediate reply. Many students about to present themselves for examination at the University of London and other places during the next year have been told by their tutors that a thorough and accurate knowledge of geometry would be better appreciated than the power to make verbal transcriptions of Euclid; and the letter referred to is calculated to shake the confidence of such students in the method they have been advised to pursue, and to produce a feeling of uncertainty as to the way in which demonstrations differing from Euclid's will be received by the examiners. But I think that an inspection of the calendars will re-assure them, and show that they have no cause to fear the result of examination, especially when the University of London is the examining body.

The papers consist of certain propositions common to Euclid and modern text-books, and a number of problems readily solved by a student of modern geometry, but almost impossible to one who has simply committed to memory Euclid's text. My own strong conviction is, that the latter would find some difficulty in passing the recent examinations. The questions given fall strictly within the University programme, and treat of important properties of geometrical figures which no student possessing a knowledge of approved modern methods could possibly be ignorant of. The "alternative" or modern side has been carefully kept in view and placed on a footing of equality with the ancient system.

During the year 1869 eight of my pupils who had *not* read Euclid were candidates for matriculation; all passed, and none were placed lower than the first class; so that I cannot see the advisability of boys returning to Euclid "in order that their prospect of good places may be enhanced."

Mr. Tucker apparently desires a series of questions which could only be answered on modern principles. This would amount to a system of protection, and could not fail to be objectionable.

The student of the New Geometry has, in fact, a great advantage. To the learner of Euclid a fact clothed in terms slightly varying from Euclid's is often new and startling, but to the modern student who learns every proposition in its most general form, and assimilates the idea apart from the external or verbal form in which it may accidentally be presented, it is already familiar and trite. The statement that a change in the London syllabus has been or will be made "as a sop to Cerberus," will strike many as singularly infelicitous and ungenerous. The Senate of the University does not say one thing and mean another; it has always shown unflinching courage in the reform of English methods of education, legislating as an initiator rather than as a follower. The tendency of the University throughout its existence has been to discourage cramming in every shape and form, in the teeth of numerous difficulties and influences to which the term "obstructive" rightly applies rather than to the University itself. It is to be regretted that a letter dating from University College School should show so little confidence in the intrinsic superiority of modern methods, and still more that it should impeach the integrity of men who have not so deserved.

Brixton, March 28 RICHARD WORMELL

DEATH OF PROFESSOR MAGNUS

On the 4th of April, 1870, at a quarter-past 10 p.m., died peacefully, after a long illness, Dr. Gustav Magnus, Professor of Physics, and Director of the Physical Cabinet in the University of Berlin. He was an experimental philosopher of great and varied excellence, executing his work with the choicest apparatus and with the most conscientious care. His numerous labours are known to all students of physics, and they are such as to secure for him an enduring fame. On the 28th of April, 1851, I first saw Professor Magnus on his own doorstep in Berlin. His aspect won my immediate regard, which was strengthened to affection by our subsequent intercourse. He gave me a working place in his laboratory, and it was there I carried out the investigation on Diamagnetism and Magne-crystallic Action, which is published in the *Philosophical Magazine* for Sept. 1851. In 1853 I was again in Berlin, and found under his roof the same ready help and sympathy. Professor Hirst and myself paid him a visit last summer; and he afterwards attended the Exeter Meeting of the British Association, where his frank, genial, and gentlemanly demeanour were conspicuous to all. Over and above his direct contributions to Science, Prof. Magnus exercised a powerful indirect influence, through the kindly aid and countenance which he lent to young inquirers. When I bade him good-bye in 1851 his last words to me were, "If you should meet any really able young fellow, willing to work, and to whom such assistance as I can render would be valuable, send him to me." There are many such, now no longer young, who, like myself, will mingle a grateful memory of his goodness with their grief for his loss.

Royal Institution, 11th April JOHN TYNDALL

THE SOURCES OF THE NILE *

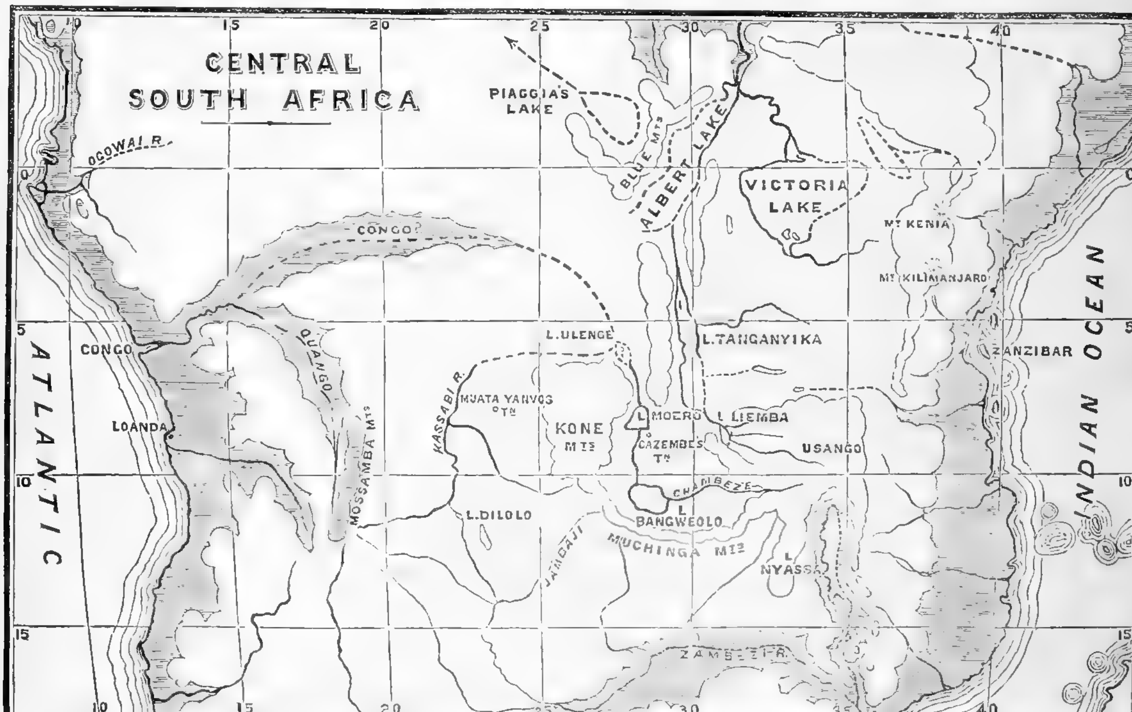
The main point of interest in the latest travels of Livingstone, and that which gives to them a distinctive importance over the great accomplishments of his former journeys, is, that in these, Livingstone has undoubtedly visited and beheld the long-sought-for sources of the Nile. It is true that there still remains considerable doubt as to which of the basins that he has explored will ultimately be acknowledged as the cradle of the Nile, but this at least is certain, that the real head streams have been seen by him, and the vexed question has by these explorations resolved itself into a choice between two or perhaps three streams. Livingstone himself has apparently no bias in favour of one or other, so that the discussion is a perfectly open one. The three rival head streams are, first, the feeders of Lake Liemba, and second the Chambeze River and its lake chain, both of which rise near the eastern edge of the great longitudinal plateau of the side of Africa next the Indian Ocean; the third is the source recently claimed for the Nile by

* An abstract of part of a paper read before the Royal Society of Edinburgh, March 21st.

Dr. Beke, in his solution of the Nile Problem, the great* Casai, or Kassabi River, which rises nearer the Atlantic side of the continent.

Of the first of these presumptive sources, the feeders of Lake Liemba, it may be said with almost absolute certainty that they are tributaries of the Nile, and it seems most probable that they are the sources of that river. Livingstone has found these "four considerable streams" flowing into Lake Liemba; a river-like prolongation unites Liemba and Tanganyika, these two lakes appearing thus to be at the same level; then Tanganyika and Nyige Chowambe, which is evidently the Albert N'yanza, are "one water," and that this last is a reservoir of the Nile is undoubted.

The union of the second possible head stream, the Chambeze, with the Nile, is less apparent; indeed the balance of evidence seems to show that it must be the head of another great river of Africa, the Congo or Zaire. If the Chambeze prove to join the Nile, then the streams to Lake Liemba become mere tributaries, since the course of the Chambeze is by far the longer of the two. The Chambeze flows down into the central valley through lake Bangweolo, and then northward through Lake Moero. Livingstone describes Lake Moero as beginning twelve miles below the position of the town of Lunda, the capital of the Cazembe (lat. 8° 40′ S., long. 28° 20′ E.), whose position may be laid down with tolerable accuracy from the former journeys of the Portuguese travellers. Since Livingstone proceeded north from Cazembe's town along the eastern shore of the Moero in his attempt to reach Ujiji in 1867, the great bulk of this lake must lie to westward of the meridian of Lunda, or about 120 miles west of Tanganyika. Dr. Livingstone has seen the river at its outflow from the lake, and also at the point where it emerged from the crack in the mountains of Rua, when, according to his own observation, the river turned north-north-west to form Ulenge, a third lake or marsh in the country west of Tanganyika. This north-westerly turn would carry the river quite out of the direction of the Nile basin, and the higher side of the continent being to the east, the probability is that the river would continue to curve to the westward. If, however, the Albert Lake prove to have a great south-westerly extension, this one difficulty is overcome. Again, the valley of the Chambeze in the plateau where Livingstone crossed it, is no doubt one of the greatest hollows in the highland, so that the height of the river bed here may be taken at 3,000 feet, the lowest level of the limits which Livingstone gives to the undulation of the plateau, or only 200 feet above Tanganyika. Descending into the "great valley"* to Lake Bangweolo from the plateau, the Chambeze must have a considerable fall, from Bangweolo to Moero there must be a second descent. The Cazembe's country, which extends round to the south of Tanganyika, is described as flat, and its rivers are currentless and stagnant. If Moero were at a higher level than Tanganyika, would not the river which leaves it take a course over this flat country instead of facing towards and making its way through a "crack in the mountains northward?" Seeing that the river does force its way through the mountains of Rua (which appear to be a continuation of the "ranges of tree-covered mountains" which "flank Lake Moero on both sides") the presumption is that Moero is at a lower level than Tanganyika; and if this be the case, the river which descends from it through the mountains cannot ascend to the level of any one of the Nile lakes to join them, but must find some other course. With regard to the third advocated source, the Kassabi River, of which Dr. Beke affirms it to be his belief that it is the head stream of the Nile of Egypt, the difficulties of its joining the Nile appear to be even greater than the last. The upper course only of this river has been explored.



MAP OF EQUATORIAL AFRICA WITH CONTOUR LINES

* *Athenæum* of February 5th, 1870.

* It has been objected that Lake Bangweolo does not lie in a valley, but on the plateau; but Livingstone's letters could scarcely be clearer on this point, since he speaks of "the great valley enclosed between Usango (the eastern plateau) and the Kone range."]

It springs in the Mossamba Mountains, which are on the inner borders of Angola and Benguela, its sources being close to those of the Quango River, a tributary of the Congo. The Kassabi is known to flow northward as far as the 8th parallel of latitude, and to the westward of the capital of the Muata Yanvo, the great negro potentate of Central South Africa. Livingstone crossed its head on his journey from the Zambesi to Loanda, and reports which he collected from the subjects of the Yanvo's kingdom all tend to prove that whatever direction its middle course may take, in its lower course the Kassabi flows round to westward, and is joined by the Quango. The trader Graça, who penetrated to the Muata Yanvo's capital in 1846, says that the territory of this chief is "shut in" by the great rivers Kassabi and Lurua (a tributary of the Kassabi), and he affirms that the Kassabi has an easterly direction beyond this.

The Hungarian traveller, Ladislaus Magyar, has penetrated furthest of the three Europeans who have visited this region, and his report agrees well with this last. He states that the Kassabi, after forming the waterfall of Muewe (in about 11° S.) bends gently to northward, but further on takes an easterly direction in its lower course, and attains a great breadth at the place where it "*touches upon*" the extensive lake Mouva, or Uhanja.* Now if we turn the Kassabi River eastward in latitude 8° south, in agreement with the above description, we find that it meets the position which Dr. Livingstone's letters give to Ulenge, the lake or marsh to which the Chambeze ultimately flows, and whose waters Livingstone tells us by report are "*taken up*" by the Lufira, a "large river which by many confluents drains the western side of the great valley." Is not the Lufira, then, the lower course of the Kassabi River, and Lake Ulenge of Livingstone, the Uhanja of Magyar? If this be the case, the same difficulties which appear in the way of the Chambeze River joining the Nile, hold also against the Kassabi, which would seem to join this river at Lake Ulenge.

Next, the question arises, If these rivers do not form a part of the Nile system, where shall we find an outlet for them? The answer to this is plainly, in the Congo River.

The Congo was described by the Jesuit missionaries who first visited its mouth as "so violent and so powerful from the quantity of its waters and the rapidity of its current, that it enters the sea on the west side of Africa, forcing a broad and free passage (in spite of the ocean) with so much violence that for the space of twenty leagues it preserves its fresh waters unbroken by the briny billows which encompass it on each side." In the introduction to his narrative of the British expedition to the Congo River in 1816, Tuckey says: "If the calculation be true that the Congo at its lowest state discharges into the sea two millions of cubic feet of water in a second, the Nile, the Indus, and the Ganges are but rivulets compared with it, as the Ganges, which is the largest of the three, discharges only about one-fifth of that quantity at its highest flood." This statement may be somewhat exaggerated, but Tuckey actually found that this vast river has a width of two, three, or even four miles, whilst flowing with a current of two or three miles an hour,† and this not at its mouth, but inland beyond the mountainous coast region. The northward wall-like continuation of the Mossamba mountains, on the 20th meridian, to beyond the equator, which Dr. Beke supposes to exist,‡ would not admit of a longer course than about 500 miles for the Congo, and a basin of that extent is utterly inadequate to collect and maintain such a body of water as that which this river is known to have, in a region where the annual rainfall averages only 12 to 15 inches (Livingstone's observation at Loanda). Such a vast river cannot be formed in a short course, but must have its rise far in the interior of the continent; and if the Kassabi River and its drainage be taken to the Nile, where shall we find a sufficiently lengthened course for the Congo?

Tuckey's unelaborated notes give the opinion that the "extraordinarily quiet rise * of the river (Congo) shows it to issue from some lake which had received almost the whole of its waters from the north of the line;" and again he says, "I cannot help thinking that the Congo will be found to issue from some large lake or chain of lakes considerably to northward of the equator." The reason of Tuckey's supposition that the lakes, which are evidently necessary to maintain the volume of water in the Congo throughout the year, would be found north of the equator, is, that he found the rising of the river beginning on the first days of September. At the time of his journey little or nothing was known of the times of the rainy seasons in Central Africa from actual experience. The observations of travellers in the continent since that time have greatly increased our knowledge of these seasons, and show them to be regulated by the apparent movement of the sun between the tropics. An area of low atmospheric pressure, with its attendant inflowing winds and rains, is constantly moving up and down the part of Africa which lies between the tropics, following the vertical sun. If every part of Africa were level and equally surrounded by water, it would result from this movement of the area of low pressure, that a rainy season would begin at each point shortly after its latitude had passed vertically beneath the sun, and a double rainy season would thus be produced: a *greater* when the low pressure area is moving equatorward in each hemisphere drawing in the sea winds; and a *lesser* when that area is passing north or south outward from the equator towards the extremities of the continent, inducing rather the land winds, whose moisture is already in great part spent. This rule holds good on the low coast lands, where other exterior influences do not disturb the arrangement, but over the high plateau of the interior of South Africa, † the commencement of the rains seems rather to precede than to follow the vertical sun, and in the equatorial regions two of the rainy seasons are prolonged into one, which lasts for eight months of the year. Under the equator at the mouth of the Ogowai River, on the west coast, Du Chaillu found the rainy season beginning in October; farther inland, in the Fan country, the rains set in in September, and in the same latitude, between Victoria Lake and Tanganyika, Burton tells us that the rainy season begins in August. Between 5° and 10° south latitude Livingstone's observation shows that on the west coast at St. Paul de Loanda the lesser rains begin in November, but in the same latitude in the centre of the continent Burton reports the rains of the Tanganyika basin beginning in September, or two months earlier; and Livingstone in his latest journey could not proceed to Lake Bangweolo from the Cazembe's town, where he arrived about the middle of September, because the rains had set in. Lake Ulenge lies between these latitudes, or in about 5° south, so that the rise of the waters of the Congo River, if its upper course be through this lake, is perfectly explicable, without the necessity of taking its reservoir lakes to the north of the equator. The lower course of the Congo is probably in a curve to north-westward from Ulenge, afterward turning south-west to meet the farthest point which Tuckey reached, where it was flowing from north-east. The rains would begin to fill Lake Ulenge, as well as the part of its lower course below this which is in the centre of the continent, in

* Magyar's journey in Petermann's Mittheilungen, 1860.
† P. 342 of the Narrative.
‡ Map to accompany a paper on Dr. Livingstone's discoveries in "Illustrated Travels," Part xv.

* The maximum rise of the Congo was observed to be only 11 feet, generally 8 or 9, or less than that of perhaps any river of equal magnitude. That of the Zambezi (above the confluence of the Shiré), a lakeless basin, has been found by Livingstone to be as much as 80 feet perpendicularly; and at Khartoum the White Nile rises nearly 18 feet.
† As also in the Abyssinian highland.

August; lower down still the rains apparently begin in September, but, as before noticed, towards the coast they are later, and so do not begin at the mouth of the river till well on in September, after the river has begun to rise. The dry season in the country west of Ulenge also agrees well with the movements of the Congo river, for Dr. Livingstone remarks that the floods in the country between Moero and Ulenge last till May or June, and the lowest state of the Congo was observed to occur in July and August.

With the Kassabi and Chambeze for its head streams, the Congo has a sufficient, though not too great area of drainage to collect the vast quantity of water which it returns to the ocean. On this supposition the area of its basin measures about 800,000 square miles, and that of the Nile nearly 1,300,000 square miles; so that the great African rivers stand in order thus:—Nile, Congo, Niger, and Zambezi. KEITH JOHNSTON, JUN.

NOTES

WE are informed that the Duke of Devonshire will probably be the President of the Royal Commission to inquire into the Present State of Science in this country.

THERE is so little evidence of scientific training or thought in most things which are done in high places, that it is almost pleasant to be taxed even by a Chancellor of the Exchequer who attempts to do it on scientific principles, or at all events quotes scientific authority as Mr. Lowe does, who, referring to the results of the recent Deep-Sea Dredging Expedition in his Budget speech, compared the British taxpayer to the frail animals which enjoy life at the bottom of the Atlantic at a pressure of three tons to the square inch. We strongly advise Mr. Lowe to sanction another dredging expedition during the present autumn, not that it may be shown how much more vitality there is at a reduced pressure—a vitality more approaching that of "My Lords"—but that even greater pressures may be found and quoted as precedents should the next Budget prove a less satisfactory one. There is a point in the Budget, moreover, of the greatest importance to men of science. The postage on printed matter not exceeding 2 oz., and on newspapers not exceeding 6 oz., is to be reduced to one halfpenny. We have waited a long time for this change: not too long, however, to welcome it warmly now it has come, for the tax on all authors of the postage of scientific papers, copies of which they wish to distribute, has been very great.

THE following are the lecture arrangements at the Royal Institution after Easter:—Four lectures by Prof. Blackie on the Principles of Moral and Political Philosophy, on Tuesdays, April 26th to May 17th. Seven lectures by Prof. Tyndall (subject not announced), on Thursdays, April 28th to June 9th. Seven lectures by Prof. Robert Grant, on Comets, on Saturdays, April 30th to June 11th. Three lectures by Prof. Seeley on History, on Tuesdays, May 24th to June 7th. The *probable* arrangements for the Friday evening meetings are as follows, viz.: April 29th, Prof. Blackie—The Interpretation of Popular Myths. May 6th, Mr. R. A. Proctor—Star Grouping, Star Drifts, Star Mist. May 13th, Rev. Canon Moseley—The cause of the Descent of Glaciers. May 20th, Prof. Williamson—On Atoms. May 27th, Principal Dawson—The Primitive Vegetation of the Earth. June 3rd, Prof. Max Müller—The Migration of Fables. June 10th, Prof Odling (subject not fixed).

THE *Pall Mall Gazette*, which gives so much space to all matters of scientific or general interest, quoting from the St. John's (New Brunswick) *Telegraph* of the 18th of March, describes an extraordinary phenomenon which took place in the harbour of that city on the previous day. Early in the morning, just before the commencement of a snowstorm, while the wind was rising so as to be heard within doors, a strange noise, similar to that accompanying the earthquake on the 22nd of October last, was heard by the residents near the harbour. It was then seen that the old ferry, which should be several feet above water, had vanished. A piece about twenty feet by seventy broke off and settled squarely down into the water. A frontage several hundred feet in extent, running from the line of the demolished wharf towards the breakwater, had also gone down, leaving a steep embankment. The soundings since made show that where the old ballast or reefer was the day before, rising above the water eight feet, were found six fathoms of water, the bottom had settled just thirty-two feet. Near where the portion of the wharf settled away, or where a moderately sized vessel used to ground at low water, there is now between six and seven fathoms at low tide. One of Messrs. Adams's buoys, moored about four or five hundred feet from the shore, had disappeared; and last evening, when the tide was at its lowest level, the current was just showing a ripple over the top of it. As the tides rise and fall about thirty feet in St. John's harbour, and the chain of this buoy had several fathoms of scope, it may be inferred that the bottom sank as much as nine or ten fathoms at this point. So far as could be ascertained, the *Telegraph* states this subsidence took place over an area of about three acres in extent.

MR. ARCHIBALD GEIKIE, F.R.S., the director of the Geological Survey of Scotland, is now at the Lipari Islands, his object being to study the volcanic phenomena of those Islands, and of some adjacent parts of Italy. He anticipates that the numerous coast sections of these islands will furnish evidence from which light may be thrown on the history of the volcanic rocks of the British Islands; the manner in which different volcanic rocks yield to the forces of denudation, subaerial and marine, is also a matter of importance that will be carefully studied.

ON Monday evening a distribution of prizes (certificates of merit) took place at the South London Working Men's College, Professor Huxley being in the chair. Previous to the distribution a lecture on the "Biography of a Plant" was given by Mr. Harland Coultas. Professor Huxley, in the course of his remarks, said that they had presented to them an analogy between vegetable and human life, and that analogy he would carry a little further, by reminding them that there was nothing more poisonous or dangerous than an uncultivated mind. He hoped that these educational establishments would do for society what the plant does for the air; namely, absorb all the poison of ignorance, and, by a similar change to that exercised in the chemical action of the plant, give off those benefits which education alone could diffuse.

IT is not often that the daily newspaper press invades a college in search of an editor, and still less often is a learned scientific professor the elect one. We have a case in point, however, of such a condition of things. Professor Jack, M.A., who has for several years held the chair of Natural Philosophy in Owens College, Manchester, has been requested, and has consented, to take the editorial management of one of the oldest and most successful papers north of the Tweed, the *Glasgow Daily Herald*, a paper which frequently discusses scientific subjects with a fulness of knowledge. Mr. Jack has not hitherto been in the toils of daily newspaper life, but he ought to have no mean qualifications for his new vocation, considering the literary and scientific culture and worldly experience which he has acquired as an alumnus of Glasgow College and of St. Peter's College, Oxford; as one of Her Majesty's Inspectors of Schools in the West of Scotland, and as a scientific professor in Cottonopolis.

THE wave of low temperature which passed over the South of England during the latter half of March, was a very remarkable one. From the 22nd of March till the 6th of April the thermometer fell below the freezing point every night, with scarcely any intermission. For the week ending April 2nd the mean temperature at Blackheath was 37·2°, or about 8° below the average of the corresponding week in the last fifty years. From the reports for sixteen different stations in England, eight in Scotland, and one in Ireland, forwarded every week by Mr. Glaisher to the *Gardener's Chronicle*, it appears that the temperature was much lower in the South than in the North of England, or in Scotland. The lowest averages are given at Portsmouth and London (Blackheath); the highest for England at Liverpool, Salford, and Newcastle; while these latter are several degrees lower than the lowest mean in Scotland. The average temperature for that week in London was 7° lower than in Edinburgh, and 11° lower than in Dublin.

MR. SYMONS'S "British Rainfall for 1869" contains an enormous mass of information respecting the distribution of the rainfall throughout the kingdom during last year, with other meteorological statistics. The extremes of rainfall during the year at the places of observation in England were 198·19 in. at the Stye, in Cumberland, and 20·09 in. at North Sunderland, while many places in the south-east of Scotland enjoy even a dryer climate, the fall at East Linton, Haddington, being only 15·77 in. So much injury is done to science by the publication of statistics based on incorrect data, that Mr. Symons's "Rules for Rainfall Observers" should be in the hands of everyone who possesses a rain-gauge.

M. BOURLOT, Professor of Mathematics in the Lyceum at Colmar, believes he has established the fact, contrary to the opinion of Arago, that during the Middle Ages the climate of Alsace was milder than at present. He traces a relation of chronological coincidence, if not of cause and effect, between the change of climate and the precession of the equinoxes.

THE honour of knighthood has been conferred on Mr. Ronalds for his early researches in telegraphy.

THE execution of the Faraday memorial has been committed to the well-known sculptor, Mr. Foley.

PROF. TYNDALL'S most recent contribution to the "germ-theory" is contained in a letter to the *Times* of the 7th instant. He has observed that the air breathed out of the lungs, especially at the close of a long voluntary exhalation, is "visibly pure," or produces, when passed across a strong beam of light, the familiar black smoke-like clouds caused by the entire absence of organic matter. He confirms the explanation given by many medical men, and especially by Prof. J. Lister, of Edinburgh, for the exclusion of air from fresh wounds, that the putrefaction of wounds is caused by the germination of the germs of organic life contained, under ordinary circumstances, in large numbers in the air. In a reply to this letter in the *Times* of yesterday, Dr. H. C. Bastian makes the startling assertion that, in conjunction with Dr. Frankland, he has met with living organisms in hermetically-sealed vessels, from which all air had been removed, and after the contained fluids had been raised to a very high temperature. Some solutions containing organic matter and other ingredients were prepared in the following manner:—After a perfect vacuum, above the level of the fluid, had been procured in the glass vessels by means of Sprengel's air-pump, the drawn-out necks of the flasks were closed by means of the blow-pipe flame. The airless flasks, containing then the fluid itself as the only possible germ-containing material, were submitted, in a suitable apparatus, by Professor Frankland, to a temperature varying from 148° C. to 152° C. for four hours, and yet, after having been placed under the influence of suitable conditions, in the course of a few weeks, living organisms—many of them altogether new and strange—were found in these fluids. These extremely important results are about to be communicated to the Royal Society.

THE *Soirée* of the Royal Microscopical Society to be held at King's College on the 20th inst., seems likely to be supplied with a large number of objects of interest. Mr. Charles Stewart prints a descriptive catalogue of 100 microscopic objects selected to illustrate the Invertebrate sub-kingdom, to be exhibited on that occasion.

IN an article in the *Artizan*, for April, on the Influence of the Suez Canal on Trade with India, Sir Frederick Arrow states that at the present moment the influence of the Canal is being felt in a decrease of the cost of fuel east of the Isthmus, which will certainly have a great effect on the cost of carriage, and therefore on the cost of laying down produce and goods. The existence of the route, he believes, will stimulate production, not only in India, but in the various countries which it brings into the family of commercial relations.

ON the 12th of March, the *Hougli*, one of the largest of the packet-boats belonging to the Messageries Impériales, of 2,000 tons burden and 500-horse power, entered the quarantine port of Frioul direct from the China seas, having traversed the Suez Canal without encountering the slightest obstacle. The cargo consisted of 1,300 bales of silk, 300 chests of tea, and other valuable freight, and there were in addition seventy passengers.

WE learn from Mr. Worthington G. Smith, in reference to a recent report of the proceedings of the Woolhope Naturalists' Field Club, that he has in preparation a *Clavis Agaricinorum*, which will be an analytical key to the genera and sub-genera of the British *Agaricini;* designed to give an immediate clue to their proper generic and sub-generic position, and thus assist in their ultimate determination.

MR. BENTLEY announces for early publication, "Travels in the Air," by Mr. Glaisher and others, with numerous full-paged coloured lithographs and woodcuts.

A NEW work is preparing for publication by Arthur Scott Donkin, M.D., Lecturer on Forensic Medicine to the University of Durham, &c., being a history of the British Diatomaceæ, with plates illustrative of each species.

THE *New York Technologist*, a new magazine especially devoted to engineering, manufacturing, and building, published in New York, describes a new contrivance for preventing people looking into a room, while light is not excluded. It consists of a number of glass rods arranged either vertically or horizontally, and secured together by appropriate frames, forming a series of cylindrical lenses which break up the light and throw it into every part of the room, thus producing a soft and diffused glow which is very beautiful and pleasant. The glass rods may be of any colour, and by an arrangement of the colours very beautiful effects can be produced. The contrivance is the invention of Mr. Demuth.

THE Pharmaceutical Society offers a silver medal for the best Herbarium collected in any part of the United Kingdom between the 1st of May, 1870, and the 1st of June, 1871, to any associate, registered apprentice, or student of the society, not over thirty-one years of age.

THE *Photographic Art Journal*, No. 2, is a very good number. It contains four excellent illustrations: "The Stirrup Cup," from a painting by Verschur, exquisitely soft in tone, done by the Woodbury process; "Netley Abbey," by Mr. Edwards's new process of printing in printing-ink in a common printing press, which seems to give exceedingly good results; "The Muleteer's Love," an example of Mr. Fruwirth's phototype process, also pulled in a common printing press, from an electrotyped surface-block which was reduced from a woodcut by the sole action of light and chemical agents; and "A Village Street in Switzerland," apparently an ordinary silver-print. The comparison of these photographs certainly gives the palm to the new processes, both as to distinctness and softness of tone.

ON THE MADREPORARIA DREDGED UP IN THE EXPEDITION OF H.M.S. "PORCUPINE."

IN continuation of Dr. Carpenter's Report of the *Porcupine* Dredging Expedition, we now present our readers with an abstract of a paper by Prof. Duncan on the Corals dredged up during the voyage.

Professor Wyville Thomson, Dr. Carpenter, and Mr. Gwyn Jeffreys have placed the collection of stony corals dredged up by them in the *Porcupine* Expedition in my hands for determination. They have kindly afforded me all the information I required concerning the localities, depth, and temperature in which the specimens were found. My report has been rendered rather more elaborate than I had intended in consequence of the great consideration of Professor A. Agassiz and Count de Pourtales in forwarding me their reports* and specimens relating to the deep-sea dredging off Florida and the Havana. They have enabled me to offer a comparison between the British and American species, which I did not hope to have done before the publication of the species noticed, but not described, in this report.

I. List of the species, localities, depths, temperatures.
II. Critical notice of the species.
III. Special and general conclusions.

I. Twelve species of *Madreporaria* were dredged up, and the majority came from midway between Cape Wrath and the Faroe Islands. Others were found off the west coast of Ireland. Many varieties of the species were also obtained, and some forms which hitherto have been considered specifically distinct from others, but which now cease to be so.†

II. Three species were found, known only on the area dredged, or in the neighbouring seas. Three species common to the area and to the Florida and Havana deep-sea faunas only. (These forms are not known in the West Indian Cainozoic fauna, and they have not been discovered in any European deposits.) *Lophohelia prolifera* (var. *affinis*) is common to the British and Florida deep-sea faunas; but it is found fossil in the Sicilian tertiaries, being moreover a member of the Mediterranean recent fauna. Three species common to the area and to the Mediterranean Sea. Five species found on the area dredged, and as fossil elsewhere.

The deep-sea coral fauna of the area dredged in the *Porcupine* and *Lightning* expeditions is therefore composed of—

5 species which have lasted since the early Cainozoic period.
1 Mediterranean species not known in Cainozoic deposits.
3 species of the deep-sea fauna of Florida and Havana.
3 indigenous species.

Two of the fossil species are represented in the recent Mediterranean fauna. If the species which I have absorbed into others (in consequence of the light thrown upon the amount of variation in the deep-sea corals) were counted, the fossil forms would be in all eight. The greatest depth from which *Madreporaria* were dredged was 705 fathoms, and the lowest temperature of the water in which they lived was 29°·9.

Caryophyllia borealis, Fleming.—Having collected a very considerable series of the *Caryophylliæ* from the seas around Great Britain, and having been supplied with several specimens of the Mediterranean species, I had compared the whole with the fossil forms from the Sicilian tertiary deposits and with each other. The numerous specimens of *Caryophylliæ* dredged up in Dingle Bay were especially interesting after I had arrived at satisfactory conclusions respecting the affinities of the above-mentioned British and southern European forms. The Dingle Bay collection presented all the varieties of shape, some of which had been deemed of specific value, which I had observed in the separate assemblages of specimens from the Mediterranean, the Sicilian tertiaries, and the British and Scottish seas. A perfect series of specimens from all these localities can be so arranged as to show a gradual structural transition from form to form, so that the most diversely shaped *Caryophylliæ* can be linked together by intermediate shapes. The *Caryophyllia clavus* and *Caryophyllia cyathus* can be united by intermediate forms, and all of these to *Caryophyllia Smithi* and *Caryophyllia borealis*. It is impossible to determine which is the oldest form, but they all appear to be reproduced by variation on some part of the area tenanted by the section of the genus. The variability of the *Caryophylliæ* of the Sicilian tertiary deposits is very marked, and it is equally so in the groups which live on disconnected spots in our waters. The Dingle Bay series presents the greatest amount of variability, and indeed is most instructive, for by applying the range of it to the classification of such genera as *Trochocyathus* and *Montlivaltia* a great absorption of species must ensue. The Dingle Bay *Caryophylliæ* are evidently the descendants of those which lived in the western and southern European seas before those great terrestrial elevations took place which were connected with the corresponding subsidence of the circumpolar land and the subsequent emigration of Arctic Mollusca. They are not closely allied to the recent West Indian species, but they occupy a position in the coral fauna representative of them. The same remark holds good with reference to the affinities of the recent and the cretaceous *Caryophylliæ*. They are not closely allied, and they belong to different sections of the genus, but in the economy of the old and new distribution of animal life they hold the same positions, and the recent forms are representative of the older. The Dingle *Caryophylliæ* prove the purely arbitrary nature of species, and that what we term one is really the sum of the variation of a series of forms.

Ceratocyathus ornatus, Seguenza.—A beautiful specimen of this rare form was dredged up from a depth of 705 fathoms with some *Caryophyllia* and a small *Isis*. The species is hitherto unknown except in the Sicilian miocene.*

Flabellum Sarsii, Sars, sp.—This is the *Ulocyathus arcticus* of the late Prof. Sars. Many specimens were dredged up, but most of them were broken in consequence of the extreme fragility and delicacy of the theca. The species links *Flabellum* to *Dermophyllum*: it is not known in the recent Mediterranean fauna.

Lophohelia prolifera, Pallas, sp., is apparently a common coral in the north-western British seas. A separate corallum, which must be referred to *Lophohelia anthophyllites*, Ellis and Solander, was dredged up in No. 54. *Lophohelia prolifera* exists in the Mediterranean Sea and the sea between Scotland and Norway. *Lophohelia anthophyllites* is an East Indian form, but its absorption into *Lophohelia prolifera* suggests explanations, considering the Cainozoic progenitor, and how it migrated eastwards. The relation of the recent East Indian coral faunas to those of the European and West Indian Cainozoic deposits has been noticed and admitted for some years past. The Cainozoic *Lophohelia* of Sicily is the earliest form of the genus, and those which are found in such remote parts of the world as the East Indies, the Florida coast, the Norwegian coast and the Mediterranean, and which have been determined to belong to different species, are, from the study of the curious assemblage of variable forms now under consideration, evidently varieties of the old type, *Lophohelia prolifera*. I have therefore absorbed the old species *L. anthophyllites*, *L. subcostata*, *L. affinis*, *L. Defrancei*, and *L. gracilis*. Two genera of the *Oculinidæ* in the classification of MM. Milne-Edwards and Jules Haime have always been most difficult to distinguish; and now the results of the dredging off the north of Scotland and off Florida and the Havana necessitate the absorption of one of them.

Amphihelia and Diplohelia.—The first, containing recent species only at the time of the enunciation of the classification just referred to, and the last, having fossil species only, were very likely to be considered separate genera. *Diplohelia* had species in the Eocene seas and in the Cainozoic also. *Amphihelia* was known to have species in the Mediterranean fauna, and in that of Australia also. Seguenza, however, described some *Amphiheliæ* and *Diploheliæ* from the Sicilian tertiary deposits which were identical, so far as generic attributes are considered, the only distinction being a doubtful raggedness of the septal edges. The habit and the method or growth and gemmation of the forms were the same. M. de Pourtales dredged up a branching form from off the Harena in 350 fathoms, and from off Bahia Houde, near Florida, in 324 fathoms, and also in lat. 28° 24′ N., long. 79° 13′ W., in 1,050 fathoms (came up with the lead). This he named *Diplohelia profunda*. On referring† to Seguenza's plates and descriptions of the fossil corals from the Sicilian tertiary deposits, there is no difficulty in deciding upon the very close affinity of the species described by Pourtales and *Diplohelia Meneghiniana*, Seg., and *Diplohelia Doderleiniana*, Seg., fossil forms from the mud-tertiary deposits. But on comparing these

* Contributions to the Fauna of the Gulf Stream at great depths by L. F. de Pourtales, 1st and 2nd Series, 1868. Bull. Mus. Comp. Zool., Harvard College, Cambridge, Mass., Nos. 6 and 7.

† One specimen came from the *Lightning* Expedition. It must be remembered that all the deep-sea corals known to British naturalists were not dredged up. The *Stylaster rosea*, for instance, was not amongst the collection.

* Seguenza, "Disquisiz. Paleont. int. ai Corall. Foss.," Mem. della Reale Accad. dell. Sci. Torino, serie ii. tomo xxi. 1864.

† Seguenza, "Disquiz. Paleont. int. ai Corall. Foss.," Mem. della Reale Accad. dell. Sci. Torino, serie ii. tomo xxi. 1864.

forms with one exquisitely figured by Seguenza, and which he calls *Amphihelia miocenica*, Seg., the generic affinities of all become startlingly evident. The very numerous specimens of small branching *Oculinidæ*, which were dredged up in the *Porcupine* Expedition (No. 54) and to the north-west of the spot in the cold area, at a depth from 363 to 600 fathoms, present singular variations of structure in the buds and calices upon the same stems. A careful examination of them, assisted by a comparison between them and the well-known recent and fossil *Amphiheliæ*, the fossil and recent *Diploheliæ*, and the smaller specimens of *Lophoheliæ*, leads to the belief that *Amphihelia* is identical generically with *Diplohelia*, and very closely allied with *Lophohelia*. Indeed, the distinction between the *Lophoheliæ* and *Amphiheliæ* is of the slightest kind. The species of the genus *Amphihelia* dredged up in the *Porcupine* Expedition are numerous:—

1. Amphihelia (Diplohelia) profunda, *Pourtales*, sp.
2. —— oculata, *Linneus*, sp.
3. —— miocenica, *Seguenza*.
4. —— Atlantica, *nobis*.
5. —— ornata, *nobis*.

The distinction between these massive and densely hard corals (whose calices are principally on one side of the cœnenchyma of the stem) and the *Stylasters* is very evident. M. de Pourtales has described a pretty red-coloured *Allopora miniata* dredged in 100 to 324 fathoms off the Florida Reef; but it is very distinct from the species discovered in the late deep-sea dredging expeditions. *Allopora* has no fossil representatives.

Balanophyllia (*Thecopsammia*) *socialis*, Pourtales.—Six specimens of a simple perforate coral were dredged up in lat. 59° 56′ N., long. 6° 27′ W., 363 fathoms, temperature 31°·8 (No. 54), and one in lat. 61° 10′ N., long. 2° 21′ W., 345 fathoms, temperature 29°·9 (No. 65). The six specimens are of different sizes and ages; and although they present considerable variation in shape and septal development, they evidently belong to one type. The solitary coral form (No. 65) is larger than the others, but it belongs to the same species. Notwithstanding the temperature in which the corals were found, and the depth of the sea, they are strong and well-developed forms, evidencing an active and abundant nutrition. There is no difficulty in classifying the specimens with the *Thecopsammiæ* of Pourtales. *Thecopsammia socialis*, Pourtales, was dredged up in from 100 to 300 fathoms, off Sombrero, near Florida, in the course of the Gulf Stream.

The varieties and the original type are very isolated forms in the great genus *Balanophyllia*. They have only a very remote affinity with the West Indian recent *Balanophylliæ*, with those of the Crag, the Faluns, and the Eastern tertiaries. The British forms appear to have emigrated from the south-west, and probably the original type wandered, through the agency of the Gulf Stream, which carried ova and deposited them in our northern sea, where they have propagated, varied, and thriven.

Pliobothrus symmetricus, Pourtales.—A specimen of this doubtful coral, which had been described by M. de Pourtales, from the results of dredging in from 100 to 200 fathoms, was sent to me by Dr. Carpenter. It came from the cold area, in from 500 to 600 fathoms. There is no doubt that this very polyzoic-looking mass belongs to the American type. The tabulæ are hardly worthy to be called such, and I place the form amongst the Zoantharia provisionally.

III. The species of *Madreporaria* belong to genera which do not and have not contributed to coral-reef faunas. None of them are reef-builders; but all are essentially formed to live where rapid growth and delicately cellular structures are not required. The forms are strong, solid, and large; and their rapid and repeated gemmation proves that their nutritive processes were active and continuous. All the species are very much disposed to produce variations; and this is especially true as regards those which have outlived the long age of the crag, the glacial period, and the subsequent time of elevations and subsidences. The least variable species are those which are not known on other areas. Two of the three species which are common to the West Indian deep-sea fauna and that of our north-western coasts are also variable. The persistence of *Madreporaria*, from the earlier Cainozoic period to the present time, has been an established fact for several years. Some of the forms which are common to the deep sea of the British area and to the so-called miocene of Sicily, are still existing in the Mediterranean. None of the species of corals found in the British crag are represented in the deep-sea fauna. The existence of Mediterranean forms in the north-west British area is in keeping with the discoveries of Forbes. It has, however, a double significance, and bears upon the presence of West Indian forms on the north-west British marine area. There was a community of species between the Mediterranean and the West Indies in the Cainozoic period, and especially of Echinodermata, Mollusca, Madreporaria, and Foraminifera. After the great alterations of the mutual relations of land and sea which took place before the cold affected the fauna of the Franco-Italian seas, this community of species diminished; but it lasted through all the period of northern glacialisation, and is proved still to exist slightly by comparing the Algæ, the corals, the Echinodermata, and the Mollusca. The presence of two very characteristic Floridan species, and one less so, off the north of Scotland, is particularly interesting, because they all live in the cold area and flourish there; whilst they appear to be less vigorous in the warmer Gulf Stream near Florida. It is impossible to fail to recognise the operation of this stream in producing the emigration of these three species, which are essentially American. It must be remembered, however, that the Cainozoic *Balanophylliæ* were very numerous in the European area, but not in the American. The solidity and the power of gemmation of the corals within the cold area appear to be greater than elsewhere. Depth does not appear to have much effect upon the nutrition of the *Madreporaria*; for those dredged up at 600 fathoms are quite as hard and solid as those dredged up at 300 fathoms. All the calices were stuffed with small Foraminifera, and there was evidently a great abundance of food.

There were numerous polyzoa, sponges, Foraminifera, Diatomaceæ, and delicate bivalves associated with or fixed upon the corals at all depths. Moreover, at from 300 to 400 fathoms a perforating mollusc had worked its way up the stems of some of the hardest specimens of *Amphihelia* and *Lophohelia*. One had left its excavation, which had been taken possession of by a small Brittle Star, and at a depth of 705 fathoms there was a pretty Isis. *Serpulæ*, moreover, abound upon the corals. This is a fauna which, if covered up and presented to the palæontologist, would be, and would have been for some years past, considered a deep-sea one. It is a fauna which indicates the existence of the same processes of nutrition and of destructive assimilation and reproduction which are recognised in association with corresponding forms at less depths and in higher temperatures. The great lesson which it reads is, that vital processes can go on in certain animals at prodigious depths and in considerable cold, quite as well as in less depths and in considerable heat. It suggests that a great number of the Invertebrata are not much affected by temperature, and that the supply of food is the most important matter in their economy.

The researches of the naturalist who obtained Polyzoa and Foraminifera in soundings at a depth of nearly 400 fathoms off the icy barrier of the South Pacific, of Wallich in the Atlantic, and of Alphonse Milne-Edwards in the Mediterranean, have had much influence upon geological thought in this age, which, so far as geologists are concerned, is remarkably averse to theory. For many years before any very deep soundings had been taken with a view of searching the sea-bottom for life, geologists had more or less definite opinions concerning the deposition of organisms in sediments at great depths. Certainly, more than thirty years ago, deep-sea deposits were separated by geologists from those which they considered to have been formed in shallower seas. The finely-divided sediment of strata containing Crinoids, Brachiopods, Foraminifera, and simple Madreporaria, was supposed to have been deposited in deeper water than formations containing large pebbles, stones, and the mollusca, whose representatives now live in shallows. The relations of such strata to each other, the first being found to overlap the last, proved that there was a deeper sea-fauna in the offing of the old shores tenanted by littoral and shallow-water species. The deposition of strata containing Foraminifera, Madreporaria, and Echinodermata, whose limestone is remarkably free from any foreign substances, has been considered to have taken place in very deep water; this theory has been founded upon the observations of the naturalist and mineralogist. Indeed, no geologist has hesitated in assigning a great depth to the origin of some deposits in the Laurentian, Silurian, or in any other formation. The "flysch," a great sediment of the Eocene formation, has been considered to have been formed at a great depth and under great pressure. Its singular unfossiliferous character was supposed to be due to the absence of life at the depths of the ocean where the sediment collected. But this was a theory of the early days of geology, when the destructive influence of chemical processes in strata upon the remains of organisms in them was hardly admitted.

The great value of such researches as those so ably carried out by Thomson, Carpenter, and Jeffreys, is the definite knowledge they impart to the geologist who is theorising in the right direction, but whose notions of the depths at which the sediments containing Invertebrata can be deposited, are indefinite. The researches contribute to more exact knowledge, and they will materially assist the development of those hypotheses which are current amongst advanced geologists into fixed theories. I do not think that any geological theory worthy of the term, and which has originated from geological induction, will be upset by these careful investigations into the bathymetrical distribution of life and temperature. Physicists have propounded theories which have been accepted by some geologists; but they are looked upon as doubtful hypotheses by others. Palæontologists and such theories have constantly been at issue. The theories involving pressure and the intensity of the hardness of deep-sea deposits will suffer from the researches; but many difficulties in the way of the palæontologist will be removed. The researches explain the occurrence of a magnificent deep-coral fauna in the Palæozoic times in high latitudes, and of Jurassic and Cainozoic faunas on the same area, and they tend more than ever to the doctrines of uniformity. They explain the cosmopolitan nature of many organisms, past and present, which were credited with a deep-sea habitat, and they afford the foundations for a theory upon the world-wide distribution of many forms during every geological formation. It is not advisable, however, to make too much of the interesting identities and resemblances of some of the deep-sea and abyssal forms with those of such periods as the Cretaceous, for instance. In the early days of geological science there was a favourite theory that at the expiration of a period the whole of the life of the globe was destroyed, and that at the commencement of the succeeding, a new creation took place. There were as many destructions and creations as periods, or, to use the words of an American geologist, there was a succession of platforms. This theory held back the science, just as the theory that the sun revolved round the earth retarded the progress of astronomy. Moreover, it had that armour of sanctity to protect it which is so hard to pierce by the most reasonable opposition. Nevertheless every now and then a geologist recognised the same fossils in rocks which belonged to different periods. A magnificent essay by Edward Forbes on the Cretaceous Fossils of Southern India, a wonderful production and far before its age,* gave hope and confidence to the few palæontologists who began to assert that periods were perfectly artificial notions; that it did not follow because one set of deposits was forming in one part of the world, others exactly corresponding to it elsewhere, so far as the organic remains are concerned, were contemporaneous; and that life had progressed on the globe continuously and without a break from the dawn of it to the present time. The persistence of some species through great vertical ranges of strata, and the relation between the world-wide distribution of forms and this persistence, were noticed by d'Archiac, de Verneuil, Forbes, and others. The identity of some species in the remote natural-history provinces of the existing state of things, was established in spite of the dogmatic opposition of authorities; and these geologists accepted the theories that there were several natural-history provinces during every artificial period; that some species lived longer and wandered more than others; and that some have lasted even from the Palæozoic age to the present. Persistence of type was the title of a lecture delivered by Professor Huxley† many years ago; and this persistence has been admitted by every palæontologist who has had the opportunity of examining large series of fossils from every formation from all parts of the world.

Geological ages are characterised by a number of organisms which are not found in others, and by the grouping of numerous species which are allied to those of preceding and succeeding times, but which are not identical. Certain portions of the world's surface were tenanted by particular groups of forms during every geological age, and there was a similarity of arrangement in this grouping under the same external physical conditions. To use Huxley's term, the "homotaxis" of certain natural history provinces during the successive geological ages has been very exact. The species differed, but there was a philosophy in the consecutive arrangements of high-land and low-land faunas and floras, and of those of shallow seas, deep seas, oceans, and reef-areas. The oceanic* conditions, for instance, can be traced by organic remains from the Laurentian to the present time, and the deep-sea corals now under consideration are representative of those of older deep seas. The species which are new, and the varieties of those which have been already noticed, will be described and drawn in other communications. It is not a matter for surprise, then, that there being such a thing as persistence of type and of species, some very old forms should have lived on through the ages whilst their surroundings were changed over and over again. But this persistence does not indicate that there have not been sufficient physical and biological changes during its lasting to alter the face of all things enough to give geologists the right of asserting the constant succession of periods. The occurrence of early Cainozoic Madreporaria in the deep sea to the north-west of Great Britain only proves that certain forms of life have persisted during the vast changes in the physical geography of the world which were initiated by the upheaval of the Alps, the Himalayas, and large masses of the Andes. To say that we are therefore still in the Cainozoic age would hardly be consistent with the necessary terminology of geological science.

During the end of the Miocene age, and the whole of the Pliocene, the Sicilian area was occupied by a deep sea. The distinction between the faunas of those times and the present becomes less, year after year, as science progresses; and it is evident that a great number of existing species of nearly every class flourished before the occurrence of the great changes in physical geology which have become the artificial breaks of classificatory geologists. That the Cainozoic deep-sea corals should resemble, and in some instances should be identical in species with, the forms now inhabiting vast depths, is therefore quite according to the philosophy of modern geology. Before the deposition of the Cainozoic strata, and whilst the deep-sea deposits of the Eocene age were collecting in the Franco-British area, there was a Madreporarian fauna there which was singularly like unto that which followed it, both as regards the shape of the forms and their genera. Still earlier, during the slow subsidence of the great Upper Cretaceous deep-sea area, there was a coral fauna in the north and west of Europe, of which the existing is very representative. The simple forms predominate in both faunas. *Caryophyllia* is a dominant genus in either, and a branching *Synhelia* of the old fauna is replaced in the present state of things by a branching *Lophohelia*. The similarity of deep-sea coral faunas might be carried still further back in the world's history; but it must be enough for my purpose to assert the representative character and the homotaxis of the Upper Cretaceous, the Tertiary, and the existing deep-sea coral faunas. This character is enhanced by the persistence of types; but still the representative faunas are separable by vast intervals of time.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 31.—"On the relation between sun's altitude and the chemical intensity of total daylight in a cloudless sky." By Henry E. Roscoe, F.R.S., and T. E. Thorpe, Ph.D. In this communication the authors give the results of a series of determinations of the chemical intensity of total daylight made in the autumn of 1867 on the flat tableland on the southern side of the Tagus, about $8\frac{1}{2}$ miles to the south-east of Lisbon, under a cloudless sky, with the object of ascertaining the relation existing between the solar altitude and the chemical intensity. The method of measurement adopted was that described in a previous communication to the Society,† founded upon the exact estimation of the tint which standard sensitive paper assumes when exposed for a given time to the action of daylight. The experiments were made as follows:—1. The chemical action of total daylight was observed in the ordinary manner. 2. The chemical action of the diffused daylight was then observed by throwing on to the exposed paper the shadow of a small blackened brass ball, placed at such a distance that its apparent diameter, seen from the position of the paper, was slightly larger than that of the sun's disk. 3. Observation No. 1 was repeated. 4. Observation No. 2 was repeated.

† Roscoe, Bakerian Lecture, 1865.

The means of observations 1 and 3 and of 2 and 4 were then taken. The sun's altitude was determined by a sextant and artificial horizon, immediately before and immediately after the observations of chemical intensity, the altitude at the time of observation being ascertained by interpolation.

It was first shown that an accidental variation in the position of the brass ball within limits of distance from the paper, varying from 140 millimetres to 230 millimetres, was without any appreciable effect on the results. One of the 134 sets of observations was made as nearly as possible every hour, and they thus naturally fall into seven groups, viz. :—

(1) Six hours from noon, (2) five hours from noon, (3) four hours from noon, (4) three hours from noon, (5) two hours from noon, (6) one hour from noon, (7) noon.

Each of the first six of these groups contain two separate sets of observations, (1) those made before noon, (2) those made after noon. It has already been pointed out,* from experiments made at Kew, that the mean chemical intensity of total daylight for hours equidistant from noon is constant. The results of the present series of experiments proves that this conclusion holds good generally, and a Table is given showing the close approximation of the numbers obtained at hours equidistant from noon.

Curves are given showing the daily march of chemical intensity at Lisbon in August, compared with that at Kew for the preceding August, and at Parà for the preceding April. The value of the mean chemical intensity at Kew is represented by the number 94·5, that at Lisbon by 110, and that at Parà by 313·3, light of the intensity 1·0 acting for 24 hours being taken as 1,000.

The following Table gives the results of the observations arranged according to the sun's altitude :—

No. of Observations.	Mean Altitude. ° ′	Chemical Intensity. Sun.	Sky.	Total.
15 . .	9 51	0·000	0·038	0·038
18 . .	19 41	0·023	0·063	0·085
22 . .	31 14	0·052	0·100	0·152
22 . .	42 13	0·100	0·115	0·215
19 . .	53 09	0·136	0·126	0·262
24 . .	61 08	0·195	0·132	0·327
11 . .	64 14	0·221	0·138	0·359

Curves are given showing the relation between the direct sunlight (column 3) and diffuse daylight (column 4) in terms of the altitude. The curve of direct sunlight cuts the base line at 10°, showing that the conclusion formerly arrived at by one of the authors is correct, and that at altitudes below 10° the direct sunlight is robbed of almost all its chemically active rays. The relation between the total chemical intensity and the solar altitude is shown to be represented graphically by a straight line for altitudes above 10°, the position of the experimentally determined points lying closely on to the straight line.

A similar relation has already† been shown to exist (by a far less complete series of experiments than the present) for Kew, Heidelberg, and Parà; so that although the chemical intensity for the same altitude at different places and at different times of the year varies according to the varying transparency of the atmosphere, yet the relation at the same place between altitude and intensity is always represented by a straight line. This variation in the direction of the straight line is due to the opalescence of the atmosphere; and the authors show that, for equal altitudes, the higher intensity is always found where the mean temperature of the air is greater, as in summer, when observations at the same place at different seasons are compared, or as the equator is approached when the actions at different places are examined. The differences in the observed actions for equal altitudes, which may amount to more than 100 per cent. at different places, and to nearly as much at the same place at different times of the year, serve as exact measurements of the transparency of the atmosphere.

The authors conclude by calling attention to the close agreement between the curve of daily intensity obtained by the above-mentioned method at Lisbon, and that calculated for Naples by a totally different method.

"On the acids contained in crab oil." By William J. Wonfor, Student in the Laboratory of the Government School of Science, Dublin. Communicated by Dr. Maxwell Simpson.

* Phil. Trans. 1867, p. 558.
† Phil. Trans. 1867, p. 555.

Crab-oil is obtained from the nuts of a tree named by botanists *Hylocarpus carapa* and also *Carapa Guianensis.* The tree grows abundantly in the forests of British Guiana; the oil is prepared by the Indians, who bring it to George Town for sale. The oil is obtained from the kernels by boiling them for some time, and then placing them in heaps and leaving them for some days; they are then skinned, and afterwards triturated in wooden mortars until reduced to a paste, which is spread on inclined boards and exposed to the sun; the oil is thus melted out, and trickles into receiving vessels.

As no investigation, so far as I have been able to ascertain, has ever been made of the acids contained in this oil, Professor Galloway, to whom I am indebted for the samples of the oil, recommended me to examine them, and the examination was conducted under his direction. The acid, when pure, presents the appearance of a white glistening radiated crystalline mass. The percentage composition obtained was as follows :—

Carbon	74·856
Hydrogen	12·570
Oxygen	12·574
	100·000

These analyses agree very closely with the formula for palmitic acid, $C_{16}H_{32}O_4$.

Royal Geographical Society, March 28.—The president, Sir R. Murchison, in the chair. A paper was read by Sir Charles Nicholson, Bart., on Forrest's Journey in Western Australia; Goyder's survey of the neighbourhood of Port Darwin, and on the recent progress of discovery in Western Australia, and remarks on Papua or New Guinea. Intense interest had been felt in the fate of Leichhardt and his party, who were last heard of in 1849 S.W. of the Gulf Carpentaria; a report was brought to the government of Swan River, of the existence of the remains of two white men and horses in the unexplored region N.E. of the colony. An expedition was fitted out, under Mr. Forrest, with whom Mr. Monger and Mr. M. Hamersley were associated, and the native Jimmy Mungaro acted as guide. The place indicated was Koolanobbing, lat. 30° 53′ S., and long. 109° 14′ E. The expedition was exceedingly well managed, and the country was thoroughly examined. They left Newcastle April 19, 1869; passed through a sandy country without grass; water was scarce; salt lakes nearly dried up were met with; from the limit of Gregory's exploration, 118 long., they travelled north; found granite hills, with spearwood and acacias; in May 5 they reached Lake Moore, and learned that the remains were those of horses which had been poisoned, having strayed from an out station; some unfriendly natives, who threatened to kill and eat the white men, were met with; several large dry salt lakes were discovered, one of which, named Lake Barlee, was conjectured to be 80 miles in length, the farthest point, 28° lat. 41′ S., and 122° 50′ E. long., was reached July 2nd. The country throughout of the same barren worthless character, granite hills, no grass, and scanty supplies of water. The return journey was made to north of Lake Barlee, westward to Bunnaroo, and southward to Mount Singleton on July 23rd; the result was that no traces of Leichhardt were found, and the country explored was pronounced unfit for either pasture or agriculture. In the sea board districts and about Mount Singleton there was excellent land, all Western Australia wanted was population. Sir Charles Nicholson then proceeded to notice the recent survey of Port Darwin, in North Australia, which region, between 128° and 138° E. long., and north of 26° S. lat., had been most unreasonably annexed to South Australia. The South Australian attempt to open communication through the interior, and found a colony at Port Essington, had failed, and the colony had been abandoned. Port Darwin lies to west of Adelaide River, on northern coast, opposite Melville Island; it possesses a good harbour, a million acres of good land have been surveyed, fit for horses and cattle, not for sheep, climate from May to September is good, then moist and hot; intercourse by sea between the Malays of Macassar and this port exists. Port Darwin has been recommended as a port for shipping horses for the Indian market, the central region is impracticable, but the route followed by M'Kinlay from Northern Queensland is, in the opinion of Mr. Goyder, Colonial surveyor, the best; this, Sir Charles Nicholson thought showed that North Australia ought to form part of Queensland. Sir Charles gave a rapid *résumé* of the progress of discovery in Australia from Captain Cook's voyage, and the foundation of Port Jackson in 1788; the labours and journeys of Dr. Bass, Sturt, Mitchell, Eyre, &c., were glanced at. Dr. Leichhardt was absent two years on his first expedition to Port Essington, and was given up for lost, a monument, with an epitaph composed by a friend, having been erected to him. In conclusion a hope was expressed that geographical discovery would be still prosecuted, especially with reference to the magnificent but almost unknown Papua or New Guinea, the position, fauna, and flora of which constitute it a natural appendage to Australia, a line of small islands connecting it with our settlement at Cape York. Captain Blackwood in H.M.S. *Fly*, in 1845, examined 140 miles of coast, lat. S. 8° 45', long. E. 143° 35', to 7° 40' lat. 144° 30' long., containing the delta of a large river. In the south-eastern peninsula, mountains 11,000 ft. to 13,000 ft. high, were observed by Captain Stanley, these were in sight for several days coasting, with richly wooded slopes. The Government survey vessel at Cape York might be used for exploration of this country. The natives were hostile, and had the reputation of being fierce and warlike. The president said that he had urged on the Government the impolicy of uniting North and South Australia, and the necessity of forming a port of refuge, and a naval station at Port Darwin. He alluded to Mr. Crawford's estimate of the Papuan climate as most unhealthy. General Lefroy reminded the meeting of the omitted name of his brother, a successful explorer of Western Australia. The question of the suitability of Port Darwin as a depôt for the horses to be sent to India was discussed. The project had been favourably reported on to Lord Mayo by Sir James Ferguson, the North-eastern or Flinders river route being preferred. With regard to the climate, Mr. Findlay mentioned the excellence of the Timor ponies. Mr. Saunders pointed out that the navigation would be much safer if a port were selected in the Gulf of Carpentaria.

Chemical Society, March 30.—Anniversary meeting, Prof. Williamson, F.R.S., President, in the chair. The following officers have been elected for the ensuing year:—President, Dr. A. W. Williamson; Vice-presidents who have filled the office of president, Sir B. C. Brodie, Warren De la Rue, A. W. Hofmann, Dr. W. A. Miller, Dr. Lyon Playfair, Col. P. Yorke; Vice-presidents, Dr. J. H. Gilbert, Dr. E. Frankland, Dr. A. Matthiessen, Dr. H. M. Noad, Prof. W. Odling, Dr. T. Redwood; Secretaries, A. Vernon Harcourt, W. H. Perkin; Foreign Secretary, Dr. H. Müller; Treasurer, F. A. Abel; ordinary members of the Council, Dr. E. Atkinson, H. Bassett, E. T. Chapman, F. Field, David Forbes, Dr. M. Holzmann, Dr. E. J. Mills, Dr. W. J. Russell, Dr. Maxwell Simpson, Dr. R. Angus Smith, Dr. John Tyndall, Dr. A. Voelcker. After communication of the above list the president delivered the following address:—"Gentlemen,—On behalf of the council I feel very great pleasure in congratulating you on the rapidly increasing usefulness and prosperity of our Society. The most interesting incident in the history of the past year has been the delivery by M. Dumas of the inaugural Faraday lecture. It was indeed an impressive tribute to the memory of our great countryman which was paid by that noble veteran of science, and one of which the record ought to occupy a place of honour in our journal. We still hope to receive from M. Dumas a manuscript of his classical discourse. The council have had the pleasure of accepting the offer of a munificent donation of Palladium from Messrs. Johnstone and Matthey to be used for the preparation of the ten first Faraday medals. Your council have felt it to be of considerable importance to give greater publicity to the proceedings of the society, and they have accordingly made provisional arrangements for the preparation of abstracts of the papers, and in some cases of the discussions, for transmission to such papers as desire to publish them. These abstracts already appear in several papers and are read with interest. Another matter of considerable importance has been brought under the notice of your council, and has been by them referred to the careful consideration of a sub-committee who will report to the new council. The great activity of chemists in France and Germany leads to the publication of vast quantities of important matter in languages not easily intelligible to many of our members, and a feeling has been entertained for some time past that the progress of our science and of its applications would be greatly promoted by the regular publication in the English language of accurate reports of all chemical papers. For many years past annual reports of this kind have been published in Germany, first under the auspices of the great Berzelius, and latterly under those of Liebig and Kopp. The French Chemical Society has also added very greatly to the value of their journal by publishing in it reports of a great number of important papers from various sources, and I am happy to say that the eminent chemists who are at the head of that society concur with us in desiring to publish reports combining the completeness of the "Jahresberichte" with a much greater celerity of appearance, so that our respective members may have presented to them every month an outline of all that has been done in the science since the last report. It appears that considerable facilities would be afforded for the preparation of such reports by a joint action of the two societies, and our friends in Paris have expressed the utmost readiness to co-operate with us in this important matter. I hope at our next anniversary meeting to be able to congratulate the society on the commencement of a system of international working."

The president proceeded by giving the present number of fellows, of the foreign members, the list of the deceased, and concluded with a commemorative speech on Thomas Graham. The greater part of this speech is to be found in the biographical sketch in the first number of NATURE. The following additional remarks, however, are worthy to be quoted here. "In 1837 Graham was appointed to the chair of chemistry in the newly-founded London University, now called University College, London. It was here that the young philosopher found adequate scope for his abilities. Young men, thirsting for knowledge, crowded to his lectures, and in those lectures he explained the principles of chemical science with an exactness and clearness never before attained. The success of these lectures was not due to eloquence, nor to any smoothness of diction, for all such matters Graham usually neglected to a degree which in an ordinary person would hardly have been excused. He had a truly philosophical method which carried away the listener with irresistible force. The same exactness of thought, the same logical arrangement of matter, in a word, the same purely scientific mind pervades his work, the 'Elements of Chemistry,' a work which is too well-known to chemists all over the world, for it to be necessary to speak here of its great merits." After having sketched the outlines of the most important of Graham's investigations, the president alluded in the following manner to Graham's activity as Master of the Mint:—"He remained at University College till the year 1855, when he was appointed Master of the Mint, an office which Sir John Herschel had recently resigned. His illustrious friend Hofmann, from whom I have already freely quoted, shall tell how he discharged these responsible duties. 'It would be difficult to picture the extensive activity which Graham exercised in the high office entrusted to him. The new master of the mint showed a circumspection, a mastery of details, an amount of industry and energy, and, when occasion required, an impartial severity, which astonished every one, more especially some of the officials of the mint. Such requirements had not hitherto been made, nor such control exercised. A strong resistance was made to the plans of innovation and alteration of the new master.' The author of these lines, Hofmann, at that time held an office in connection with the Mint, and was therefore witness of Graham's struggles in his new position. It was years before he gained a complete victory, and before he was able to return to his favourite study. But at last this longed-for period came, and a series of happy years followed. Not an instant was lost. A convenient laboratory was fitted up in the official residence of the Master of the Mint, whose handsome rooms the simple and independent man never occupied, and there his old labours were resumed with greater zeal than ever. Some of Graham's most beautiful researches date from this period. They sprang from the pure love of science. Graham needed to earn no name or position. Both had long been his undisputed property. But the same earnest desire to study nature, which in early youth had induced him to bear without murmurs the greatest privations and the bitterest sorrows, still animated him and armed him against the new dangers which threatened his scientific labours from the splendour of his official position and the distractions which it entailed on him." The proceedings of the meeting terminated with a vote of thanks to the president for the able and effective manner in which he had discharged his official duties during the past year.

Geological Society, March 23.—Warington W. Smyth, F.R.S., Vice-President, in the chair. Mr. F. A. Potter, B.Sc., Assoc. Royal School of Mines, Cromford, Derbyshire, was elected a Fellow of the Society. The following communications were read:—Professor Huxley communicated a letter received by him from Dr. Emanuel Bunzel, of Vienna, giving a short account, illustrated with figures, of the posterior portion of a skull obtained by Professor Suess from a coalmine of Upper Cretaceous (Gosau) age. Dr. Bunzel stated that at the first glance this skull appeared to possess Reptilian characters, but that the convexity of the occiput, and its gentle passage into the roof of the skull, the presence of a transverse ridge in the occipital region, the absence of sutures, the globular form of the condyle, and some other peculiarities, prevent the animal to which this skull belonged from being referred to any known order of reptiles. The author compared this fragment of a skull with that of a bird, and suggested the establishment of a new order of fossil Reptiles (*Ornithocephala*), closely related to Prof. Huxley's *Ornithoscelida.* He proposed to refer his fossil to a new genus, which he named *Struthiosaurus.*

"On the discovery of organic remains in the Caribean Series of Trinidad." By Mr. R. J. Lechmere Guppy, F.L.S., F.G.S. The author described the rocks of the "Caribean group" as consisting of gneiss, gneissose, talcose, and micaceous slates and crystalline and compact limestones, and remarked upon the probable distribution of rocks of the same series on the continent of South America. In Trinidad the uppermost member of the series is a compact dark blue limestone, which contains obscure, but very abundant fossils; in the subjacent clay-slates and quartz rocks calcareous strings and bands containing more distinct traces of organisms occur. The author believed that he had detected an *Eozoon* (which he called *E. caribeum*), a *Favosites* (named *F. fenestralis*), a coral, and fragments of echinoderms. He considered it probable that the Caribean series was pre-silurian. Dr. Carpenter, from the slight examination he had been able to make of the fossils, was unwilling to speak decidedly about them. There was, however, no doubt of numerous organic remains occurring in the rocks, and among them serpuline shells and echinoderms. As to the supposed *Eozoon*, he had not been able to recognise any of the characteristics of that fossil; and by treating the Trinidad specimens with acid, he found no traces of structure left, and yet there had not been sufficient metamorphism to destroy other organisms. In some dredgings from the Ægean Sea he had found fragments of echinoderms and other organisms, in which a siliceous deposit had replaced the original sarcode in the same manner as had occurred in the Canadian *Eozoon*, thus proving the possibility of this form of substitution, which had been warmly contested. Mr. Tate offered some suggestions as to the age of these beds, which were certainly older than Neocomian. The Californian gold-bearing beds appear to be Jurassic. Similar beds occurred in New Mexico, Guatemala, and were observed by him in Nicaragua and Costa Rica. These present lithological and mineralogical affinities to the Venezuelan and Trinitation metamorphic series, and were conjectured to be of the same age.

"On the Palæontology of the Junction-beds of the Lower and Middle Lias in Gloucestershire." By Mr. R. Tate, A.L.S., F.G.S. The object of this paper was to show that the attachment of the zone of *Ammonites raricostatus* to the lower lias and that of *A. Jamesoni* to the middle lias harmonises with the distribution of the organic remains: 50 species were catalogued from the united zones of *A. oxynotus* and *A. raricostatus*, 8 of which pass up into the middle lias, whilst 13 occur in the lower horizons; 115 species were enumerated as occurring in the zone of *Ammonites Jamesoni*, 60 of which pass to higher zones, whilst 11 made their first appearance in the lower lias; the number of species common to the contiguous zones being 14. The author inferred that, as the conditions of depth and deposit of the upper part of the lower lias are repeated in the lower part of the middle lias, accompanied by a total change in the fauna, a break in the stratigraphical succession existed between the lower and middle lias. This view is supported by the fact of the numerical decrease of species in passing up through the several stages of the lower lias, and that of the introduction of many new generic types with the zone of *Ammonites Jamesoni.* Many new species were described. Prof. Boyd Dawkins had attempted to test these liassic zones as a means of classification of the rocks in Somersetshire, and the result had been that he had been unable to accept them as fixing hard and fast lines of demarcation; for he had found three of the distinctive Ammonites together in one bed. On our present shores the change of one form of molluscan life for another seemed to take place in limited areas, and to be dependent on some slight variation of physical conditions rather than on any great change. He had not been able to trace any stratigraphical unconformity between the middle and lower lias in many parts of England, whatever might be the case in Gloucestershire. Mr. Tate, in reply, gave an account of the manner in which he had arrived at his conclusions, and expressed his assent to the view that ammonite-zones were only of value over limited areas, but considered that a triple division in the lower and a dual division in the middle lias were well established on palæontological and lithological features. The break which he had pointed out was palæontological rather than stratigraphical, though the one might be inferred from the other.

"Geological Observations on the Waipara River, New Zealand." By Mr. T. H. Cockburn Hood, F.R.S. In this paper the author described the general features of the locality from which he has obtained bones of *Plesiosaurus*, *Ichthyosaurus*, and *Teleosaurus.* The bones were not obtained *in situ*, but from large boulders and blocks scattered in the ravines of the Waipara and its tributaries. Professor Boyd Dawkins remarked on the presence of Crocodilia in New Zealand being proved by the procelian vertebra.

Mr. R. H. Scott, F.G.S., communicated an extract from a letter addressed to him by M. Coumbary, Director of the Imperial Observatory of Constantinople, containing an account received from M. L. Carabello of the reported fall of a large meteorite near Mourzouk, in the district of Fezzan, in lat. 26° N., and long. 12° E. of Paris. It fell on the evening of the 25th December last, in the form of a great globe of fire, measuring nearly a metre in diameter; on touching the earth it threw off strong sparks with a noise like the report of a pistol, and exhaled a peculiar odour. It fell near a group of Arabs, who were so much frightened by it that they "immediately discharged their guns at this incomprehensible monster."

PARIS

Academy of Sciences, April 4.—The following mathematical papers were read:—Description, with plans, of an instrument, by which spherical triangles may be solved without the aid of tables of logarithms, by M. Blanqui; On the fundamental points of two surfaces, of which the points correspond one by one, by M. H. G. Zeuthen; on the theory of equations with partial derivatives, by M. G. Darboux (second memoir); and On a mode of approximation of the functions of several variables, by M. Didon.—M. de Saint-Venant presented a memoir on a second approximation in the rational calculation of the pressure exerted against a wall of which the posterior surface has a certain inclination, by incoherent soil rising in a talus from the top of this surface of the wall; and M. Boussinesq an integration of the differential equation which may furnish a second approximation in the calculation of the same pressure.—M. Jamin communicated a note on the latent heat of ice, and presented a note by MM. Wecker and Robin on an objective with prisms, to be used in an ophthalmoscope which will enable two persons to observe the eye at the same time.—M. Phillips presented a memoir by M. Martin de Brettes on an apparatus for the demonstration of the phenenomena of the trajectory of oblong projectiles driven by rifled guns.—M. Delaunay communicated an extract from a letter from M. G. Oltramare on the existence of a law of repartition, analogous to Bode's law, for each of the systems of satellites of Jupiter, Saturn, and Uranus; and a note by M. R. Wolf on the frequency of the sun's spots, and its relation to the variation of magnetic declination. The author gave a table of his observations of solar spots during the years 1864–1869, showing a minimum in 1867, in conformity with his period of $11\frac{1}{9}$ years. He also applied his formula for the calculation of the magnetic variation in relation to the solar spots, to the results of observation at the Observatory of Christiania, and cited the data of several years to show at all events a close approximation.—A paper was read by M. Chapelas on the centres of mean position of shooting stars, which is the name he gives to the points from which the groups of meteors seem to issue.—M. C. Viollette presented a paper on the existence of selenium in commercial copper. The author stated that by oxydising copper in a muffle-furnace and then heating the oxide to redness for several hours in a current of dry pure air, crystals of selenious acid are obtained. The copper operated upon by lime was probably from Chili; he proposes to examine other coppers, and requests manufacturers to forward to him, at the Faculty of Sciences of Lille, specimens of copper of known origin. M. Viollette also presented a note on the cause of the acidity of the water of organic analyses, which he ascribes to the presence of selenious acid in the oxide of copper employed in the combustion tubes.—M. E. Royer read a paper on the reduction of carbonic acid into formic acid. The author, having found that formic acid is produced by the reduction tof oxalic acid in the porous vessel of a Bunsen's battery in presence of hydrogen, has subjected carbonic acid to the same treatment, and found that this also furnishes formic acid.—M. Mauméné forwarded a further note on his general theory of chemical action; and M. Dubrunfaut a paper on the law of dilatation of gases.—M. Guyon communicated some remarks on a paper by M. Ramon de la Sagra, describing an anomalously branched structure in the stem of a palm-tree (*Oredaxa regia*). M. Guyon stated that a similar anomaly is very common in the date palm.—In a note presented by M. de Quatrefages, on the inversion of the viscera and its artificial production, by M. C. Dareste, the author stated that he had produced this condition in young chicks, by maintaining a temperature at the heating point of 105·8°—107·6° F., whilst the surrounding temperature was allowed to oscillate from 21° to 28°.—M. Bouley communicated an important report on the results of the inquiry instituted by the Ministry of Agriculture into the occurrence of hydrophobia in France during the years 1863-1868. From his statements, which unfortunately rest on rather imperfect documents, it appears that a large number of persons bitten by dogs supposed to be rabid, escape all serious consequences of the bites; that the summer is not more dangerous than any other season; and that immediate cauterisation of the bite appears to be the only sure remedy.—M. H. Sainte-Claire Deville presented a note by M. Piarron de Montdésir on ventilation by means of compressed air, accompanied by a purification and cooling of the new air, and a disinfection of the vitiated air. The author proposed to employ strong jets of compressed air, which would carry with them a considerable body of uncompressed air; the cooling and purification of this air from dust is to be effected by means of a small jet of water in the midst of each air-jet; and the purification of the vitiated air by substituting a disinfecting liquid for the water in the jets of compressed air in action at the bottom of the ventilating flues. With regard to M. Wœstyn's recent proposal to purify the vitiated air of hospitals, &c., by burning it, which is rejected on the score of expense by the author, M. Montanier remarked that in 1864 he had suggested a similar plan.—MM. Mille and Durand Claye presented a memoir giving the results of the experiments made for the utilisation of the sewage waters flowing into the Seine, which they propose to divert entirely from their direct influx into the river, and to apply as manure to the neighbouring country.

VIENNA

Imperial Academy of Sciences, February 17.—The president noticed the decease of Dr. Franz Unger, the well-known botanist and vegetable palæontologist, on the 13th Feb.—The following papers were read:—1. On the observation of oscillations by Prof. E. Mach of Prague. He stated that a very simple and effective form of vibroscope is obtained by placing a row of König's burners along one side of an organ pipe, and described some of the effects observable by means of this instrument.—2. On the intestinal movements, by Dr. S. Mayer, containing the results of a series of experiments, relating especially to the innervation of the intestines, which had been made by him in conjunction with Dr. S. von Basch.—3. Dr. Boué completed his address on the petrographic and geognostic results of his travels in European Turkey.—The reports of observations at the Central Institution for meteorology and terrestrial magnetism during the month of January, were communicated.

March 10.—The president announced the death of Professor Joseph Redtenbacher on the 5th March. The following papers were read:—1. On the renal pelvis of the mammalia and of man, by Professor Hyrtl, in which the author described in detail the structure of the urine-secreting organs in a great number of mammals.—2. Phanological studies, by M. Karl Fritsch, containing the results of observations made in Austria and Hungary on the blooming and maturity of plants, and on the first and last appearances of periodically occurring animals.—3. On the after-pictures of excitant changes, by M. V. Dvorák, showing that the after-pictures of movements observed by Plateau and Oppel are not isolated phenomena, but that similar effects are produced by changes of brightness.—4. On the rational triangle by M. H. Rath.—5. On the simple construction of obliquely turned hyperboloids and paraboloids by Professor R. Niemtschik.—6. On a cosmical attraction exerted by the sun through its rays, by M. C. Puschl, in which the author sought to prove that by means of the æther-waves issuing from it the sun exerts an attraction upon opaque bodies, equivalent to the repulsion which it must have produced, according to the hypothesis of emanation, by the material particles emitted by it.—7. On the atomic heat of oxygen in its solid compounds, by M. J. Tollinger.—8. On the action of *Digitalis* and *Tinct. Veratri viridis* upon the temperature in crupose pneumonia, by Dr. L. von Schrötten.—9. Prof. V. von Lang delivered an address upon a new method of investigating the diffusion of gases through porous septa. His apparatus consists of a porous cell united by a thin caoutchouc tube with the air-tube of a Mariotte's bottle, so arranged that the gas in the cell is always under the atmospheric pressure, and as soon as an increase of volume takes place in it the excess flows over into the bottle, displacing an equivalent amount of water, which is determined by weighing.—10. The second part of investigations on ammonites by Prof. Suess, in which the author treated chiefly of the structure of the shell in the Cephalopodous mollusca. He showed that the shell which exists in the females of the existing genus *Argonauta*, is to be regarded as a rudimentary ammonite shell, consisting of an ostracum or outer layer without a nacreous layer, and that *Argonauta* belongs to a great group, commencing with *Trachiceras* and including *Cosmoceras*, *Toxoceras*, *Crioceras*, many *Scaphites*, and the *Flexuosi*.

DIARY

THURSDAY, April 14.

Mathematical Society, at 8.—On the Mechanical Description of a Nodal Bicircular Quartic: Prof. Cayley.

MONDAY, April 18.

Royal Asiatic Society, at 3.

TUESDAY, April 19.

Anthropological Society, at 8.—On the Hypothesis of Pangenesis applied to the Faculty of Memory: Mr. Alfred Saunders.—Note on Consanguineous marriages: Mr. G. C. Thompson.

WEDNESDAY, April 20.

THURSDAY, APRIL 21, 1870.

ON ORIGINAL EXPERIMENTAL RESEARCH IN RELATION TO EMPLOYMENT FOR WORKMEN.

IT is an important national question, "By what means can employment for workmen in this country be increased?" My reply is, "By encouragement of experimental scientific research."

I have observed that increased employment of workmen constantly results from original experimental research in science in the following order: Experimental researches in science lead to scientific discoveries; scientific discoveries lead to practical inventions; and practical inventions lead to increase of employment. Usually, a scientific investigator first discovers some new fact or principle in science; next, an inventor applies this discovery, in the form of an invention, to some useful purpose; and then a manufacturer or man of business brings it into general use, and employs workmen or servants to assist him. In some cases, however, the discovery of a new truth in science, its application by invention, and its practical carrying out, are all effected by the same individual.

The following examples will illustrate the foregoing observation:—The discoveries of voltaic electricity, electro-magnetism, and magneto-electricity, by Volta, Oersted, and Faraday, led to the invention of electric telegraphy by Wheatstone and others, and to the great manufactures of telegraph cables and telegraph wire, and of the materials required for them. The value of the cargo of the *Great Eastern* alone in the present Bombay telegraph expedition is calculated at three millions of pounds sterling. It also led to the employment of thousands of operators to transmit the telegraphic messages, and to a great increase of our commerce in nearly all its branches by the more rapid means of communication. The discovery of voltaic electricity further led to the invention of electro-plating, and to the employment of a large number of persons in that business. The numerous experimental researches on specific heat, latent heat, the tension of vapours, the properties of water, the mechanical effect of heat, &c., resulted in the development of steam-engines and railways, and the almost endless employments depending upon their construction and use. About a quarter of a million of persons are employed on railways alone in Great Britain. The various original investigations on the chemical effects of light led to the invention of photography, and have given employment to thousands of persons who practise that process, or manufacture and prepare the various materials and articles required in it. The discovery of chlorine by Scheele led to the invention of the modern processes of bleaching, and to various improvements in the dyeing of textile fabrics, and has given employment to a very large number of our Lancashire operatives. The discovery of chlorine has also contributed to the employment of thousands of printers, by enabling Esparto grass to be bleached and formed into paper for the use of our daily press. The numerous experimental investigations in relation to coal-gas have largely been the means of extending the use of that substance and of increasing the employment of workmen and others connected with its manufacture. The discovery of the alkali metals by Davy, of cyanide of potassium, of nickel, phosphorus, the common acids, and a multitude of other substances, have led to the employment of a whole army of workmen in the conversion of those substances into articles of utility.

The foregoing examples might be greatly enlarged upon, and a great many others might be selected from the sciences of physics and chemistry, but those mentioned will suffice. There is not a force of nature, nor scarcely a material substance that we employ, which has not been the subject of several, and in some cases of numerous original experimental researches, many of which have resulted, in a greater or less degree, in increasing the employment for workmen and others.

The variety and extent of the employments which have resulted from scientific research are so great that they ramify in some form or other through nearly all our manufacturing, artistic, and commercial occupations, our social relations, and our every-day life; and those employments have become of such common occurrence that we are apt scarcely to think how much experimental research has had to do with their production, and we are thus led to undervalue original experimental investigation as a means of producing employment. Persons in general can easily understand that an acorn planted in the ground will, in the course of time, become an oak, because it is a palpable and visible effect; but they cannot so readily perceive that the abstract scientific fact discovered by experiment to-day will probably soon become an invention of practical daily use, not because it is less real, but simply because it is a phenomenon less evident to the senses, and requires a greater exercise of intellect to perceive it.

In many instances the application of original experimental science in new inventions has superseded, and in a limited sense diminished, manual labour, but it has in such cases either substituted more intellectual occupation for it, or has opened up new sources of employment to a far greater extent by increasing trade and manufacture. For example, the number of waggoners and horses now employed to collect and deliver all the goods for railways is much greater than the whole of those employed for conveying the goods of the country before railways were constructed.

The capability of developing increased employment by the means proposed is immense, and practically unlimited, because scientific discovery is quite in its infancy, and we are at present only on the very threshold of a knowledge of the forces of nature and of the constitution of material substances; in this sense, therefore, experimental scientific research may be viewed as *the* great fountain-head of employment for workmen.

The reason why original experimental science is the great fountain-head of industry in manufactures and trades trades is, that it is only by means of such research that we can become accurately acquainted with the forces and substances involved in manufactures, and be enabled to use them to the greatest advantage. The intimate connection between science and industry is shown by the fact that when new scientific discoveries are published there are numerous inventors who immediately endeavour to apply them to useful purposes, and men of business ready to carry out the inventions practically.

The great and important results already obtained by the cultivation of original experimental research show that it is a national necessity, and naturally suggests the idea, can we not by a greater degree of encouragement of such research still further increase employment for working men, and still further elevate their intellectual condition?

At the present time there is in this country no recognised payment for the labours of scientific discovery, and no provision for the support of men who investigate science; any person is at liberty to take the published results of scientific men from the Transactions of the Royal Society, the Chemical Society, and other learned bodies, and employ them as the basis of inventions and patents, without the slightest payment, notwithstanding these results have been obtained at an immense cost of study, time, and labour, and a large amount of money. I do not mean by these remarks to conclude that scientific discoveries should not, on publication, become at once public property, but that some means of support should be provided for the men who make them, and thus the development of employment for workmen be increased.

Experimental scientific research, in the stricter sense of the words, is a comparatively modern thing, and though it has existed in a more limited degree during many centuries, it can only freely exist and thrive in civilised countries. Even at the present time, in consequence of the peculiar nature of the occupation, its hopelessness as a source of emolument to the investigator, the great skill and extreme self-denial required, and frequently danger incurred in its pursuit, and the consequent great difficulty of achieving success in it, *scarcely one person in one million of the population of England is exclusively devoted to it*, although a much greater proportion occupy a small amount of their time in its advancement.

The extension of physical and chemical knowledge by means of experiments and observations is *national* work: it benefits the nation, but does not pay the investigator. The various scientific men who discovered the chief facts and principles of science upon which steam-engines, electric telegraphs, and all the modern applications of science are based, received no remuneration for their researches. The results of purely scientific investigations are generally unsaleable, because, instead of benefiting a single manufacturer only, they benefit the whole nation; the nation, therefore, being the gainer, should pay and provide for those who make such researches. And when we consider that in this country upwards of 576 millions of pounds have been expended in the construction of railways alone, and immense sums upon electric telegraphs, which would never have been expended but for such labours, and nearly all of which have given employment to numberless workmen, it is evident that the magnitude and national character of the results would fully justify national encouragement of original experimental research.

The more abstract an experimental investigation is, the more important and widely diffused are its practical results. Who would have thought, when Oersted in his original abstract research in electro-magnetism first made a magnetized needle move by the influence of an electric current, that his labours would lead to the expenditure of many millions of pounds in the laying of telegraphs all over the earth, and the employment of many thousands of persons in their construction, maintenance, and use? And who can tell how many similar important discoveries have been lost to the nation, and how much of the present deficiency of employment for workmen has arisen, in consequence of experimental scientific investigators not having been paid for their labours?

At present, original experimental researches are generally made by teachers of science who expend a portion of their incomes in making experiments and observations; but the very limited means of such men is a serious loss to the nation by greatly retarding the progress of discovery, and consequently also of improvements in manufactures. Many of the experiments, also, necessary for the development of new discoveries are beyond the means of such persons at present, and cannot be made without the command of greater wealth.

If England is to keep pace with the progress of foreign intellect and of foreign manufacture, and keep her workmen fully employed, there must not only be a general diffusion of scientific knowledge throughout this country, but there must also be national encouragement of original scientific investigation.

Has it been wise in our Governments thus to overlook a great source of the nation's wealth, to disregard a most important means of national economy, to neglect the great fountain-head of industry? Shall we allow foreigners to supplant us in manufactures, and shall our fellow-men continue to be driven to emigration by want of employment? or shall we develope for them new sources of labour by means of original experimental research? It needs only to bring the subject fairly and effectually before the attention of our present enlightened and progressive Government, to ensure its careful and early consideration.

The neglect of original experimental science in this country by our Governments has long been noticed by scientific men and others, and a suggestion has been made to the British Association by Lieut.-Colonel Strange, to found "National Colleges of Original Research," in which science should be investigated, but not taught. This would be *one* way of supplying the want; the funds for supporting such colleges might with propriety be obtained from the fees paid for patents, because patents are in many cases based upon the published results of original experimental researches; other ways of supplying the want might also be indicated.

GEORGE GORE.

OUR DOMESTIC FIRE-PLACES

Our Domestic Fire-places. By Frederick Edwards, jun. A new edition, &c. (London: Longmans, Green, and Co. 1870.)

THIS book, although bearing considerable traces of having for its object the advocacy of a particular manufactured article—nevertheless shows the author to have so much mastery over his subject as to justify its publication; and if the work be considered merely as the contribution of a highly qualified producer, the duty of the reviewer would be almost entirely to commend it; but if it is proposed as a complete and unbiassed treatise on the domestic fire-place he finds a good deal of reason to dissent.

After a somewhat diffuse essay on the hearth of the ancients—in which, by the way, the theory is too easily adopted that the Romans were entirely ignorant of the chimney—we come to the methods of our ancestors. Why the cosy folding screen must henceforth be given up, and why, in speaking of the introduction of the smoke-jack, the past services of the turnspit dog are entirely ignored, may be asked in passing.

Page 17 introduces some interesting particulars of the first use of coal, and page 30 a well-merited eulogium on the labours of Count Rumford in the improvement of fire-grates, and we now approach the pith of the whole matter, namely—how to burn our coal so as to get the maximum of heat with the minimum of smoke and soot. (pp. 44 *et. seq.*) Here the author, having one excellent contrivance to recommend (namely, Dr. Arnott's smoke-consuming grate), has allowed himself to be unfair to other inventors whose grates for certain purposes are preferable. Of this class perhaps the most conspicuous example is the manner in which Taylor's stove, manufactured by the Coalbrookdale Co., is treated in the work before us. It is indeed mentioned (page 51) as an ingenious contrivance but full of deficiencies in practice, and as one which "now appears to have become forgotten." As respects its deficiencies, several instances are well known to us in which this grate of Mr. Taylor's has given the greatest satisfaction. No unsightly contrivances—no troublesome machinery—a bright fire—the whole apartment pervaded by the fresh warm air brought from an external source to the back of the stove, and emitted from the radiating tiles—the chimney-sweeper's visits for years dispensed with—such are some of its characteristics; and as to its "having become forgotten," assurance has been received from good authority that the demand for these grates is well kept up.

There are also several stoves which in a work like the present should have been noticed, *e.g.* Wright's, Woodcock's, Rosser's, and especially Galton's.

At page 54 the author discusses the recommendations of the committee appointed by the Board of Health, and gives some valuable comments upon them, and then proceeds to consider the question of the *Stove of the Future*, in its materials and management. Nothing has been more clearly established than the superiority of fire-brick over iron for the "fire-pot," or actual inclosure of the fuel. But the benefit of this discovery has, as yet, only reached the upper and middle classes of society, "but," says the author, p. 66, "in small houses and in the apartments occupied by skilled and unskilled workmen, the use of fire-brick is unknown, so that those who most require to use economical grates are those who are most ill provided. The working classes have either the most trumpery contrivances that Thames-street can furnish, and which are put into the fire-place at the smallest possible expense for labour and materials; or they use, in streets which have become gradually deserted by the classes which once lived in them, the badly arranged fire-places of thirty or fifty years ago."

We hope that these valuable observations will not be lost. Such fire-places as Pierce's Cottage Grate, described p. 39, are scarcely more expensive than the cheap and trumpery contrivances referred to, and if the proper arrangement of the chimney throat could also be secured in all newly constructed houses for the working-classes, the effect would be soon apparent both in favour of their health and of their pockets.

This improvement of the chimney throat is described by the author p. 73, and consists in contracting the flue to its ordinary capacity at once at the top of the fire-place opening, instead of the more common practice of gathering it in by degrees.

In p. 85, the plan of having a single main chimney-shaft for all fire-places which are situated in the same part of the house is advocated. It is not evident, from the text, whether the author is aware that this plan has been carried out, in several instances, in different parts of the country. It is a subject, certainly, which deserves more attention than it has yet received.

In the last chapter (p. 90), the general warming of halls, corridors, &c., is considered. It may be mentioned in connection with the Russian and Swedish method referred to, that the Germans, who have hitherto adopted generally the same plan, are beginning to place the fire-front of the stove in the apartment that is to be warmed by it, instead of in the corridor, with the stove surface only in the apartment, and, as may be supposed, with a manifest improvement in the ventilation.

This chapter is well worth attention: exception must, however, be taken to the way in which Gurney's stove is mentioned, p. 108. "The prestige attaching to the name of its producer," may, indeed, have not been without its use in obtaining for these stoves their first trial, but would hardly have been sufficient, apart from their intrinsic good qualities, to have obtained for them the wide reception both at home and abroad which they have had; or to have created the almost invariable satisfaction with which their use has been attended.

The book is a useful contribution to the literature of the subject, and well illustrated by engravings. F.C.P.

OUR BOOK SHELF

The Mammalia of Massachusetts. By J. A. Allen. (Trubner & Co.)

FROM this carefully drawn-up report we learn that there are sixty-five mammals at present indigenous to this American State. The common ones, with a few exceptions—as the mink (*Putorius lutreolus*), weazel (*P. erminеus*), and skunk (*Mefitis mephitica*), among the carnivores; *Vespertilio subulatus* and *Lasiurus noveboracensis* among the bats—belong to the families of the rodents, the squirrels, mice, and hares, and to the *Balænidæ* and *Delphinidæ*, which latter are of course marine. The panther, moose, reindeer, elk, and beaver have comparatively recently become extinct. A notice is appended to the work by Prof. Agassiz, earnestly requesting friends to forward to him males, females, and young of almost any of the European mammals. Books on mammalia would be equally valued, and in exchange he offers on the part of the museum at Cambridge, U.S., representatives of the North American fauna and American books.

Effects of Climate and Soil upon Plants.—*Die Abhängigkeit der Pflanzengestalt von Klima und Boden.* Von A. Kerner. Pp. 48. (Innsbruck, 1869. London: Williams and Norgate.)

THIS pamphlet is of greater importance than would be indicated by its mere size, as a contribution towards an investigation of the causes which lead to the diversities of floras, and hence towards a knowledge of the laws on which depends the great problem of the origin of species. M. Kerner has made a special study of the flora of the

Tyrolese Alps, and has even attempted to introduce into a small plot of ground in the mountains surrounding Innsbruck, a number of plants indigenous to the lowlands of the Tyrol. In this enterprise, however, he met with no very encouraging success; "the greater number of the plants which I brought to those heights with inexpressible toil, succumbed to the uncongenial Alpine climate; and in the remaining small portion, I have noticed at present only very unimportant changes." His conclusion from these experiments is "that changed conditions of life can kill the species, or they can reduce it to a starved existence, but can in no case produce a *direct* change into a new permanent species adapted to its altered conditions." Such change can only take place by the slow process of natural selection among slightly varying offspring from the parent species. The writer notices a number of interesting features that characterise the Alpine flora with which he is familiar, as contrasted with those found under other climatal conditions. One of these is the very small number of annual plants, which bear to perennials the proportion of 4 to 96, as contrasted with that of 42 to 58 in the Mediterranean district, and of 56 to 44 in that of south-eastern Europe; a result of the very short period of summer warmth, varying from $1\frac{1}{2}$ to $3\frac{1}{2}$ months, which does not allow time for the seeds to ripen. The same cause produces also the appearance in many Alpine species of the flower-buds at the close of the summer, ready to burst into blossom during the first days of returning warmth in the spring. The remarkably large proportion of Alpine plants with evergreen rosettes of fleshy or succulent leaves, *Primulas*, *Gentianas*, *Androsaces*, *Saxifragas*, *Drabas*, &c., he attributes to the advantages of some contrivance for obviating the effects of the intense heat of the sun during the long days in their short summers, and also to the necessity that the plant should possess leaves at the very commencement of the warm season, in order to afford it a store of nourishment, and thus economise the whole of the brief period of vegetation. With this peculiarity he contrasts the poverty of the Alpine flora in plants possessing stores of *underground* nourishment in the form of bulbs, a class so abundant and prominent in the south of Europe. The necessity for great caution in deriving general conclusions from a small array of facts, is shown by the mention by M. Kerner, among the plants well adapted by their constitution to withstand the great alternations of an Alpine climate, of *Dryas octopetala*, a species which flourishes equally well in the remarkably uniform climate of the west coasts of Ireland and Scotland. The want of any considerable number of large shrubs and forest trees is obviously due to the rigours of the climate; and the almost entire absence of climbing and creeping plants indicates that protection from the sun is not one of the first conditions of existence, as it is in tropical forests. The large proportion of plants with flowers of intense hues, and the deficiency of spiny and stinging species, are not so easy to account for, though the author attributes the latter to the comparative absence of destructive animals; and the former may possibly have some connection with the advantage derived from the speedy attraction of insects, after the flowers expand, to assist in their fertilisation. We can conceive no greater service to biological science than a series of observations on the floras of limited areas, both with respect to what they possess and to what they are deficient in, carried out with the care of those recorded in the work before us.

A. W. B.

The fourth volume of the *Atti della R. Accademia delle Scienze di Torino*, contains several important papers on various departments of science. We may notice especially Prof. Salvadori's memoir on some birds from Costa Rica, and the same author's monograph of the genus *Ceyx;* a memoir by M. F. Giordano, on the orography and geological constitution of the Gran Cervino; and mineralogical papers by Prof. Strüver and Dr. Cossa.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Evidence concerning Heterogeny

THE question of the truth or falsity of "heterogeny," as it is called, is perpetually recurring both in your columns * and elsewhere, in connection with several of the most important scientific controversies of the day. It is a subject which has engaged my attention for several years, and I am anxious to be permitted to lay before your readers as concisely as possible a statement of what appears to me to be its present position.

I think the impression which most recent references to it are likely to leave on the minds of readers is this—viz., that while amongst the most advanced thinkers there is a gradually strengthening conviction that the weight of theoretical considerations is in favour of the actual existence of heterogeny as a real mode of origin of living beings, yet that the authority of M. Pasteur's famous researches inclines the balance of experimental evidence heavily the other way.

I am perfectly willing to admit the principle of authority in matters scientific as far as any reasonable person can admit it—that is to say, I believe it is natural and right that when a scientific man of so deservedly high reputation as M. Pasteur publishes a long series of carefully conducted researches, and announces the conclusions to which they lead him, and when no evident flaw can be shown in his processes, either of experimentation or of reasoning, his conclusions should be accepted as against those of another comparatively unknown experimenter. But in the present case neither of these conditions is fulfilled. In the first place, instead of merely an unknown experimenter we have in this case a consensus of at least eight experimenters—some of them by no means unknown—who have given their best attention to the same investigation in different parts of the world and under widely differing conditions, and who agree in disputing M. Pasteur's results.†

In the next place, there is a step in M. Pasteur's experimentation which has been pointed out as a flaw, and of which it is in the power of any one of your readers to judge for himself by a process of simple inspection as to whether it really be a flaw or not. I refer to the subject of the microscopic power used by M. Pasteur in his investigation. The organisms which I found during my own experiments on this subject appeared often but little larger than a full point in the type used in your columns, even when seen with a power of 1700 diameters. In the woodcuts attached to my paper in the Proceedings of the Royal Society (April, 1865), they may be seen as they were kindly drawn for me by my friend Dr. Beale, who, though an uncompromising opponent of the doctrine of heterogeny in all its forms, is a very high authority in microscopy; there can therefore be no question as to their size, nor as to their actual presence in the experimental vessels. Now under the power used by M. Pasteur (350 diam.) these organisms would be about $\frac{1}{25}$ part of the size which they appear in the drawings. Yet it is upon the authority of observations made with such a power that M. Pasteur has pronounced, not upon the *presence* of these objects, but upon their *absence.* It is now nearly five years since my observations were made public. Since that time several critics have noted them as requiring an answer, but, so far as I am aware, no answer has been made to them; and meanwhile naturalists have gone on complacently quoting M. Pasteur's experiments as having settled the question against heterogeny, even though they have not failed to acknowledge the weight of the theoretical considerations which tell in its favour.

The theoretical aspect of the question I have fully discussed elsewhere,‡ and I will only here state my entire agreement with the belief expressed by Dr. Charlton Bastian in your issue of February 24, viz. "that the time is not far distant when the doctrine of the evolution of living things will be as much an

Prismatic Ice—Sandstone Boulder in Granite.

THE "two phenomena" observed on Dartmoor by Mr. C. Spence Bate and Mr. W. Morrison, and described by the former in NATURE of the 31st ult., have been previously noticed.

The late Rev. Dr. Scoresby, F.R.S., published a paper "On Columnar Crystallisation of Ground Ice," in the *Edinburgh New Philosophical Journal* for January 1850 (vol. xlviii.), and illustrated it with a plate containing eighteen figures. A presentation copy of this paper is now before me.

The so-called *sandstone boulders* in granite are by no means rare. They occur in various parts of Devon and Cornwall. I first noticed them at Shaptor, near Bovey Tracey, in Devonshire, and have subsequently seen them in several other localities, but nowhere in such abundance as at Sennen Cove, near the Land's End, in Cornwall. There are several good specimens in my private collection. The following description of them occurs in a paper on "The Age of the Dartmoor Granites," which I read to the British Association at Manchester, and to the Royal Geological Society of Cornwall in 1861, as well as to the Devonshire Association in 1862. "Nodules, apparently segregative, sometimes occurring in the substance of the ordinary granite, might, from the fineness of their grain, be almost mistaken for sandstone; indeed, I not long since heard them appealed to as proofs of the metamorphic origin of granite. 'Here,' said the appellant, 'are unaltered remnants of the old sandstone rocks, which, with these exceptions, metamorphism has converted into granite. I do not quote this for the purpose of endorsing it, but simply to show the general dissimilarity of the nodules to granite proper. Excepting their darker colour, they reminded me much of the granite veins which pass through the older granite of Goatfell, in the Isle of Arran; nevertheless, they are not veins but nodules, and capable of being extracted as such from the granitic mass containing them. . . . They consist of very fine grains of quartz and schorl in about equal quantities, or with the latter somewhat preponderating."*

Irrespective of the origin of the nodules, it is no doubt "clear that when this granite was formed, the temperature of (the surface of) the earth must have cooled down to below the boiling point of water," for the granite, as has long been established, is of post-carboniferous age; or, in other words, was formed after the rich faunas and floras of the Silurian, Devonian, and Carboniferous periods had successively passed away, to say nothing of the pre-Silurian organic eras.

The Transits of Venus in 1874 and 1882

IN the paper on this subject by P. L. S., there occurs a remark which is calculated to convey a mistaken impression. He states that "an Antarctic station is only required for the transit of 1882, and there is ample time to make a preparatory Antarctic expedition to ascertain" whether a suitable station can be found. The reverse is the case. No Antarctic expedition can be of any service in 1882, so that in a preparatory expedition the lives of our seamen and men of science would be uselessly risked. On the contrary, there are several Antarctic stations suitable for observing the transit of 1874; and I have shown that the comparison of observations made at such stations with observations made in Siberia would give the most effective means of determining the sun's distance available before the 21st century.

I may remark here, that the choice of stations for observing the transits of 1874 has been founded on calculations admittedly inexact, and it would be to the credit of English astronomy that the whole matter should be re-examined while there is yet time for a change to be made. In saying this, I am not by any means insisting upon the views put forward in my own papers on the subject; though the only error pointed out by the Astronomer Royal in my charts and calculations consists in the fact that they aim at an unnecessary exactness. But the utilisation of the coming transits is a matter too important to be endangered for any personal considerations whatever. If errors have been made it behoves men of science to see that those errors shall not be suffered to prejudice the cause of scientific progress.

RICHARD A. PROCTOR

Euclid as a Text-book

I REGRET that Mr. Wormell has imported so much of a personal nature into his reply to my former letter. Personality and unintentional misrepresentation appear to me to be its predominating features. Unintentional, I say, for I know little of the writer beyond the fact of his being the author of two or more admirable text-books, and that he is a distinguished member of the London University.

Though I feel that the columns of NATURE ought hardly to be taken up with such matter, yet, in self-defence, I am compelled to say a few words. As I have neither time nor inclination for controversy, I hope that the discussion, if continued, will be entirely *ad rem*, and not diverge into personalities. Owing all my geometrical ability (*quod sentio quam sit exiguum*) to a twenty-three years' acquaintance with Euclid, and having had, as a teacher, to use that author for the last fourteen years, it would not be strange if I *were* a favourer of the old system, which I *am not* to the extent Mr. Wormell seems to think.

My plan of teaching geometry under the old system was to overcome Euclid's deficiencies by *viva voce* explanation, and, offering slight assistance, to get my classes to work a number of geometrical exercises. With my sixth class I have generally got well through three or four hundred such exercises as are given in Todhunter's edition of the Elements.

This is not the same as sending out boys who have merely "committed Euclid to memory," and certainly my pupils have found no great difficulty in the matriculation papers. Pupils thus prepared have taken first, second, third, and other high places in the examination, which places, I think, were in a measure due to their "flooring" the geometrical papers—with the exception, perhaps, of a "rider;" also, during the time I have held my present post, my pupils have carried off the Andrews Entrance Exhibition at University College each year, with one exception, when the finest geometer I have had was beaten. This is not the place for chronicling successes in other examinations.

I did not state that it was advisable for students to read Euclid only; what I did say was to the effect that I had heard of boys who were doing this with the idea that such a course would "pay" best. Mr. Wormell charges me with using an "infelicitous and ungenerous expression." That I willingly retract, as it has struck myself as being uncalled for; but Mr. Wormell must have read my purposely concise letter hastily, for I nowhere say that I desire a change in the syllabus; the syllabus is excellent, and I quite agree with him in the remarks he adds about the "unflinching courage in the reform of English methods of education" as far as regards the matter under discussion. But what is possible is, that the examiners, being chosen from the older universities, may overlook this distinction; until now, I have had to regard the papers from the old point of view, in which light they have suited me exactly; Mr. Wormell has viewed them from the modern stand-point, and bears the like testimony; this being so, it must be admitted that the examiners have well carried out the syllabus. That I should "impeach the integrity" of such men as the present examiner, from whom I have always experienced the greatest kindness, or the late examiner, one of the most successful teachers of my own university, would be absurd, were it not that it pains me to have it supposed. To return, I do not want quite such a change as Mr. Wormell thinks; the difficulty in my case has not yet arisen, for I have not yet sent in pupils whose training has been wholly confined to the new Geometry, and I wished to have the change made, if any were necessary, before sending them in. The difficulty will not be so great when we have obtained a thoroughly good modern text-book; ours is a very good one, but there are blemishes which will doubtless be removed in a new edition, and to adapt it to the matriculation scheme more propositions than at present must be proved, as I think, independent of proportion. I applied the term "Euclidean type" to the recent examination paper, because the questions are given in the exact words of Euclid; I would have this changed; they follow in the order assigned in the Elements, and perhaps my experience of

Cambridge Examinations leads me erroneously to think that the proofs are expected to be given in the same order. In drawing this personal statement to a close, I may say that I am not singular in the view I took, as I learn from several gentlemen who have spoken to me on the point, and indeed, had it not been that the authorities* of University College School thought I had some ground for my views, I should have kept silence altogether. I believe the matter will come under the consideration of the proper authorities, and in their hands I am perfectly willing to leave the settlement of the question, if there be any need for a change.

R. TUCKER

University College School

Science and the University of Cambridge

ONE of the last sentences in your paragraph concerning the report of the Syndicate for providing better opportunities for the study of physical science in the University of Cambridge, though founded upon a partial misconception of the state of affairs, suggests what is probably the best solution of the difficulty. The colleges, if polled upon the simple question, "Shall we aid in promoting the study of physical science?" would, I believe, reply by a considerable majority in the affirmative. It is upon the best mode of contributing that there is so much division of opinion; and this has caused the apparently "lame and impotent conclusion."

The question of taxing the college revenues is one of considerable difficulty; some colleges already support out of their corporate funds teachers of natural science, some have recently taxed themselves heavily to improve their buildings. Most would think that non-resident fellows who do little for the college should be taxed more heavily than those who reside to do much work for no great amount of pay; but to bring about this would require much alteration of statutes. The question, therefore, being so complicated, and there being, as I believe, a general willingness to contribute, if only a just and equitable mode of raising the funds can be devised, and proper control retained over them (for the University is not generally considered to manage its property so well as the colleges), I believe that the difficulties would be most simply solved by the appointment of a commission composed of a few well-qualified persons, thoroughly acquainted with the University, to devise a scheme and to draw up an act for carrying it into effect.

T. G. BONNEY

St. John's College, Cambridge

EXPLORATION OF CAVES AT SETTLE, YORKSHIRE

IN the mountain limestone of the West Riding are many caves, some of which are empty, some traversed by water, which is silting up their lower chambers, while others are full up to the very roof with débris of various kinds. All have been, at some time or other, subterranean watercourses, and have been formed, partly by the friction of the substances set in motion by the current, but principally by the chemical action of the carbonic acid of the rain-water by which the insoluble carbonate of lime in the rock is converted into the soluble bicarbonate. Some have been inhabited, at various times, by man, and by wild beasts, and therefore may be expected to furnish valuable evidence of a condition of things that has now passed away. The last recorded case of their being used by man as a place of refuge was during the rebellion of 1745, when the eldest son of one of the gentlemen in the neighbourhood was hidden in a large cave, in the fear that the Scotch would pass southwards in that direction instead of by the Preston route.

The gentlemen of the West Riding have formed a committee for the systematic exploration of these caves, and will doubtless obtain from them evidence of the very highest archæological value, relating to a time of which we know next to nothing,—that begins with the disappearance of the mammoth, hyæna, and lion from Northern Europe, and extends as far down as the dawn of history in Britain, during which the neolithic and bronze-using races spread over Europe from the south-east. The older caves have been explored in many parts of Britain, while the pre-historic of the later have only been systematically examined in Somersetshire and Denbighshire by myself and Mr. Sanford. That the work in Yorkshire is planned well is clear from the following extracts from the Resolutions:—

That the following scheme, proposed by Sir James Kay-Shuttleworth (chairman), be adopted, viz.:—

1. To examine the ground around the mouth of the caves for signs of fire, implements, utensils, remnants of food, or traces of sepulture.
2. To make a survey of the caves in order to provide a plan of the interior drawn to scale, and of a sufficient size to enable a record to be made on it of the situation in which each thing is found.
3. To ascertain by one or more vertical excavations of limited extent what are the deposits chronologically arranged.
4. Then to proceed to examine these strata from the mouth of the cave inwards, so as to secure the discovery of all remains throwing any light on the history of each stratum.
5. To keep a record of the things discovered.

The first cave chosen by the committee is that found by Mr. Jackson, high up in a limestone cliff near Settle, on the coronation-day of our Queen, and which is therefore known as "the Victoria cave." It consists of a series of large chambers and passages, which are nearly filled to the roof with a reddish grey clay and stones. It must at one time have been of wonderful beauty, for there are the remains of massive stalactites, and of thick stalagmitic pavements; but now these are so decomposed by the carbonic acid that they are reduced to the condition of very soft mortar. Curiosity-hunters have also been doing their usual ruthless mischief. When it was first opened, Mr. Jackson obtained from a chamber at the original entrance a large series of ornaments and implements of bronze, iron, and bone, along with pottery and remains of animals. There are in his collection bronze fibulæ, iron spear-heads, iron nails, bone spoons, spindle whorls of stone and pottery, fragments of Samian ware, and other pottery turned in a lathe, cockle-shells, flint flakes, whetstones and stone balls. The remains found with these belong to the red deer, roebuck, pig, horse, and Celtic short-horn (*Bos longifrons*), sheep or goat, badger, fox, otter, and dog. There are also Roman coins of bronze and silver. All these were derived from a superficial deposit, and could not be assigned to an earlier date than that of the Roman occupation. The pottery was of the same kind as that so commonly found in the refuse heaps near Roman villas. It is worthy of note that the two domestic animals, the Celtic short-horn and the sheep or goat, were those that had been most abundantly used for food. The exploration committee resolved to follow up this discovery by a thorough examination of the cave, which they are able to undertake by the courteous permission of the owner, Mr. Stackhouse.

Outside the entrance of the cave, and at a lower level, is a small plateau composed of *débris*, which occupies the exact point where daylight could be seen through chinks, from the inside of one of the large chambers. As both the plateau and the chamber were undisturbed, the committee determined to begin work by removing the *débris* and making a new entrance into the cave. While this was being done, the following section was exposed. On the surface there was a layer of fragments of limestone that had fallen from the cliff above, two feet in thickness. Underneath was a layer of dark earth with stones about eighteen inches in thickness. It furnished large quantities of bones, nearly all of which had been used for food, and several articles of bronze, iron, or bone of the same kind and age as those I have already mentioned. The pottery is also of the same Roman character. Fragments of charcoal were also abundant, and stones bearing the

* What strong views in favour of the modern methods are held by Prof. Key, may be seen from Prof. Hirst's preface to our Geometry.

marks of fire. There can be no doubt that this stratum marks the place where the dwellers in the cave, during Roman or immediately post-Roman times in Britain, kindled their fires and cooked their food. Underneath is a talus of limestone fragments detached from the cliff by atmospheric action, like the superficial accumulation. It is from six to seven feet in thickness. In some places the fragments were cemented together with a soft decomposing stalagmite. It rested on a layer of grey clay, of a thickness which at present has not been ascertained. At the bottom of the talus, and close to the entrance that is now being made into the chamber, there were found two rude flint flakes, a remarkably large lower jaw of bear, the broken bones of the Celtic shorthorn (*Bos longifrons*), and of the red-deer. On the 4th April a most remarkable bone harpoon was dug out from the same horizon. It is between four and five inches in length, and is furnished with two barbs on each side, arranged opposite each other, composing the head of the implement. The base presents a form of attachment to the handle which, so far as my knowedge extends, is new to Britain. Instead of having a mere projection to catch the ligatures, there is a well-cut barb on either side that points in a contrary direction to those on the head. Were the bases of a barbed arrowhead and of a harpoon joined together, the resultant form would be analogous to the one in question. Therecan be no doubt from the position of these remains, that man occupied the spot before the accumulation of the overlying *débris*. Ample use for his harpoon he would find in the mere, now drained and turned into green fields, which are almost overlooked by the cave. So far as the work has proceeded there is no trace of metal at this horizon in the section.

The value of the evidence hitherto obtained lies in the fact that the Roman stratum is separated from the lower level, in which the flints, harpoon, and bear were found by the talus of angular stones. And this in a rough way enables a computation to be made of the date of the lapse of time between them, if we allow that for a considerable time past, immediately outside the historical epoch, the disintegration of the cliff has been equal, in equal times. For since, in twelve hundred years, to put it at the lowest, only a thickness of twenty-four inches has been accumulated above the Roman remains, it would take three thousand six hundred years for a deposit of six feet to be formed, and thus the harpoon and flint stratum would be about four thousand years old. The accuracy of this calculation is indeed injured by the possibility that the winter cold was more intense, and the splitting action of the frost greater in Pre-, than in Post-Roman times. Nevertheless, the change from the Arctic severity of the post-glacial winter, to the climate which we now enjoy in Britain, has been so gradual, and has been spread over so long a period, that it may be assumed to have been very small in so short a time as four or five thousand years.

This account is merely an outline of the results obtained up to April the 4th. The cave promises to be a rich one, and will probably add very much to our knowledge of the Pre-historic dwellers in Yorkshire.

W. BOYD DAWKINS

THE ABRADING AND TRANSPORTING POWER OF WATER

I.—MECHANICAL PROPERTIES OF WATER

IT is not my intention to lay down definite rules or formulæ regarding the flow of water, but rather, by drawing attention to generally-acknowledged facts, to throw out suggestions which may serve to lead to the discovery of some general laws of practical use to the hydraulic engineer.

In 1857 a paper was read by me before the Royal Society of Edinburgh, "On the Delta of the Irrawaddy," in which I expressed an opinion that depth somehow affected the abrading and transporting power of water.

My experience of Indian rivers and canals during the succeeding ten years went to confirm this opinion, and before the Institution of Civil Engineers, as well as on two occasions before the British Association in 1868 and 1869, I ventured to give expression to my views of this law, as affecting artificial rivers for irrigation, and the bridging of rivers which flow through the alluvial plains of Northern India.

In the *Artizan* there have appeared during the last six months several short articles bearing on the same subject, showing how all questions relating to flowing water are affected by this supposed law, which may be stated as follows: "*the abrading and transporting power of water increases in some proportion as the velocity increases, but decreases as the depth increases.*"

The first question that arises in this inquiry is—What is water in a mechanical point of view?

This may be briefly answered by saying that it is a fluid, the particles of which, though easily separated, do again unite, and exert a certain affinity towards each other, and also to other bodies, so that a certain amount of power is necessary to effect a separation. The attraction of the particles of water to other bodies varies with different substances; for instance, in all bodies of a fatty nature the facility for wetting is very slight; and different temperatures also affect this property of water. This attraction or force is technically known as "skin friction," and deserves the most careful investigation; for it is owing chiefly, if not altogether, to the fact that water has the power of abrasion, and it is this property which introduces the most difficult problems that a naval architect has to solve.

The affinity of one set of particles of water to another set, may possibly be measured by noting the size of a drop of water which falls from a wetted surface of a given area. By thus determining accurately the weight of water a given area can support, some approximate results of an instructive character may be arrived at; but what adds to the complication of the question is, that the cohesion of the particles probably differs according to the temperature and the purity of the water experimented on. Thus, when water reaches the boiling point the affinity, it is believed, becomes very much lessened; and, again, it is thought that with pure or distilled water the particles probably have less affinity to each other than with water less pure. This impurity may arise from various causes; sewage, for example, would probably give much heavier drops from the same wetted area than rain water, in the same manner that drops of treacle are much larger than those of water; that is to say, the affinity, attraction, or cohesion of the particles is as a general rule increased by the introduction of foreign matter held in solution. With solid matter held in suspension a similar result is obtained, not by increasing the cohesion of the particles of water, but by increasing the surface area wetted; for each grain of foreign matter, be its shape what it may, must have all its surface in contact with the water. This probably explains how a drop of mud should be so much larger than one of water, and, at the same time, it may possibly explain why thick muddy water, or more properly speaking, liquid mud, with the same section and slope, cannot travel so fast as water.

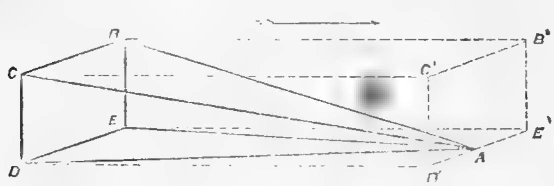
From this it may reasonably be supposed, that when muddy water runs down an inclined plane, the solid particles cannot by their own gravity sink so rapidly towards the bottom as to overcome the power dragging them in a different direction. As a consequence, the flow of water is retarded by having solid matter held in suspension in some proportion according to the load. On large rivers where this proportion may be only $\frac{1}{1000}$ or $\frac{1}{2000}$ part of the weight of water in motion, the retarding force may not be appreciable by the most careful experiments; so when calculating, the discharge may be left out altogether; but with torrents transporting 5 per cent. and more of solid matter, and with the discharge of sewage, it is believed that the retarding power is quite appreciable. The whole question is no doubt a very complicated one; yet by a set of careful experiments, conducted with a view to discover this adhesive power of water, it appears highly probable that an important step would be gained, towards the solution of some other difficult but important problems.

The next point to consider is—How does water travel? This also is a very abstruse question; but I believe that the true answer is given in the brief statement that water *rolls* rather than *slides*.

Were it not so, a ship with a foul bottom could not be so much retarded when passing through the water as experience shows she is. For example, supposing there are two ships in every respect the same, only that the first is covered with a coating of clean pitch a quarter of an inch thick all over her bottom to above her water line; and that the second, in place of the pitch, has got all her bottom covered with marine animals and weeds, so that when this second ship is passing rapidly through the water, none of the sea-weeds or marine animals extend more than this ¼ inch beyond the ship's sides, which is the thickness of the coating of pitch on the first ship: in such a case the displacement and the lines are exactly the same, but it is hardly necessary to ask any sailor which of the two ships, with the same wind and sails, would pass most rapidly through the water, and, in the case of two steamers, the extra resistance caused by the foul bottom could be easily measured in extra horse power required to force the foul vessel through the water at a speed equal to the other.*

If the motion of the water was a *sliding* one only, the speed in both cases would be the same with the same power, for the resistance would be simply the separation of the two films of water, the one in contact with the ship's sides and the other with the surrounding sea; and these, in both cases, would be identical, the displacement being the same. If, however, as is believed, on a body passing through water, or water flowing down a channel, the particles of water are set in motion in a revolving direction, the convolutions increasing directly in proportion to the wetted surface, then by this hypothesis some assignable reason for this retarding of the foul-bottomed ship can be given.

If the particles slid over each other rather than rolled, they would, so to speak, pass each other in parallel straight lines; but any one in a gale of wind, going behind a high square block of building, would very soon discover that, in air, such is not the case: for if he went a few yards away in the direction the wind was blowing, he would soon discover that the building no longer afforded any protection from the blast, but that there was some certain point to leeward where the currents again converged, while beyond this the storm raged with the same violence as at any other point. (Every boatman knows what it is to get under the lee of a very high island; the sea may be smoother, but the sudden gusts of wind are often more dangerous than when exposed to the full force of the gale.) Immediately in rear of the wall itself he would find eddies of air whirling about in all directions. Within the space



A B C D E there would be a partial protection from the storm, and instead of the wind being in the direction shown by the arrow, there would be whirling eddies within this space, which could not exist were the air to pass off in straight lines as represented by the dotted lines B B', C C', D D', E E'; neither could the several currents of air converge at the point A, which it is well known is always the case.

In the same manner any obstruction placed in a stream of water, causes eddies in rear of it; that is to say, the water does not pass on in straight lines, but within this space it goes revolving about in all directions, the distance of A probably depending on the velocity: showing that there is neither a sliding motion nor a parallelism in the direction of the lines of current.*

T. LOGIN

* Possibly by the introduction of an elastic medium, such as air, between the ship's bottom and the water, the skin friction may be reduced, as it may, in a measure, reduce this rotatory action.

* By an experimental study of this subject, it may be discovered how far these eddies extend with different velocities, which may throw light on the proper length of the after portion of ships intended for different speeds.

THE CLIMATE OF IRELAND

IN the science of nature there is no chapter more interesting than that which treats of Physical Geography, which, properly understood, means the account of physical phenomena as they are modified by geographical position; and at the present moment the physical geography of Green Erin, or it speculiarities of soil and climate, presents a theme of no slight importance. It has been stated in the House of Commons as a proof of the retrograde condition of Ireland, that its production of cereals has of late years diminished, while its pasture lands have increased. To this it ought to have been answered that the decreased cultivation of cereals, and of wheat in particular, was a proof of improved knowledge. Years ago, at the meeting of the British Association in Cork, a communication was read, pointing out that agriculturists in general are governed wholly by example, their scanty science not allowing them to quit the beaten path. Hence Irish farmers, when they aim at improvement, endeavour to imitate the farming of Norfolk or the Lothians, and in so doing fail miserably, owing to the wide difference between the climates of the western isle and of the eastern side of Great Britain. It is commonly stated that Ireland has a very wet climate. It has undoubtedly a humid atmosphere, owing, perhaps, in some measure, to a great extent of undrained surface. But the total quantity of rain that falls in Ireland, little, if at all, exceeds the rainfall of England. In its distribution through the year, however, it differs much from the latter. The vicinity of the Atlantic gives Ireland in the highest degree an oceanic and, to some extent, an equatorial climate. Winter in the Green Isle is extremely mild. The southern and western coasts, though seldom free from wind and drizzling rain, never experience severe cold. Vegetation remains in mid-winter brilliantly green and undepressed. As spring advances, everything seems to flourish; crops of all kinds promise abundance, and already, in May, harvest seems to be close at hand. But now the scene changes. There is little or no dry summer. When the sun is highest in the meridian, there is a constantly clouded sky and no sunshine. Rain begins to fall in June. The rainfall of July is the heaviest in the year. In August the rain begins to abate; but clear skies and bright sunshine cannot be reckoned on till September, when the shortened days and the sun's declination have much reduced the solar heat. The crops in the meantime, arrested in their progress, are not the better for two months' slumbering under the clouds They have summer rain in excess, and too little sunshine. From this it will be seen that the character of the Irish climate is, that under it everything grows well, but that the process of ripening is painfully slow and uncertain. Now, to cultivators of the cereals the success of this process is of the utmost importance. The corn harvest in Ireland falls late in the year, in September and October, when the days are short and nocturnal frosts not unfrequent. The plains of Southern Russia, or of the Red River in Canada, with a comparatively rigorous climate, far excel Ireland as wheat-producing countries, because their short summer is one of uninterrupted fierce sunshine; their vegetation suffers no check; the grain is ripened all at once, and the harvest gathered without delay or difficulty. The deficiency of ripening power in the Irish climate produces a secondary defect, which meets with less attention than it deserves. The grain which lingers on the stem two or three months before it hardens is sure to be unequally ripened; some of it is immature, while more is tending to decay. Consequently, it is bad seed, and the Irish farmer habitually sows perhaps six or eight times as much as Mr. Mechi would deem requisite. Under these circumstances, it is evident that the Irish farmer ought to cultivate cereals no further than is requisite for the economy of his farm, and to look to other productions for his profit. Fortunately, there is a husbandry for the pursuit of which he enjoys peculiar advantages. In green crops no country can compete with Ireland, where, nevertheless, they are still little known or esteemed by the multitude. From this it may be inferred that sheep and cattle ought to be the chief objects of Irish husbandry. In truth, the Green Isle, under proper management, could easily supply England with beef, mutton, poultry, milk, and butter, and grow rich by giving abundance at a cheap rate to her neighbours. But then this could be effected only under a system of large farms. The grazier and cattle dealer, to make their business profitable, must do it on a large scale. Butter of the best quality cannot come from a small dairy. The improvement of Ireland, therefore, as dictated by climate and natural capability, can be effected only under a system of large farms. The popular wish, however, is for small holdings. It is thought that the country, when divided into potato gardens and all covered with cottages, will be a paradise. But this poor man's paradise, beginning with a few years of felicity, will assuredly lead to the pauperism of ages. The Legislature cannot countenance schemes opposed to the wholesome development of society, and which would make poverty an institution; neither can it prevent their diffusion; but it may counteract them by spreading enlightenment and by presenting plain truths to the common sense of the community. This might be done by the publication of some statistics, showing the relative amount of cost and production of wheat and of green crops in England and Ireland, with some illustrations of the gain derivable from large farms and the use of machinery. W. D. C.

THE STONE AGE IN EGYPT

At a recent meeting of the French Academy, two communications were read relatve to the discovery of relics presumably belonging to the Stone Age in Egypt. The one of these was merely a claim on the part of M. Arcelin to priority in the discovery of various localities abounding in such remains. The other, by Messrs. Hamy and Lenormant, while according priority in the discovery to M. Arcelin, gives a list of the various spots at present known in Egypt on which the manufacture of flint implements was carried on in early times—or where *ateliers de fabrication* have been discovered. For the benefit of our countrymen travelling in Egypt, we here reproduce the list, arranged in the order in which the places occur in travelling southwards.

1. SAQQARAH, where have been found "scrapers" and other worked flints.

2. NEG-SALMANI, a small *atelier* in the desert, at some distance from the Libyan chain, and to the north of the ruins of Abydos. Flakes of whitish flint have been observed here.

3. HARABAT-EL-MADFOUNEH, another small *atelier* to the west of the great temple of Seti I., at the foot of the mountain. The worked flints, principally flakes, are of a fine texture, and pink in colour.

4. BAB-EL-MOLOUK, at the entry of the Valley of the Tombs. M. Arcelin here found flakes, "scrapers," &c.

5. GEBEL-QOURNAH. Here are traces of the manufacture on a large scale of worked flints of various types. Among these are said to be "lance-heads" of a curious character, like some of those from the Valley of the Somme, and the Cave of Le Moustier, arrowheads, knives with or without a shoulder, "scrapers," hammer-stones, and nuclei, not unlike those of Pressigny. The flint is brown or blackish, and fine in texture.

6. DEIR-EL-BAHARI, and 7, DEIR-EL-MEDINEH, at the foot of the mountain of Thebes. Nuclei and flakes, like those of Gebel-Qournah, are found here occasionally, and it is suggested may have come from some unexplored locality on the summit.

8. EL-KAB, where, at the foot of the cliff, flakes, arrowheads, and other forms have been found.

Besides these localities, where worked flints occur on the surface of the soil, there is ABOU-MANGA, where the containing bed is not superficial, and some spots in the plain of Thebes, where MM. Hamy and Lenormant have found implements comparable in type with those of St. Acheul, and in connection with the old alluvia of the Nile, the relative date of which has, however, not been fixed.

It is stated that the instruments are not all of flint, but in some cases of porphyry, amphibolic rock, or other hard kinds of stone. J. EVANS

THE PROJECTED CHANNEL RAILWAYS

III.

WE have already considered two modes of crossing the English Channel by a railway, viz. one above the water by a bridge, and another below the water by a tunnel through the chalk. The two shores might be also connected by a submerged roadway passing direct through the water. It might be constructed either on the bottom of the channel or at a certain distance below the level of the sea. Submerged roadways have been proposed, some of iron, others of concrete; of the former of these we shall only consider such schemes as appear to have received sufficient attention from their originators.

These structures may be simply called tubes, because of their circular shape, which is, we all know, the most favourable form to resist pressure against collapse. The various propositions for the construction of iron tubes may be divided in two classes, viz.: 1st, schemes in which the parts of the proposed submerged tube are to be constructed on shore in certain lengths, afterwards to be united under water to form the permanent structure. 2nd, Schemes in which the whole tube is to be at once built in deep water.

Among the designs which belong to the first class, the best and most elaborate is that of the late Mr. Chalmers. His design is well known from his publication on the Channel Railway, which we consider a meritorious and ingenious production. He proposes a line of tube between the South Foreland and Blanc-Nez on the French coast, with a gigantic tower—or ventilator, as he terms it—midway in the channel in thirty fathoms of water. Having made this tower, he proposes to construct wrought-iron tubes on shore, each about 400 feet long, closed at both ends by watertight bulkheads. These tubes are to be floated, one by one, to the tower, and to be there submerged, "being drawn down by means of endless chains passing round pulleys or drums attached to massive anchor boxes on the bottom of the Channel." The separate parts to be submerged at one operation are to have each a floating-power equal to about 100 tons. A short description is also given how the ends of the tube about to be submerged should be drawn and attached to that part already permanently secured to the tower and the bottom of the Channel.

The deep sea tower or ventilator is probably not practicable, but we consider it does not form an essential part of the scheme. The whole tube might be formed of 240 separate pieces, each 400 feet long, and submerged without the tower by working from one shore end. The submerging and joining together of these parts in deep water would, however, be a perilous operation. No doubt this is the main difficulty of every plan of this class of scheme. In the present case it must be overcome and the operation 240 times successfully repeated, in order to complete the structure, and we may accordingly appreciate the chance in favour of the completion of this kind of submerged roadway.

Of the second class of works, viz. building the whole tube in deep water, we have but one scheme. It is the more satisfactory to observe that, of all the schemes which have been proposed with a view to establish a permanent railway communication between England and France, it is the most elaborate and complete, offering a solution on all material points in connection with this subject. The authors of this project—Messrs. Bateman and Révy—have published a full account of their scheme, and we cannot do better than refer to their work for a short description of the plan they adopt.

Our object has been to devise a scheme by which all difficulties of operating in water should be avoided. We propose to lay a tube of cast iron on the bottom of the sea, between coast and coast, to be commenced on one side of the Channel, and to be built up within the inside of a horizontal cylinder, or bell, or chamber, which shall be constantly pushed forward as the building up of the tube proceeds. The bell or chamber within which the tube is to be constructed will be about 80 ft. in length, 18 ft. internal diameter, and composed of cast-iron rings 8 inches thick, securely bolted together. The interior of the bell will be bored out to a true cylindrical surface, like the inside of a steam cylinder. The tube to be constructed within it will consist of cast-iron plates in segments 4 in. in thickness, connected by flanges, bolted together inside the tube, leaving a clear diameter of 13ft. when finished. Surrounding this tube and forming part of it, will be constructed annular discs or diaphragms, the outside circumference of which will accurately fit the interior of the bell. These diaphragms will be furnished with arrangements for making perfectly water-tight joints for the purpose of excluding sea water and securing a dry chamber, within which the various operations for building up the tube, and for pressing forward the bell as each ring of the tube is added, will be performed. Within this chamber, powerful hydraulic presses, using the built and completed portion of the tube as a fulcrum, will, as each ring is completed, push forward the bell to a sufficient distance to admit the addition of another ring to the tube. The bell will slide over the water-tight joints described, one of which will be left behind as the bell is projected forward, leaving three always in operation against the sea. The weight of the bell and of the machinery within it will be a little in excess of the weight of water displaced, and therefore the only resistance to be overcome by the hydraulic presses when pushing forward the bell, is the friction due to the slight difference in weight and the head or column of water pressing upon the sectional area of the bell against its forward motion. In like manner, the specific gravity of the tube will be a little in excess of the weight of water which it displaces; and in order to obtain a firm footing upon the bottom of the sea, the tube will be weighted by a lining of brick in cement, and for its further protection will be tied to the ground by screw piles, which will pass through stuffing boxes in the bottom of the tube. These piles will, during the construction of the tube within the bell chamber, be introduced in the annular space between the outside of the tube and the inside of the bell, and will be screwed into the ground as they are left behind by the progression of the bell. The hydraulic presses and the other hydraulic machinery, which will be employed for lifting and fixing the various segments of the tube, will be supplied with the power required for working them from accumulators on shore, on Sir William Armstrong's system, and the supply of fresh air required for the sustenance of the workmen employed within the bell and within the tube will be insured also by steam power on shore. As the tube is completed, the rails will be laid within it for the trains of waggons to be employed in bringing up segments of the rings as they may be required for the constructions of the tube, and for taking back the waste water from the hydraulic presses, or any water from leakage during the construction.

The tube will be formed of rings of 10 feet in length, each ring consisting of six segments, all precisely alike, turned and faced at the flanges or joints, and fitted together on shore previous to being taken into the bell, so that on their arrival the segments may, with perfect certainty and precision, be attached to each other. The building of the tube will be commenced on dry land above the level of the sea, and will be gradually submerged as the tube lengthens. The operations on dry land will be attended with more difficulty than those under water, but all these circumstances have been carefully considered and provided for.

The precise line to be taken betwixt the English and French coasts can hardly be determined without a more minute survey of the bottom of the Channel than at present exists. It will probably be between a point in close proximity to Dover on the English coast, and a point in close proximity to Cape Grisnez on the French coast. On the line suggested the water increases in depth on both sides of the Channel more rapidly than elsewhere, although in no instance will the gradient be more than about 1 in 100. The tube at each end would gradually emerge from the water, and on arriving above the level of the sea would be connected with the existing railway systems, so that the same carriage may travel all the way from London to Paris, or, if Captain Tyler's anticipations be realised, all the way from John O'Groat's to Bombay.

The distance across the Channel on the line chosen is about 22 miles. The tube as proposed is large enough for the passage of carriages of the present ordinary construction, and to avoid the objections to the use of locomotives in a tube of so great a length, and the nuisance which would be thereby created, and taking advantage of the perfect circular form which the mechanical operation of turning, facing, &c., will insure, it is proposed to work the traffic by pneumatic pressure. The air will be exhausted on one side of the train and forced in on the other, and so the required difference of pressure will be given for carrying the train through at any determined speed. Powerful steam-engines, with the necessary apparatus for exhausting and forcing the air into the tube, will be erected on shore at each end; and supposing one tube only to exist, the traffic will be worked alternately in each direction.

It has been found by calculation, that, for moving a large amount of tonnage and a great number of passengers, the most economical arrangement will be to send combined goods and passenger trains through the tube at 20 miles an hour, with occasional express trains at 30 miles an hour. Thus, an ordinary or slow train would occupy about 66 minutes in the transit, and a quick or express train about 45 minutes. In this way the tube, if fully worked, would permit the passage of 16 ordinary slow trains (8 each way), and 6 express trains (3 each way), each conveying both goods and passengers. About 10,000 tons of goods per day, or upwards of 3,000,000 per annum, and 5,000 passengers, or nearly 2,000,000 per annum, might be taken through, or a less amount of goods and a larger number of passengers, or *vice versâ*, if circumstances rendered other proportions necessary or desirable.

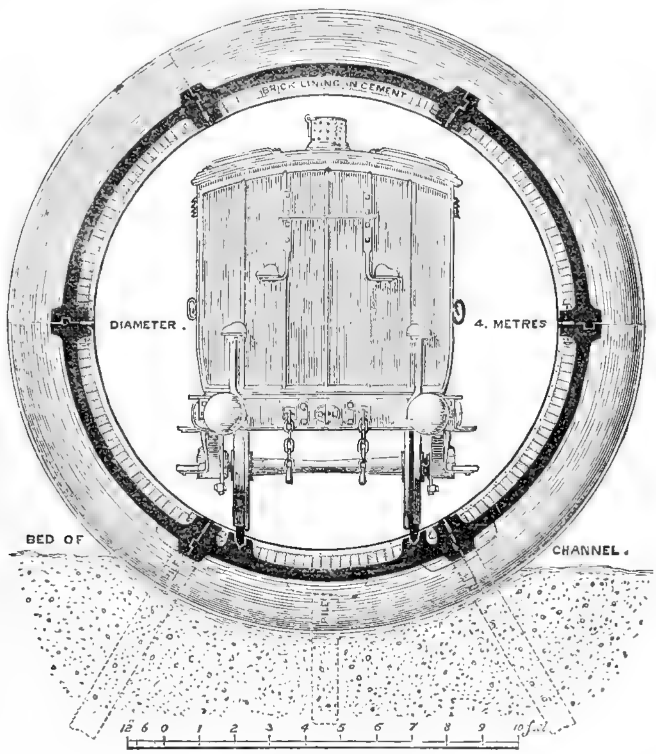
The horse power required for working the traffic with the above number of ordinary and express trains will be, on the average, 1,750 indicated, or about 400 nominal horse power at each end.

We should gladly have referred to many other interesting and important statements contained in this work, but our limited space does not admit of our doing so. A general idea of the proposition may be gathered from the above description of the authors, taken from the popular part of their work. The Appendix, which really contains the substance of the scheme, is too elaborate and technical for the general reader, without devoting special study and attention to it. Suffice it to state, that the amount of information conveyed in those 40 pages of close print is very great, being an account of a succession of results of elaborate investigations of physical, mathematical, and even of a chemical nature. One gains confidence from the mere fact, that in treating the subject the authors are evidently "at home," and do not evade a difficulty.

The general principle of the scheme, as invented and elaborated by Messrs. Bateman and Révy, may be easily understood by the ordinary reader. He can, however, have little idea how the practical difficulties attending the execution of such immense works have been overcome by these engineers. Take, for example, the first sentence or two we have quoted above. The general proposition is this: "A tube of cast iron to be built up inside a horizontal cylinder or chamber."—No doubt this may appear simple enough, but when we come to consider what the operation of *building* means,—when we come to consider that no part of the tube to be so built up weighs in one piece less than *ten tons*,—that those solid pieces of iron could not even be stirred by the power of scores of men, much less lifted or deposited in the right place—that this "building up" is to take place in a comparatively small space, not exceeding 13 feet in diameter, the larger part of which is already occupied by the very plate weighing 10 tons;—we may in a measure realise what the word "building" under these circumstances signifies.

But we have further to bear in mind, that it is not enough that we should be able somehow to "build up" the tube inside that chamber, but that it must be done quickly, without delay or a hitch, and that unless it could be so done the operation of "building up" would take generations in crossing the Channel, and make the whole proposition, though practicable in every detail, yet a forlorn hope, because of the length of time. If thus we come to consider, that the authors have not contented themselves with saying that "their tube is to be built up in that chamber," but have given us the precise designs and the exact mode of proceeding to be adopted; that the designs and arrangements are so complete that they might be forthwith placed in the hands of a contractor; that these mechanical arrangements would enable a boy of ordinary intelligence to take hold, lift, and place, and finally deposit these monster plates with the same ease, quickness, and certainty as a bricklayer would lay his brick in the construction of an arch, we venture to say the authors have made out their case.

We believe it is the first time that any of the projectors or designers of Channel railways have paid serious attention to the important question, how such a submerged railway or tunnel could be used and worked to advantage for the enormous traffic between England and France. Most of them seem to assume, as a matter of course, that such a tunnel of iron or brick would be worked as ordinary railways. It appears, however, from the investigations of Messrs. Bateman and Révy that there is but one way of working such a tunnel to advantage, and unless the arrangements and the construction of the works be kept in accordance with that mode of working the traffic, the tunnel, when completed, would be of no use for practical purposes. The authors find that the power for the propulsion of trains must be pneumatic pressure; not as applied in the old-fashioned style above ground, and known by the name of atmospheric railways, but a pressure of air applied by powerful pumps directly upon the train, which would form a kind of loose piston inside the tube. On the old plan, the train was outside a little tube; on the new plan, the train is inside a large tube; and with this simple alteration all the difficulties which led to the abandonment of the former, disappear on the latter plan. The difficulties of the old atmospheric railways were: (1) mechanical difficulty of connecting the piston of the little tube with the train outside it; (2) The high pressure required on the small area of the piston for the propulsion of the train, and consequent development of an excessive amount of heat within the pumps, leading to their rapid destruction and great loss of power by subsequent cooling of the air. By the new mode of atmospheric propulsion all these difficulties are done away with, for there is no connection



SECTION OF THE TUBE.

between a piston and the train wanted, and the pressure of the air over the large sectional area of the tube required for propulsion is but a small fraction of that formerly employed; there is, consequently, no heating, no inordinate wear and tear, and no loss of power. Equally ingenious is the construction of the proposed air pumps. Very large volumes of air are wanted to accompany and press forward the train—several hundred thousand cubic feet per minute. And what is the nature of the pumps to supply these? Are they to be blast engines? No; they are to be air pumps, in the shape of gasometers. We are all familiar enough with the sight of gasometers, but their application for such a purpose is certainly new.

We find throughout the work the same invincible spirit which seems to seek a difficulty for its immediate destruction. That a permanent railway across the English Channel will be built, we doubt not; we are equally confident that Messrs. Bateman and Révy's scheme is a practicable solution of the problem. No less an authority than the Emperor Napoleon III., after mature consideration of the scheme, wrote to say:—"*C'est le seul realisable*," and as the design is one that belongs essentially to England, His Majesty's opinion acquires enhanced value and importance. Let us, then, hope that the engineering and enterprising powers of this eminently engineering country will heartily support, advance, and improve the plan, which seems to ensure inestimable advantages to England and France.

NOTES

THE Secretaries of the Royal Astronomical Society have circulated the following notification. "We are instructed to communicate to you the following Resolution, which was passed at a Committee of the Council held yesterday, April 8th:—Resolved—'That the Fellows be informed that there is a possibility of the Government providing means of transit to and from stations on the Mediterranean for about sixty observers, who may be willing to take part in the Observation of the Total Eclipse of December 22, 1870; and that persons willing to undertake a portion of the Observations on a plan to be arranged by the Council, be invited to send their names to the Secretaries, and also to state the branch of observation which they would be prepared, or prefer, to undertake, and the instruments they would be willing to contribute.' It is desirable that the names of those who are willing to take part in the observation of the Eclipse should be sent in, if possible, before the next meeting of Council, May 13."

WE are informed that M. Fahnehjelm, the Swedish Commissioner for the forthcoming series of Annual International Exhibitions, has applied for permission to exhibit a full-sized model of a school-room, just as it exists in the country parishes in Sweden, with all the books, maps, apparatus, forms, desks, &c., in order to give a complete idea of the Swedish system of elementary instruction. Her Majesty's Commissioners will, there can be no doubt, gladly place a sufficient space at the disposal of the Swedish Commissioner for so interesting an exhibit. It is to be hoped that encouragement will be given to other countries to follow this excellent example. An easy comparison of international appliances for educational purposes would be most useful to visitors to the Exhibition, and would be beneficial and stimulating to the countries exhibiting.

YET another contribution to Mr. De Morgan's "Budget of Paradoxes." A pamphlet reaches us under the title of "The New System of Astronomy" by "Incognito" (Spon, Charing Cross), reviving, as "more in accordance with ascertained observations, and more capable of exact proof than any yet propounded," the old idea that the earth is the centre of our system, the sun revolving round it in an orbit intermediate between those of the Moon and Mars, with Mercury and Venus as his satellites.

PROFESSOR H. J. CLARK, of Lexington University, Kentucky, sends us a paper entitled "Polarity and Polycephalism, an essay on Individuality." He applies the term "polarity" to the tendency of the vertebrate individual to arrange its organs in two opposing sets, cephalic and caudal, and again dorsal and ventral. An individual is generally understood to be a monocephalic being. In the case of so-called "alternation of generation" among the Acalephic, since the sexual and sexless are necessary to make up a distinct organism, *i.e.*, vegetative and reproductive, the one a completement of the other, neither alone can represent the individual unit or whole cycle of life; and cephalism is therefore, Professor Clark contends, a better term to indicate the potentiality of these subdivisions to live apart.

MR. T. PAYNTER ALLEN reprints from the "Journal of the Society of Arts" an Inquiry into the existing state of education in Richmond, Twickenham, and Mortlake. He finds that of the whole number of children in the district, one-third are absolutely uninstructed, scarcely one half are in average attendance at school, one-fifth alternate attendance at school with fluctuating labour injuriously to themselves and to the school; one-sixth are of the maximum school age without having reached the maximum of proficiency, and above one-half are children of eight years, and therefore in training in infant or mixed schools, the classification, methods, and teaching power of which are very imperfect and inferior.

PROFESSOR PIAZZI SMYTH publishes "A Poor Man's Photography at the Great Pyramid in the year 1865." The "poor man" is Professor Smyth himself, who details the difficulties encountered in pursuit of his undertaking in the face of a "coalition of rich ones against him." Whatever may be thought of Professor Smyth's theory of the object for which the Great Pyramid was built, there can be no question that he has brought to the subject an immense amount of patient self-denying research which demands acknowledgment, and some of his meteorological observations may yet lead to important results.

MESSRS. LONGMAN's latest list of forthcoming works includes the following, in different departments of science:—The Origin of Civilisation, and the Primitive Condition of Man, by Sir John Lubbock; Other Worlds than Ours, by R. A. Proctor; The Historical Geography of Europe, by E. A. Freeman; Le Maout and Decaisne's General System of Descriptive and Analytical Botany, translated by Mrs. J. D. Hooker; Researches on Diamagnetism and Magnecrystallic Action, by Professor Tyndall; Lectures on Surgical Pathology, by James Paget; A Course of Elementary Problems in Practical Plane Geometry, by John Lowres; Principles of Mechanism, by Professor Willis; Smoking Fires—their Cause and Cure, by Rev. A. C. Ainslie; On the Manufacture of Beet-root Sugar in England, by W. Crookes; and A Handbook of Dyeing and Calico-printing, by the same author.

THE continental subscription list on behalf of the late Professor Sars now exceeds 10,000fr. A young naturalist, Mr. C. Jobert, called a public meeting at Havre in its support, which was a great success, the mayor granting free use of a room in the Hotel de Ville, and the printer refusing to be paid for printing the circulars: a worthy example for imitation.

Apropos of Professor Tyndall's "Dust and Disease," we extract the following from the *Scientific American*:—"The dust obtained from the places of amusement in New York has recently been analysed by the scientific officers of the Metropolitan Board of Health. Over one hundred specimens of the particles floating in the air, and falling as dust, were collected on plates of glass, and were examined under the microscope. The proportions of the different ingredients varied, but the same substances were found in all the specimens. The composition of the matter subjected to the microscope was as follows:—'The dust of the streets in its finer or coarser particles, according to the height at which it had been collected, with a large proportion of organic elements; particles of sand, quartz, and feldspar; of carbon, from coal-dust and lampblack; fibres of wool and cotton of various tints; epidermic scales; granules of starch of wheat, mainly the tissues of plants; the epidermic tissue, recognised by the stomata or breathing pores; vegetable ducts and fibres, with spiral markings; vegetable hairs or down, either single or in tufts of four or eight, and of great variety, and three distinct kinds of pollens. Fungi were abundant, from mere micrococcus granules to filaments of mould. When water was added to a portion of dust from whatever source, and exposed in a test tube to sunlight or heat for a few hours, vibriones and bacteria made their appearance, and the fungous elements sprouted and multiplied, showing that they maintained their vitality, and proving that the germs of fermentation and putrefaction are very widely diffused.'"

IT is said that Professor Nordenskiold is organising another Polar Expedition for 1871-2, and that he intends, amongst other things, to attempt to reach the North Pole by starting from Spitzbergen, or its neighbourhood, in the spring, and travelling by sledge over the frozen sea. It is reported that he intends to visit Greenland this year to procure dogs for his enterprise. We fear that if he relies upon dogs, he will not succeed better than his predecessors, and he may even experience great difficulty at the outset in obtaining the requisite number for his purpose; for, by the latest accounts from Greenland, the disease among the dogs in that country (which proved such a hindrance to Mr. Whymper in his attempt to penetrate to the interior in 1867) has spread, in spite of all efforts to check it, from one district to another, and is still continuing its fatal ravages.

THE new number of the *Proceedings of the Royal Institution*, commencing the sixth volume, includes Professor Tyndall's lecture "On Dust and Disease," Professor Odling's "History of the Scientific Work of the late Professor Graham," and Dr. Carpenter's lecture on the "Temperature and Animal Life of the Deep Sea," with briefer notices of the other Friday evening discourses before Easter.

AT the meeting of the French Academy on the 11th inst., Marshal Vaillant communicated the curious fact that Cuvier's name was not *George*, but *Jean Leopold Nicolas Frederic*. According to M. Dumas, this circumstance was well known to persons familiarly acquainted with Cuvier, but no reason is given by him for such a singular change of name.

THE second of Sir Edward Sabine's conversaziones as President of the Royal Society will be held on Saturday evening next.

THE *Engineer* states that a new method of warming first-class carriages in express trains has been adopted in Bavaria: a special van is attached to the train and contains a powerful "calorifere," and the heated air is conveyed to all the carriages of the train by means of india-rubber tubes. The experiment with first-class carriages is reported upon so favourably that the authorities have determined to apply it to all the carriages on the Bavarian lines, and it is expected that it will soon be adopted on all the German railways.

THE herbarium of the late Von Martins, which was offered to and refused by the Bavarian Government, has been purchased for 30,000 fr. by the Belgian Government to form the basis of a national collection, to be located at Brussels. It consists, 1st, of the general herbarium, containing 60,000 species, represented by 300,000 specimens, nearly half of which are Brazilian; 2nd, of the great collection of palms; 3rd, a collection of fruits and seeds; 4th, a series of woods; 5th, a collection of drugs and economic specimens, in great part formed by his brother Theodore Martins, Professor of Pharmacy at Erlangen.

ACCORDING to the *Photographic News*, the oft-reiterated statement that the eye of a dead animal has impressed upon it an image of the last object seen in life has been the subject of serious investigation in Germany. Americans have gone so far as to state that the eye of a murdered man had been found in which a portrait of the murderer was distinctly traceable. In the investigation in question the eyes of thirty different animals, all of which had been killed with a view to subsequent examination, were carefully inspected; but in no case was there any evidence discovered to warrant the statement referred to.

A COMPACT and valuable little "Route-map and Index to the more interesting objects in the Royal Gardens, Kew," is about to be issued under official sanction by Messrs. Macmillan and Co It contains an excellent map of the gardens, and index to some o the more interesting plants: and as it is to be sold for the low price of *2d.* it will doubtless have a very large circulation.

DR. E. SYMES THOMPSON, Gresham Professor of Physic, will deliver his two courses of three lectures each at the Gresham College, Basinghall-street, after Easter. The first course on April 22nd, 23rd, and 24th, will be on Cough, on Tonics, and on Climate and Health Resorts. The second course, on June 2nd, 3rd, and 4th, on the Epidemics of the Middle Ages, on Sedatives, and on Narcotics. The Lectures are illustrated with diagrams, and chemical experiments, and are free to the public. They commence at 7 o'clock.

DR. CLARK, assistant to the late Dr. Penny, who continued the winter course of lectures on Chemistry after that gentleman's death, will deliver the summer courses. Further arrangements are dependent upon the proposal of Mr. Young, the President, to endow a chair of Technical Chemistry.

THE statistics of the American Pennsylvania crude oil industry for the past year are now published. The total production of the year was the enormous amount of 4,215,142 barrels, being a daily average of 11,548 barrels. The production of 1868 was 3,715,741 barrels, the increase during 1869 over the previous year thus being 499,401 barrels, or about 1,460 barrels per day.

PROF. H. WURTZ has presented to the New York Lyceum of Natural History a report of an extraordinary outburst of gas in the township of West Bloomfield, co. of Ontario, State of New York. It issues from a bore-hole in the solid rock, about five inches in diameter, and when burning, gives in a still atmosphere a flame some thirty feet in height, the flow amounting to 400,000 cubic feet per day, which has now been going on for more than four years, without any perceptible diminution of rapidity. The density is 0·693, and the result of several analyses shows the following composition:—

Marsh gas	82·41	per cent.
Carbonic acid	10·11	,,
Nitrogen	4·31	,,
Oxygen	0·23	,,
Illuminating hydrocarbons . .	2·94	,,
	100·00	

The most remarkable feature of the discharge is the lack of diminution of the flow for so long a time in connection with the low pressure indicated, corresponding to that of but a few inches of water. Dr. Stevens has examined the geological formation of the rock from which the oil proceeds, and finds it to belong to the Hamilton Group, the gas proceeding doubtless from the "Marcellus Shale," which is highly charged with bitumen and carbonaceous matter, and flames on ignition. The four great gas-producing strata of New York, Pennsylvania, and Ohio thus all belong to the Palæozoic formation.

THE quinquennial prize of 5000fr. of the physical and mathematical sciences of the Belgian Academy has been awarded to Prof. Plateau for his researches on the figures of equilibrium of a liquid mass without weight; a fitting sequel to 26 years' unremitting work, the professor being now blind. The Argenteuil prize of 12,000fr. has been bestowed on M. Champonnois, inventer of the method of distilling beet-root.

THE Council of the Entomological Society offers two prizes, of the value of five guineas each, for essays, of sufficient merit, drawn up from personal observation in the anatomy or economy of any insect or insects; the essays to be sent in before the end of November next.

NOTWITHSTANDING the numerous investigations that have been made upon the process of gastric digestion, the ulterior changes that the food undergoes in the alimentary canal exclusive of the action of the pancreatic and biliary fluids, in other words, the action of the fluid secreted by the walls of the alimentary canal itself on the various constituents of our food, admitted on all hands to be considerable, has received but little attention. In the "Untersuchungen aus dem Institut für Physiologie" in Graz, edited by Prof. Rollett, an essay appears written by Dr. Alexis Dobroslawin of St. Petersburg on this subject. In order to obtain the intestinal juice, he made a fistulous opening into an isolated portion of the intestine and inserted a canular into the orifice, which was properly secured. The dog was fed with a pound of horse-flesh and a single supply of water daily. Investigations were in the first instance made with a view of ascertaining the quantity of intestinal secreted juice. The material obtained consisted of a thin fluid and of a mucous portion, the relative proportion of which varied to a considerable extent under different circumstances, but from an isolated portion of intestine (having a length of 13 centim.) in one dog he obtained 34 grains, and in another, where the isolated portion of intestine had a length of 17 centim. 28 grains per hour. The results of electrical excitation by means of induction currents were very similar to those previously obtained by Thiry, and showed a considerable increase in the amount of the secretion during the passage of the current, and further researches showed that the secretion thus obtained did not differ materially from that produced in the healthy and uninjured animal by the application of electricity to the freshly-exposed intestinal tract. The most interesting part of his researches, however, bears upon the action of the intestinal juice on starch, albumen, and fat respectively. In regard to the former, he was able to convince himself, in opposition to the statements of Thiry, that the intestinal juice possesses a distinct power of converting starch into sugar, and this occurred in whatever state the juice might be, whether clear, or troubled, or filtered, or mingled with flocculent masses of mucus. The time required was in all instances nearly the same, or about two hours. In one instance, evidence of the presence of sugar was obtained in a quarter of an hour. In regard to albumen, his experiments were made with portions of raw fibrin of blood. These were kept at a temperature of about 100° Fahr., in contact with some of the recently-obtained intestinal juice, and it was found that a solvent action did occur, but with great slowness, from twenty to forty, or even forty-eight hours being required. The dissolved fibrin underwent conversion without the development of any putrefactive odour into peptones, as was demonstrated by the action of a series of tests. The researches made with a view of ascertaining the action of the juice on fats, as olive oil and butter, had a negative result; he was never able to discover any of the fatty acids.

IN the last part of Schultze's "Archiv. für Mikroskopische-Anatomie," M. Schwalbe describes the lymphatic spaces of the eye. In this paper he shows that there is a large space comparable to a lymphatic sac lined by nucleated epithelium, as shown by the action of nitrate of silver situated between the choroid and sclerotic coats. When injected with a coloured fluid the injection escapes from the globe by channels surrounding the venæ vorticosæ, and then distends the space known as the capsule of Tenon. From thence the fluid passes backwards through a sheath surrounding the optic nerve, and so penetrates into the arachnoid space of the brain.

THE Rev. W. P. Clarke, vice-president of the Royal Society of New South Wales, sends us an interesting paper on the Causes and Phenomena of Earthquakes, especially in relation to shocks felt in New South Wales and in other provinces of Australasia.

IN a letter to *Hardwicke's Science Gossip*, Mr. W. W. Spicer states that the colour of insects is greatly influenced by the length of time during which they have remained in the chrysalis condition, well-marked varieties being produced by preserving the chrysalis in a state of abnormal torpidity through the autumn and winter, which can be done by keeping it in ice.

THOSE of our readers who are interested in the theory of vision will find an instructive paper by Mr. G. Joseph Towne, in the last issued volume of the "Guy's Hospital Reports" (1870). It deals chiefly with the subject of binocular vision, with a criticism on the views recently promulgated by Professors Hering and Helmholtz, and at the conclusion of his essay he makes the following statements :— "That the images of all objects placed within the transverse visual plane are referred to the opposite side of the field; that is, to the side of the field opposite to that occupied by the object viewed, and we remark that this phenomenon is special to the transverse visual plane. That in selecting the transverse visual plane as the region for his experiments, and in having applied to the field generally the exceptional phenomena special to this region, Hering has committed an error, which is fatal alike to the consistency of his experiments and to the soundness of his conclusions. That the phenomena on which Hering has based his theory are inseparably connected with a near convergence of the eyes, and it may be asserted that similar phenomena cannot occur, the field being viewed with the optic-axes parallel." Mr. Towne's statements are supported by much ingenious reasoning, and references to numerous experiments, some of which are illustrated.

LARGE beds of rock-salt have been discovered by borings, in the neighbourhood of Middlesborough-on-Tees, and shafts are now being sunk with a view to work the valuable deposits. In this we have another example of the mineral character of that north-east corner of Yorkshire. Iron ore and smelting furnaces abound. Mineral waters well-up in sundry places. Alum used to be made at Guisborough, near the foot of Rosebury Topping; and now the rock-salt offers a new resource to a large and busy port, which, forty years ago, was a wild waste with two or three houses only.

IT is perhaps a sign of a wider awakening interest in geology among the Italians, that a new journal—*Bolletino R. Comitato Geologico d'Italia*—was brought out at Florence, at the beginning of the present year. The second number has just appeared. It contains papers and notices on geological and mineralogical subjects, illustrated by engravings, and so far fulfils its purpose of making "better known than hitherto the geology and topography of Italy." We are glad to welcome this new periodical; for the more the Italians become acquainted with the natural resources of their country, the better will it be for all concerned.

BOTANY

Variegation of Leaves

M. EDOUARD MORREN attributes the variegation of leaves to a disease which is contagious and which may also be communicated from one species to another by inoculation, as by the grafting of a variegated plant on to a healthy stock, or even from the stock to a healthy graft. The discoloured or variegated portions of a leaf have lost their power of reducing carbonic acid, the plants are generally weaker and smaller, their flowers and fruit inferior, and they are more liable to be injured by cold. It is the sign of an organic disease produced by various causes, as the deterioration of the seeds, dampness of the ground, want of light, &c. None of the higher classes of plants can exist if entirely deprived of chlorophyll, except such as are parasitic. Some of our common variegated cultivated plants, such as *Pelargonium zonale* and *Hydrangea*, sometimes put out branches which are entirely colourless, but these only live a parasitic life on the rest of the plant. That the disease is an individual one is shown by the fact that it can be propagated by buds, layers, or grafts, even by the insertion of the petiole of an infected leaf beneath the bark; while the seeds of variegated individuals will generally produce healthy and fully-coloured plants. A. W. B.

Dimorphic Leaves of Water-plants

FOLLOWING out his observations on the leaves of *Marsilia* (see NATURE, No. 11 p. 293) Prof. Hildebrand finds that some other water plants exhibit a similar peculiarity, as, for instance, *Polygonum amphibium*, and the common arrow-head, *Sagittaria saggitifolia*, frequently producing, when growing in very deep water, floating leaves of a different form from the ordinary leaves, and exhibiting also differences in structure and in the arrangement of the stomata. In the latter species the floating-leaves are round and heart-shaped, similar to those of a water-lily, instead of arrow-shaped. A. W. B.

THE MARQUIS DE POMPIGNAN asserts that a remarkably fine quality of truffle is cultivated in the vicinity of the Garonne, on a district almost solely arenaceous.

PHYSICS

Phosphorescence of Gases

IT is a well-known fact, the discovery of which appears due to Geissler, of Bonn, that certain highly attenuated gases have the power of remaining luminous for a short time after the interruption of an electric current by which they have been traversed. M. Becquerel attributed this phenomena to the presence of oxygen, either free or combined; M. Morren has since denied that pure oxygen itself can exhibit the electric phosphorescence, but that it does so when mixed with other gases, more particularly nitrogen. Such being the state of the question, M. de la Rive requested M. Edouard Sarasin to execute a series of critical experiments, an account of which appears in the Archives des Sciences physiques et naturelles [135, p. 243] and is summarised in the following paragraphs.

The experiments were made in a large glass jar, 20 centimetres in diameter and 30 centimetres high, which was placed on the platinum plate of a Babinet's air-pump, capable of giving a vacuum of half a millimetre. The electrodes consisted of two brass stems, to the extremities of which were screwed two thin disks of either brass, platinum, or silver. One of them was fixed on the brass screw-plate in the centre of the platinum, the other occupied the middle of the flat glass cover of the jar. They were also connected with the two poles of a Ruhmkorff's coil of medium size, traversed by the current from four Grove's cells. The interior of the jar communicated with (1) a desiccating apparatus, through which the gases were introduced; (2) a manometer reading to 0·04 millimetre, and (3) a brass tube in which were placed chemically pure gases, contained in bulbs which could be broken in a vacuum.

A number of experiments were made with oxygen, both as prepared from potassium chlorate and as yielded by electrolysis. Closing his eyes during the intense and blinding glow of the continuous discharge, and suddenly opening them on the interruption of the current, the observer witnessed, in every case, a pale, whitish glimmer, directed, though but momentarily, over the path of the preceding display. At and below a pressure of three millimetres, but especially at two millimetres, this light fills the whole jar. Simultaneously with this occurrence, ozone is produced, as proved by testing with finely divided silver; whence, as might be expected, the phosphorescence is considerably diminished by employing electrodes of silver. No gas, other than oxygen, exhibits this property. Hydrogen, nitrogen, chlorine, iodine-vapour, ammonia, coal-gas, hydrogen chloride, and even atmospheric air, alike failed to produce it.

When highly concentrated hydrogen sulphate was placed in a capsule on the platinum plate, and nitrogen, air, nitrous oxide, carbon moxide or dioxide was admitted under the usual conditions, a phosphorescence was obtained of greater intensity and larger duration than in any of the other experiments. Here, also, ozone was formed. The presence of silver diminished, the presence of hydrogen entirely obliterated the phenomenon.

Sulphur dioxide gave a feeble but decided phosphorescence. Hydrogen nitrate and nitrogen peroxide showed a weak effect. Carbon monoxide and dioxide were very perceptibly phosphorescent, and still more on the introduction of hydroge sulphate. It was noticed that the addition of this sulphate invariably diminished the conductibility of the gas.

The most curious results were observed with nitrous oxide. During the passage of the spark, at ten millimetres (and even higher) pressure, a narrow jet appears, of a bright rose colour, and exhibiting fine clear striæ. Surrounding the jet is a sheath of the most brilliant yellow mist of eight to ten millimetres in thickness, and perfectly defined. As the jet grows with diminishing pressure, this sheath loses its brilliancy, advances farther in the jar, and, at two millimetres, fills it entirely. At half a millimetre, there is a large rosy jet, with enormous striæ extending to the walls of the jar, all the interstices being filled with yellowish mist. Nitrous oxide shows a phosphorescence at all pressures below ten millimetres. At first this is very bright but only instantaneous, occupying exactly the place previously assumed by the yellow sheath. As the vacuum improves, the phosphorescence becomes more permanent; and ultimately, at one millimetre, and after the interruption of the spark, a yellow mist is visible for three seconds, and is bright enough at first to illuminate surrounding objects very evidently.

The preceding experiments lead the author to infer that oxygen is the sole cause of the phosphorescence in question, which is also and necessarily produced by most oxygenated gases.

SCIENTIFIC SERIALS

Berg-und huttenmannische Zeitung. The last number of this journal contains the following account of a new locality for the mineral Knebelite, by L. J. Igelström, of Filipstadt. For some time Knebelite was only known as occurring at Ilmenau and then it was afterwards discovered at Danemora. During a journey in the year 1866 he discovered it at the Hilläng iron mine in the parish of Ludovika, province of Dalarne, Sweden. It is found there in great quantities, sometimes in masses twelve feet thick. It occurs in the hälleflinta, the ore-bearing rock, in connection with magnetic iron limestone and traces of magnetic pyrites, with all of which it is impregnated. The mineral from Ilmessau and Danemora has a pretty constant composition, containing 30—32 silica, 32—34 protoxide of iron, and 34—35 protoxide of manganese (*vide* Dana, 1868). The composition of the Knebelite from Hilläng, which is somewhat different, is as follows:—

Silica	33·14	with		16·74	Oxygen
Protoxide of iron .	40·96	,,	9·09	15·38	,,
Protoxide of manganese	19·35	,,	4·42		,,
Lime	6·55	,,	1·87		,,
	100·00				

This difference may, perhaps, have been caused by the mineral not being entirely free from intermixed magnetic iron. There is, nevertheless, no doubt whatever, if one compares the external characters, that the Hillängs mineral is the same as that of Danemora, and, indeed, it was this identity of external appearance which occasioned its discovery at Hillängs. Both varieties of the mineral have the characteristic of gelatinising with hydrochloric acid.

IN *The Journal of the Quekett Microscopical Club* for April, is the commencement of an article by Mr. M. C. Cooke, on Microscopic Moulds, restricting the term "moulds" to the *Hyphomycetes*, and including all those filamentous fungi which bear naked spores (sporiferous, in contradistinction to sporidiiferous) at the apex of simple or branched threads. It promises to contain much valuable information. Other interesting papers are by Dr. Braithwaite, on the Geographical Distribution of Mosses; M. de Brebisson, on French Diatomaceæ; and Mr. B. T. Lowne, on the Cornea of the Bee.

THE *Journal of the Ethnological Society* for April contains a valuable report by Lieut. Oliver, R.A., illustrated by several very beautiful lithographs, on the present state and condition of Pre-historic Remains in the Channel Islands. Notwithstanding the wholesale and wanton destruction of these monuments in the Channel Islands within the last half-century, there are nevertheless few localities, Brittany excepted, in which the sepulchral stone structures of the neolithic period can be studied with greater advantage. Lieut. Oliver describes in detail the monuments still remaining in Guernsey, Herm, Serk, Jersey, and Alderney; and notes the remarkable resemblance borne by them to the monoliths and stone tombs of Madagascar, erected by the hill-tribes of Hovas even at this very day. Mr. C. T. Gardner contributes an essay on the Chinese Race, their Language, Government, Social Institutions, and Religion; Mr. G. Busk, a description of, and remarks upon, an ancient *Calvaria* from China, which had been supposed to be that of Confucius; and Mr. H. H. Howorth, a continuation of his article on the Westerly Drifting of Nomades, from the fifth to the nineteenth century.

Geological Magazine, vol. vii. No. 4, April 1870.—This number opens with the first of a series of notices of eminent living geologists, and the editor's choice has worthily fallen upon the veteran Professor Sedgwick. Professor Huxley has a paper, illustrated with a plate, on the milk-dentition of *Palæotherium magnum*. From Professor Rupert Jones we have a series of notes on the Tertiary Entomostraca, containing supplementary remarks and corrections to his monograph of those minute fossils published by the Palæontographical Society in 1856, and including a revised list of the species. The other papers are, an article on the superficial deposits of Belgium, illustrated with a map prepared by Mr. H. M. Jenkins for his paper on Belgian agriculture, published by the Agricultural Society; a notice of the Basaltic Rocks of the Midland Coal-fields, by Mr. S. Allport; a note on the Middle Drift-beds in Cheshire, by Mr. J. E. Taylor; and an extract from a letter of Mr. F. B. Meek to Dr. Bigsby, giving an account of the fossils found in some silver-bearing rocks near Central Nevada, which appear to be of Devonian age. The number contains the usual notices, reviews, reports, and miscellaneous matter.

THE *Revue des Cours Scientifiques* for April 9th is occupied by a sketch of the biological labours of the late Prof. Sars, by Emile Blanchard; a translation of Mr. Andrews' paper, read before the Royal Society, on the continuity of the liquid and gaseous states of matter. The number for April 16th contains a translation of the Anniversary Address before the Hunterian Society by H. J. Fotherby; and a report of a lecture by Claude Bernard on Blood and its General Properties.

IN the *Monthly Microscopical Journal* for April we find a description (with illustrations) by Dr. Carpenter of some peculiar fish's ova, the peculiarities having reference to the shape of the ova, the mode of their attachment to the surface of the shell, and the position and remarkable distinctness of the micropyle; and a description (with plate), by Mr. C. A. Barrett, of a new tube-dwelling stentor, found on a piece of weed taken from the Thames at Moulsford; an article on the polymorphic character of the products of development of Monas lens, by M. Johnson, with others of less importance.

THE *Zeitschrift der Gesellschaft für Erdkunde zu Berlin*, vol. 5, section 1, contains several very interesting papers of travel. An Ascent of the Peak of Teneriffe, by E. Häckel, Sketches of a Journey from Chartum to the Gazelle River, by G. Schweinfurth, both these articles being abundantly full of valuable natural-historical details; a report of the Western-Australian Expedition, by Mr. Forrest, in search of traces of Leichardt; an account of Dr. Nachtigall's Journey to Tibesti, and other shorter articles.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 7.—"On supraannual cycles of temperature in the earth's surface-crust." By Prof. C. Piazzi Smyth, F.R.S. The author presents and discusses here the completely reduced observations, from 1837 to 1869 inclusive, of the four great earth-thermometers sunk into the rock of the Calton Hill, at the Royal Observatory, Edinburgh, by the late Principal Forbes, pursuant to a vote by the British Association for the Advancement of Science. Leaving on one side the several Natural-Philosophy data which have been investigated from smaller portions of the same series of observations both by Principal Forbes and Sir William Thomson, the author applies himself solely to trace the existence of other cycles than the ordinary annual one, in the rise and fall of the different thermometers. Of such cycles, and of more than one year's duration, he considers that he has discovered three; and of these the most marked has a period of 11·1 years, or practically the same as Schwabe's numbers for new groups of solar spots. Several numerical circumstances, however, which the author details, show that the sun-spots cannot be the actual cause of the observed waves of terrestrial temperature, and he suggests what may be; concluding with two examples of the practical use to which a knowledge of the temperature cycles, as observed, may at once be turned, no matter to what cosmical origin their existence may be owing.

"On the Constituent Minerals of the Granites of Scotland, as compared with those of Donegal." By the Rev. Samuel Haughton, M.D., Dubl., D.C.L. Oxon., Fellow of Trinity College, Dublin. This paper contains analysis of Orthoclase from the following localities:—

No. 1. Stirling Hill, Peterhead. Occurs in an eruptive Granite, in veins, in well-developed reddish pink opaque crystals, encrusted with crystals of Albite.—No. 2. Rubislaw, Aberdeen. Large beautiful reddish pink opaque crystals, in veins, associated with white Mica. The Granite of Rubislaw is of metamorphic origin, and different in character from the eruptive Granite of Peterhead. No Albite has been found in it.—No. 3. Peterculter, Aberdeen. In Metamorphic Granite; white, translucent, large crystals.—No. 4. Callernish, extreme west of Lewis. In Metamorphic Granite; in large grey crystals, with a slight shade of pink, translucent.—The Granites of central and western Scotland are metamorphic rocks, like those of Donegal and Norway, with which they are geologically identical; and truly eruptive Granite occurs at only a few localities, as, for example, near Peterhead. The second felspar, associated with Orthoclase in the Metamorphic Granites, is Oligoclase, as in Donegal; while the second felspar associated with Orthoclase in the eruptive Granites, is Albite, as in Mourne, Leinster, and Cornwall. The fact thus indicated by the Scotch Granites is completely in accordance with the mode of occurrence of Oligoclase and Albite in the Irish Granites. (Then follow analyses of two Oligoclases.)—No. 1. This Oligoclase occurs in the Granite of Craigie Buckler, near Aberdeen; it is white and opaque, and so much resembles Cleavelandite in appearance as to have been mistaken for that variety of Albite; its analysis proves it to be Oligoclase. The crystals do not exhibit striation.—No. 2. From the Granite of Rhiconich, in the west of Sutherlandshire; it is greyish white, semitranslucent, in large striated crystals, and resembles the Oligoclase of Ytterby, in Sweden.—Analysis of an Albite which occurs at Stirling Hill, near Peterhead, in eruptive Granite, and is found associated with red Orthoclase in veins. It encrusts the large crystals of Orthoclase, and is semitranslucent; and is generally stained on the surface by peroxide of iron. This mineral is evidently a typical albite. There are two kinds of mica found in the Scotch granites, and both micas resemble very closely the corresponding minerals of the Donegal granites. The specimen of mica analysed came from veins in the granite quarry of Rubislaw, near Aberdeen, and occurs in large plates, associated with red orthoclase. It was carefully examined for lithia, but no trace of this alkali could be found in it. The angles of the rhombic plates were 60° and 120° exactly, and the angle between its optic axes was found to be 70° 30′. The black mica, in large crystals, is very rare, but it seems abundantly disseminated, in minute scales, through most of the Scotch granites. An analysis was made on specimens found near Aberdeen by Professor Nicol, and kindly forwarded to me by him, for the purposes of this paper. This mica was carefully examined for fluorine, and found not to contain any.

Researches on Vanadium. Part III.—Preliminary Notice. By Henry E. Roscoe, B.A., F.R.S.—I.—Metallic Vanadium.—II.—Vanadium and Bromine.—1.—Vanadium Tribromide, VBr_3, molec. wt. = 291.3.—2—Vanadium Oxytribromide, or Vanadyl Tribromide, $VOBr_3$, molec. wt. = 307·3.—The specific gravity of the oxytribromide at 0° is 2·967.—3.—Vanadium Oxydibromide, or Vanadyl Dibromide, $VOBr_2$, molec. wt. = 227·3.—III.—Vanadium and Iodine.—Iodine-vapour does not attack either the trioxide or the nitride at a red heat, both these substances remain unchanged, and no trace of vanadium can be detected in the iodine which has passed over them.—IV.—The Metallic Vanadates.—Sodium Vanadates.—1.—Ortho- or Tri-Sodium Vanadate, $Na_3\ VO_4 + 16H_2\ O_2$.—2.—Tetrasodium Vanadate, $Na_4\ V_2O_7\ 18H_2\ O$.—Lead Vanadates.—1.—Tribasic or Ortho-Lead Vanadate, $Pb_3\ 2(VO_4)$.—2.—Vanadinite, the Double Orthovanadate and Chloride of Lead, $3Pb_3\ VO_4 + Pb\ C_1l_2$.—3.—Basic Dilead Vanadate, $2(Pb_2\ V_2O_7) + Pb\ O$.—Silver Vanadates.—1.—The Ortho-silver Vanadate, $Ag_3\ Vo_4$.—2.—The Tetrabasic Silver Vanadat, $Ag_4\ P_2\ O_7$.

Anthropological Society, April 5.—Captain Bedford Pim, R.N., V.P., in the chair. A paper, by Mr. Hodder M. Westropp, was read, on Phallic Worship. The author, after asserting the spontaneity and independence of certain beliefs and superstitions in the human mind, at all times and in all climates, proceeded to trace out the rise and development of phallic worship as one of the most ancient of those religions that have extensively prevailed among various sections of the human race. In the earlier ages the operations of nature made stronger impressions on the mind of man than in the later periods of his history. There were two causes which must have engaged the attention of the savage observer of nature, the generative and the productive, the active and passive. The author then described what he conceived to have been the process of thought, founded on analogies from the observation of the great forces of nature by the Egyptians, Assyrians, Hindus, Chinese, Phœnicians, Greeks, Romans, the aborigines of America, Australasia, and Polynesia, and on the unquestioned evidence of phallic worship in its various phases belonging to those peoples. That worship was always, among the ancients, of a purely reverential kind, and partook of nothing obscene, either in its teaching or its observance; it was a homage paid to the most potent and most mysterious of the powers of nature.—Mr. C. Staniland Wake then read a paper on the Influence of the Phallic idea in the Religions of Antiquity.

Chemical Society, April 7.—Prof. Williamson, president, in the chair. The following gentlemen were elected Fellows:—F. Andrews, jun., W. Martindale, and A. H. Palmer.—Dr. Divers concluded a paper, commenced in a previous meeting, "On the combination of carbonic acid with ammonia and water." The elaborate and very extensive memoir does not permit of any convenient abbreviation.—Dr. Gladstone communicated a paper "On the refraction equivalents of the aromatic hydrocarbons, and their derivatives." In a previous paper it was shown that the refraction values of organic compounds may easily be calculated when the refraction equivalents of the constituent bodies are known. The present paper enumerates a large number of substances which do not conform to the rule. The so-called aromatic hydrocarbons give, by experiment, higher figures than required by calculation. Dr. Gladstone accounts for this anomaly by regarding the nucleus phenyl, $C_6\ H_5$, as an entity having, like some elements (for instance, iron and phosphorus), the peculiarity of changing its refraction value.—Mr. Hunter, of Belfast, communicated a paper "On Deep-Sea waters," a sequel to a note read before the society in December last.—Messrs. Bolas and Gloves read a note "On Bromopicrin" and announced also the discovery of tetrabromide of carbon.—Prof. How, of Nova Scotia, reports of a feed water occurring at Stellarton, N.S., which contains traces of free oil of vitriol.—For the meeting on April 21st a lecture "On Vanadium," by Prof. Roscoe, is announced.

Ethnological Society, April 12.—Professor Huxley F.R.S., president, in the chair. It was announced that Dr. Bonavia had been elected a member of the Society; Dr. Carl Semper, of Würzburg, an honorary foreign member; and Lieutenant S. P. Oliver, R.A., a corresponding member.—An interesting paper by Hodder M. Westropp, Esq., described very fully the ancient tribal system and land tenure in Ireland under the Brehon laws, and gave rise to a spirited discussion which was sustained by Mr. G. Campbell, Colonel Lane Fox, the president, Dr. Hyde Clarke, and Mr. McLennan.—A communication was then read "On the Danish Element in the population of Cleveland in Yorkshire." The author pointed out that not only many words in the Cleveland dialect and a very large proportion of personal and local names in the district are of Scandinavian origin, but also that many of the idioms in use are markedly Scandinavian. He also sought to trace an old Anglian element in the population. Mr. Jón. Hjaltalin (an Icelander,) Dr. Hyde Clarke, the Rev. Dr. Nicholas, and Col. Lane Fox, took part in the discussion which followed the reading of this valuable communication.

Entomological Society, April 4.—Mr. Alfred R. Wallace, F.Z.S., &c., president, in the chair. Exhibitions were made of *Coleoptera* by Mr. Jenner Weir and Mr. Janson; of *Lepidoptera* by Mr. Jenner Weir and Mr. Howard Vaughan; of *Hymenoptera* by Mr. F. Smith; and *Orthoptera* by the secretary.—The ravages committed in granaries by *Calandra granaria* and *C. oryzæ*, and the means of preventing the same, were the subject of a lengthy discussion, in which Messrs. Jenner Weir, Vogan, Janson, Westwood, McLachlan, F. Smith, and the president took part.—Mr. Albert Müller read a note on the odour of certain *Cynipidæ*, and Mr. G. R. Crotch communicated some observations on British species of *Dasytidæ*.

BIRMINGHAM

Natural History Society.—Geological Section.—A paper on the Igneous Rocks of the Midland Coalfields was read by Mr. S. Allport, F.G.S. The author had examined carefully the mineral constitution of the igneous rocks of the Shropshire, Staffordshire, and Warwickshire coalfields, and also the so-called loadstone of Derbyshire, and was of opinion that they all belonged to the carboniferous age, and in the case of the traps of the coalfields he had no doubt the said traps were contemporaneous and not intrusive. These rocks, now found in patches over the several coalfields of the Midlands were probably all derived from one source, just as the coalfields themselves were probably only remnants of a coalfield of great extent. In conclusion the author made some reference to the nomenclature of igneous rocks, which he said at present was in a very unsatisfactory state.

CAMBRIDGE

Philosophical Society, March 21.—Communications made to the society: 1. By Mr. Röhrs (Jesus College) "On carmine and the colouring principles of cochineal." The author described the process which he had followed in some experiments in making carmine. He found that the presence of carbonate of lime in the water used was essential to success. The hard and shelly (Mexican) cochineal, of a colour inclining to foxy red, made the best carmine. Whitening was a most important ingredient in the process. He then discussed the theory of this, and inferred that two colouring principles existed in cochineal—purpureo-carminic and coccineo-carminic acid, whereof the latter was unstable.—2. By Mr. Lewis (Corpus Christi College), "On a Roman Lanx and other antiques found at Welney." The lanx was found about four feet below the surface. It was a specimen of the flat dish bearing this name, which often was of great size. Pliny mentions one weighing 500lbs. The metal of that exhibited (according to an analysis made by Prof. Liveing) was 80 per cent. tin, 18·5 per cent. lead. In the centre was an elaborate pattern in a circle, with letters at equal distances in angles of the pattern. This had been read "VTERE FELIX." The reading, however, was doubtful. The author then commented upon other antiques of bronze, stone, and horn, from the same neighbourhood.

DERRY

Natural History and Philosophical Society, March 4.—William Harte, C.E., F.R.G.S.I., president, in the chair. Mr. Harte communicated some observations on a remarkable meteor which passed over Donegal on the night of the 27th of December last; also a notice of a beautiful Aurora Borealis.—Mr. C. W. Dugan, M.A., read a paper on the "Gold Antiquities of Ireland," illustrated by drawings. In this paper he endeavoured to controvert some views adverse to the very early civilisation of Ireland; also some opinions advanced as to the source of gold from which the massive and gorgeous ornaments brought under notice had been fashioned. In connection with this paper there were exhibited some specimens of Irish ring money, &c., as also some splendid amber beads found on the property of Dr. Forsythe, and now in his possession.—Mr. Harte exhibited and made a few observations upon some beautiful cinerary urns found at Grange, near Strabane, and at Malins, Donegal. It is remarkable that a large urn and a small one were found together. These specimens are in good preservation. The black burnt ashes were adhering quite fresh to the sides of one of them.

EDINBURGH

Scottish Meteorological Society, March 30.—Admiral Sir William Ramsay in the chair. Dr. Keith Johnston read a paper "On the temperature of the Gulf Stream in the North Atlantic Ocean." He began by saying that he had read a paper on the Gulf Stream at the half-yearly meeting of the society in January 1862, which embodied the results of observations made in the Iceland seas by Captain Irminger, of Denmark. That paper attracted the attention of meteorologists, and the result was that new stations had been established by the society in Iceland and the Faroe Islands, each of them supplied with the best instruments, placed at the disposal of the council by the Board of Trade. The Meteorological Institute of Norway has, during the past three years, made observations of the temperature of the sea at the lighthouses round the coast as far north as 71°·6′ lat. N., and on board ships engaged in the Arctic fisheries. From these observations, together with those made at different stations off the Scottish coast, in Faroe, and in Iceland, Professor Mohn of Christiania, has just published a memoir on the temperature of this part of the Atlantic, illustrated by five charts for the four seasons of the year. The five charts exhibited were based on Professor Mohn's. The singular distribution of the temperature of the sea between Iceland, Scotland, and Norway must, as M. Mohn observes, be regarded as the best representation of the course and the extent of the Gulf Stream in these parts. The line designated as the thermal axis indicates the direction of the principal axis of the current. It is along this axis that the warm waters of the Gulf Stream are pushed forward by the current to the latitude of the North Cape and Spitzbergen. At the same time, the water is cooled as it advances, either from the effect of latitude or from the loss of heat experienced on both sides in beating the coast of Norway and in melting the ice of the sea between Greenland and Spitzbergen. The distribution of temperature during the summer months, being dominated by the solar heat, the isotherms of the sea have a greater tendency to follow the parallels of latitude. The thermal axis is, as it were, thrown on the shores of Norway, where it may be followed to the west coast of Spitzbergen and Nova Zembla. The distance of the thermal axis of the Gulf Stream from the west coast of Norway being not more than 125 miles, its effect on the climate of that country must be very remarkable. Thus we find that the west coast during winter has a temperature of the air which surpasses by from 40° to 50° that due to corresponding latitudes, if there were no current of warm water. On the shores of Norway round to the frontiers of Russia, the current of the sea is directed generally towards the north and east; and, carried by the current to this far northern region, products of the vegetable kingdom are often found which had their origin in the West Indies—a fact which proves beyond all question the existence of a north-eastern branch of the Gulf Stream thus far into the Arctic Ocean. Mr. Buchan said that, to illustrate the effect of winds upon the currents, he had looked into the question of the temperature of the air at various stations as compared with that of the sea. Over the whole of Scotland and as far west at least as Faroe, the winds were south-west in winter, there being very few easterly or north-easterly winds. In Iceland a different state of things prevailed, the mean direction of the wind being east-north-east. On the west coast of Norway, the prevailing direction was uniformly south-east, or south-south-east, that is to say the winds blow to a considerable extent off the land, where at that season the temperature is exceedingly low. In summer the winds in Iceland continue easterly, with some northing in them; but in the north of Scotland they prevail more from the west. On the coast of Norway, the summer winds take the opposite direction to those prevailing in winter. The same holds good in the south and north of Norway, where the difference was 4° in favour of the sea.—Mr. Buchan read a paper on the cold weather of May 1869. Mr. Buchan said the temperature of Scotland during May 1869, was 45·1°, which was 4·7° below the average of May in the past thirteen years, and 2½° lower than any previous May recorded.

Royal Society, March 21.—Prof. Kelland in the chair. Dr. Keith Johnston communicated a paper by Mr. Keith Johnston, jun., on the "Lake Region of Eastern Africa." See abstract of this paper in NATURE, No. 24, p. 607.

Royal Physical Society, March 23.—Professor Duns, D.D., president, in the chair. The following communications were read:—On *Crocodilus biporcatus* (Cuvier), the Muggar. By Professor Duns, New College, Note on the Capture of the Grey Seal (*Halichœrus grypus*) in the Firth of Tay. By Professor Turner. Note on the Preservation of Minute Animals in Acetic Acid. By T. Strethill Wright, M.D. Notice of an instance of Double or Vertical Hermaphrodism in a Cod Fish (*Gadus morrhua*). By John Alex. Smith, M.D.

Botanical Society, March 10.—Sir Walter Elliot, president, in the chair. On the Formation of a Museum of Vegetable Materia Medica. By William Craig, M.B. and C.M. On the Fructification of *Griffithsia corallina*, with a notice of the other *Algæ* found in Shetland, not mentioned in Edmonston's Flora. By C. W. Peach, A.L.S. On Two New British Hepaticæ. By Dr. B. Carrington. On the occurrence of *Luzula arcuata* and *Buxbaumia indusiata*, in Inverness-shire. By Dr. Buchanan White. On some recent Additions made to the Flora of Canada. By Mr. Sadler. Report on the Open-air Vegetation at the Royal Botanic Gardens. By Mr. M'Nab.

GLASGOW

Natural History Society, April 5.—Prof. J. Young, M.D., president, in the chair. The following papers were read:—1. "On shell mounds at the Machar Grogary, South Uist," by James A. Mahony. This paper was illustrated by a large collection of objects, chiefly shells of various kinds, bones of a number of animals, some of them drilled with holes, others split longitudinally, stone knives or scrapers, pieces of rude pottery, and other articles of a like nature, usually found in these refuse heaps. At the close of the paper, Prof. Young dwelt at some length in comparing these Hebridean mounds with what had been examined in the Eastern counties, especially in Caithness. 2. "On the sea anemones of the shores of the Cumbraes," by David Robertson, F.G.S. The author gave a complete list of the species taken by himself in that most interesting locality, and exhibited several living anemones in illustration of his paper.

MANCHESTER

Literary and Philosophical Society, April 5.—Dr. J. P. Joule, F.R.S., president, in the chair.—"Description of a New Anemometer," by Mr. Peter Hart. It consists first of a base board furnished with levels and levelling screws; to this is hinged the board carrying the U tube, which may be called the sloping base; on this sloping base is secured the U tube furnished with a scale and vernier capable of being read to the $\frac{1}{100}$ inch. By means of a screw passing through the sloping base, and resting on the lower base board, the former can be made to assume any angle with the latter, the angle being determined by a quadrant fixed to the lowest base board.

Mr. W. Boyd Dawkins, F.R.S., described the results of the preliminary investigation undertaken by the Settle Cave Exploration Committee. Mr. W. L. Dickinson read a paper "On the Eclipse of the Sun, Dec. 21—22." A paper was also read "On the Influence of Changes in the character of the Seasons upon the Rate of Mortality," by Joseph Baxendell, F.R.A.S.

PARIS

Academy of Sciences, April 11.—A memoir, by M. C. Antoine on screw propellers, was presented by M. Laugier. The author examined the two main questions relating to the employment of the screw-propeller, viz., the number of turns obtained by means of a given motive power, and the advance made by the vessel for each turn of the screw.—M. Cahours presented a note by M. L. Daniel, on the action of magnetism upon two currents passing simultaneously through rarefied gases. The author found that when the currents are passing in opposite directions magnetism separates them even in capillary parts of the tubes; when they are in the same direction, they are attracted or repelled like a single current. The magnetic properties of the gases have nothing to do with the condensation of the light by the magnet, which acts upon the current itself.—Notices of the Aurora Borealis of the 5th April were communicated:—From Angers by M. C. Dechanne, from Paris by M. Tremeschini, from Le Mans by M. Charault, from Louvain by M. Terby, from Auvers by M. Geslin, from Vendôme by M. Guerreau, from Betz by M. Fortier-Garnier, from Rohrbach by M. Gramant, from St. Lo by M. Lepingard, and from Loget-sur-Seine by M. Lagoret.—A memoir by M. C. Flammarion on the law of the movement of rotation of the planets, was communicated by M. Delaunay. From his calculations the author deduced the following as the law of the diurnal rotation of the planets:—*The time of rotation of the planets is a function of their densities.*

The rotatory movement of the planets upon their axis is an application of gravitation to their respective densities, and is equal to the time of revolution of a satellite placed at a distance 1, multiplied by a co-efficient of resistance representing the density of the planetary body, which is at the same time the square root of the relation of its weight to the centrifugal force. The squares of these co-efficients are equal to the cubes of the distances at which satellites would gravitate in the period of rotation of each planet, and the distance at which a synchronous satellite would gravitate round each planet is the cube root of the centrifugal force, and marks the theoretical limit of any atmosphere. By applying his law to the planets Uranus and Neptune, the author deduced a diurnal rotation of $10^h\,40^m$ for the former, and of $10^h\,58^m$ for the latter.—Facts towards the history of nitric acid by M. E. Bourgoin, were commnnicated by M. Bussey. The author described the decomposition of nitric acid at different degrees of dilution by the galvanic current. He regarded the formula of nitric acid as NO^5, $2\,H^2O^2$. With the acid in a very diluted state, only hydrogen was evolved from the negative pole; as the strength of the solution was increased the hydrogen evolved reacted upon the nitric acid, and caused the production of ammonia, free nitrogen, deutoxide of nitrogen, and nitrous acid, according to circumstances. With 15 equivs. of water nitrous acid remains in solution.—M. H. Sainte Claire Deville presented a note by M. Deschamps, on the metallic tartrates, in which the author described the preparation and characters of a double tartrate of sesquioxide of manganese and potash, having the formula: $Mn\,^2O^3\,KO$, $C^8H^4O^{10}$, $4\,HO$.—M. P. Duchartre read some observations on the turning of certain fungi. The author described a case in which numerous examples of an agaric (probably *Coprinus radians*, Desmaz.) grew in perfect darkness from the bottom of a water tank, and consequently in a reversed position. They were all upon the southern portion of the tank, but their stems sloped towards the north, and in the mature examples were bent upwards at an angle towards their summits, so as to bring the head into its natural position with the hymeneal lamellæ downwards. The author cited also some experiments made with *Claviceps purpurea*, specimens of which placed in a reversed position curved upwards towards maturity, and thus brought their heads into the natural position. He considered these observations, especially the former, to be strongly opposed to the mechanical theories of the direction of growth in plants.—A note was read by M. H. Baillon, on the dissemination of the stones of *Dorstenia contrayerva*. The author noticed the structure of the fruit in *Dorstenia* and the allied plants, which he stated to consist of a number of small drupes. He stated that the parenchyma of each drupe is much more developed towards the base, and that the cells composing it acquire a great amount of elasticity, which, acting upon the stone when this is set free by the lesion of their upper part, projects it to a considerable distance.—M. Dumas in presenting M. Pasteur's great work on the diseases of silkworms, gave an excellent summary of its contents; and M. Guyon accompanied the presentation of his natural history of the chigoe (*Rhynchoprion penetrans*, Oken), with an elaborate analysis of the work.—M. Roulin communicated a note containing observations on the chigoe, supplementary to M. Guyon's remarks.—M. A. Duméril presented an account of the production of a white race of axolotls at the menagerie of the Museum, with some remarks on the transformations of those batrachians. The white race of axolotls has been established by breeding from ordinary females with an albino male, and again breeding from pale-coloured females thus produced with the same male. Some of the white individuals have undergone their complete transformation. The author stated that hitherto the transformed axolots (*Amblystoma*) have never propagated, and that an examination of their sexual organs showed ova and spermatozoids in plenty, but not in the perfect condition. The generative products seemed to have undergone an arrest of development at the metamorphosis.—A note by M. E. Duchemin was read, describing a singular cause of the death of carp in a piece of water at Montigny. The fish thrive in this water, but every spring a considerable number are found dead, and all these are blind. This blindness is ascribed by the author to the attacks of toads, which fix themselves upon the heads of the fish, and do not quit their hold even when taken out of the water. As remarked by the Secretary of the Academy, this habit of the toad has been long known.—M. C. Robin presented a note by M. Legros on the real origin of the secretory canals of the bile.—M. Guyon presented statistics of the cases of hydrophobia observed among Europeans in Algeria from 1830 to August 1851.—A note on the operation of artificial pupil, by M. Liebreich, with figures of an instrument employed in the operation, was communicated.—Of several other papers no particulars are given.

Brussels

Royal Academy of Belgium, March 5.—The following papers were read:—1. On the Aurora Borealis in the months of January and Febuary 1870, by M. A. Quetelet.—2. On commensalism in the animal kingdom, by M. P. J. Van Beneden. The author distinguishes under the name of commensalism those cases in which one animal lives upon another, but not at its expense. In the present paper he described some new examples of this phenomenon. On the authority of M. Alex. Agassiz, he noticed a *Lepidonotus* which lives near the mouth of *Asteracanthion ochraceus*, Brandt, a small *Clupea* which resides among the fringes of a Pelagian Medusa (*Dactylometa quinquecina*, A. Agass.), a species of Hirudinea which lives in a Beroid (*Mnemiopsis Leydii*), a *Philomedusa*, (named *Biccidium* by L. Agassiz) which haunts the buccal fringes of the great *Gauea arctica*, a *Hyperina* which infests the disc of the American *Aurelia*, and a *Planaria* (*P. angulata* Müll,) which attaches itself to the lower surface of the King Crab, near the base of the tail. M. Agassiz also states that the young *Comatulæ* like to affix themselves to the basal cirri of the adults. M. Van Beneden also noticed, on the authority of Risso, that the Fishing Frog (*Lophius*) lodges a species of Murænid (*Apterichthys oculata*) in its great branchial sac. He referred to the polype, which so generally coats specimens of *Hyalonema*, as furnishing an example of commensalism, and in connexion with *Hyalonema* as a Sponge reaffirmed his opinion that Sponges represent the polype type reduced to its simplest expression; a notion very like that which has lately been put forward by Häckel.—3. Remarks on the equation $x^m - 1 = 0$, by M. E. Catalan.—4. Note on the nature of the sun, by M. G. Bernaerts, in which the author maintained that the sun consists of a gaseous nucleus covered with a thin, incandescent liquid layer and luminous clouds.—5. On the meteoric stone which fell at Saint Denis-Westrem, near Ghent, on the 7th June 1855, by Dr. Stanislas Meunier. The author stated that the material of this meteorite, of which a portion, weighing 723 grammes, was picked up, is identical with that of many others, including the meteorite of Lucé (1768), whence he proposes to call it *lucéite*. He gave the analysis of another stone, which fell in the Lower Pyrenees in 1868, and remarked upon the occurrence of *lucéite* in various brecciiform meteorites, associated in some with an oolitic mass which he denominated *montrejite*, from the stone of Montrejeau (1859), and which, in other meteorites occurs alone. The author maintained that the formation of meteorites is due to the natural breaking up of larger celestial bodies at the close of their development, and that the moon is now approaching this stage of its existence.—6. On Bryonicine, a new nitrogenous substance extracted from the roots of *Bryonia dioica*, by MM. L. de Koninck and P. Murgart.—This was described as of a very pale, yellow colour, crystallising from dilute alcohol in slightly flattened and irregularly intermixed needles, neutral, insoluble in cold water, potash, ammonia and dilute mineral acids, soluble in alcohol, ether, &c., and in glacial acetic acid, and concentrated sulphuric acid, with the last giving a blood-red solution. The formula was stated to be $C^{19}H^{16}N^2O^9$.—7. Investigations on the embryogeny of the Crustacea, by Dr. E. Van Beneden.—In this paper the author described in detail the development of the genera *Anchorella, Lerneopoda Brachiella and Hessia*, the last-named a new genus.—8. Discovery of a deposit of phosphate of lime beneath the town of Louvain, by Prof. G. Lambert. This bed was discovered in 1869, in boring an artesian well; it commenced at a depth of 105-50 mm., and was 5 mm. in thickness, containing nodules of phosphate of lime like those worked for manure in this country.

Vienna

Imperial Academy of Sciences, Feb. 17 (continued from p. 618).—11. Prof. Brücke communicated the results of his investigations of the digestive products of the albuminous bodies.—12. Experimental investigation on the diffusion of the gases without porous septa by Prof. Loschmidt. The author had investigated the rapidity of diffusion of two gases superimposed in layers and in contact upon a horizontal plane. His experiments related to air and carbonic acid, carbonic acid and hydrogen, and hydrogen and oxygen. Their chief result is the law of the proportionality of the constants of diffusion with the squares of the respective absolute temperatures.—13. Project for preliminary operations in connection with the transit of Venus in 1874, by Dr. G. Neumayer, in which the author discussed at considerable length the measures to be taken in the observation of that important phenomenon.—14. Prof. E. Ludwig noticed an investigation made by himself and Dr. C. Graebe upon some derivatives of napthaline allied to the chinones.—In presenting the fourth part of Dr. Manzoni's "Bryozoi fossili Italiani," Prof. Reuss noticed its contents, which include the descriptions of twenty-four species of fossil *Chilostomatous Bryozoa*, partly from the pliocene of Calabria and Castellarquato and partly from the miocene of Turin, &c. Nine species are described as new. This part also contains a critical examination of all the Italian fossils of this class. The report of the observations made during February at the Central Institution for Meteorology and Terrestrial Magnetism was communicated.

Imperial Geological Institution, March 16.—M. C. Griesbach, in a letter dated Port Natal, January 3, 1870, relates that he found fossils in the sandstone of the Table mountain. On a journey into the Griqua-land, he discovered also a large series of very well-preserved fossils, which he thinks belong to the Tithonic series.—Baron O. Petrino, On the origin of the Löss. Researches in the territories of the Dniester, the Pruth, and the Sereth rivers have led the author to the following conclusions:—(1) The Löss is the product of slowly running rivers, deposited from the upper part of the mass of water which during inundations overflows the surrounding country; (2) the time of its formation begins with the end of the glacial period, and has continued up to the present day; (3) within the löss-deposits layers of different periods are, locally, easily to be distinguished. The old river terraces and banks of pebblestone and sand are the product of quicker running rivers, which excavate their bed more rapidly. They are contemporaneous with the löss-deposits.—Dr. Bunzel exhibited a series of fossil bones from the upper chalk formation of Grünbach, near Neunkirchen in Austria. They form one of the most interesting palæontological discoveries which we have met with in the last few years. Dr. Bunzel recognised among them remains from animals of the families of the *Crocodilians*, *Lacertilians*, *Dinosaurians*, and *Chelonians*. The *Lacertilians* are especially represented by a new genus very nearly allied to the gigantic *Mosasaurus* from Mästricht, which genus has received the name *Danubiosaurus*. To the *Dinosaurians* belongs a new species of *Iguanodon*, *I. Suessi* Bunz. A very peculiar type is indicated by a skull of a saurian, in many respects resembling that of a bird, which he has called *Struthiosaurus*.—Charles von Hauer, On the deposit of Potassium-salts at Kalusz (Galicia). They form a layer seventy feet thick. The whole mass contains on an average 15·5 per cent. potassium, and consists of a mixture of the mineral species, kainit, sylvin, and salt. The presence of sulphuric acid renders it more suitable for all industrial purposes than the well-known layer of Stassfurth, Prussia.—D. Stur has shown by an accurate examination of a large series of fossil plants, that the red sandstones of the Banat belong to the Permian (Dyas) formation, and that the coal-measures below it belong to the fifth or fern-zone (Geinitz) of the carboniferous formation.

Anthropological Society, March 22.—Prof. Rokitansky in the chair. Prof. Müller on the origin of the writing of the Malayan peoples. The author argued against the views defended especially by the English ethnologist, Crawfurd, the famous Malayan scholar, that the Malayan alphabets (the writing of the Battak, the Redschang, Lampong, Bugi, Makassar, and Tagulo peoples) are an independent invention. By the form of the single letters, as well as by the manner used to indicate the vowels, he proved that these alphabets originate from the old Indian writing which is to be found in the Buddhistic inscriptions. In connection with this question he spoke also of the origin of the Indian writing generally, and by a comparison of the old Indian with the Malayan alphabets, he comes to the conclusion that the Indian writing originated from an old Semitic alphabet. He remarked especially on the close relation between the language and the writing, and pointed out the progress which the people made by developing the writing with syllables (Silbenschrift) to a pure sound-writing (Lautschrift).—Franz v. Hauer offered to the society a large series of pre-historic archæological objects found in different parts of the Austro-Hungarian monarchy. Of very high interest among them are stone (Obsidian) implements, recently discovered by H. Wolf in the environs of Tokaj (Hungary). They have been found in many different spots, partly actually on the surface, partly in a particular stratum, covered with a bed eight feet thick of quicksand. The implements are not polished, they are accompanied by fragments of very rude vessels, by bones, and rarely by metal objects. The analysis of one of the latter, made by A. Patera, gave in 100 parts 63·75 silver, 32·5 copper, 2·0 tin, 0·125, gold, and traces of iron. The collection contains further perfectly well preserved rude vessels from Morovan near Pistyan in Hungary, fragments of similar vessels from Waitzen on the Danube, many objects from Olmütz, &c., Von Hauer remarked besides that all the remainder belong to the alluvial period, and that we have hitherto possessed very few indications of the existence of man in the diluvial (postpliocene) period in Austria. Count T. Wilczek dedicated to the society a sum of 2,000 flor. (200 l. sterl.) for excavations in the celebrated sepulchral field of Hallstatt, and for an exploration of the lakes of Upper Austria for pile-buildings.

DIARY

THURSDAY, April 21.

Linnean Society, at 8.—On the Vertebrate Skeleton: Mr. St. George J. Mivart.
Chemical Society, at 8.
Numismatic Society, at 7.

FRIDAY, April 22.

Quekett Microscopical Society, at 8.

MONDAY, April 25.

Royal Geographical Society, at 8.30.
London Institution, at 4.

TUESDAY, April 26.

Royal Institution, at 3.—On Moral Philosophy: Prof. Blackie.
Ethnological Society, at 8.—On the Philosophy of Religion among the Lower Races of Mankind: Mr. E. B. Tylor.—On the Brain in the Study of Ethnology: Dr. Donavon.
Society of Antiquaries, at 2.—Anniversary Meeting.

WEDNESDAY, April 27.

Society of Arts, at 8.
Geological Society, at 8.

THURSDAY, April 28.

Royal Institution, at 3.—Electricity; Prof. Tyndall.
Royal Society, at 8.30.
Zoological Society, at 8.30.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

*"To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH

No. 26] THURSDAY, APRIL 28, 1870

THURSDAY, APRIL 28, 1870.

WHAT IS ENERGY?

It is only of late years that the laws of motion have been fully comprehended. No doubt it has been known since the time of Newton that there can be no action without reaction; or, in other words, if we define momentum to be the product of the mass of a moving body into its velocity of motion, then whenever this is generated in one direction an equal amount is simultaneously generated in the opposite direction, and whenever it is destroyed in one direction an equal amount is simultaneously destroyed in the opposite direction. Thus the recoil of a gun is the appropriate reaction to the forward motion of the bullet, and the ascent of a rocket to the downrush of heated gas from its orifice; and in other cases where the action of the principle is not so apparent, its truth has notwithstanding been universally admitted.

It has, for instance, been perfectly well understood for the last 200 years that if a rock be detached from the top of a precipice 144 feet high it will reach the earth with the velocity of 96 feet in a second, while the earth will in return move up to meet it, if not with the same velocity yet with the same momentum. But inasmuch as the mass of the earth is very great compared with that of the rock, so the velocity of the former must be very small compared with that of the latter, in order that the momentum or product of mass into velocity may be the same for both. In fact, in this case, the velocity of the earth is quite insensible and may be disregarded.

The old conception of the laws of motion was thus sufficient to represent what takes place when the rock is in the act of traversing the air to meet the earth; but, on the other hand, the true physical concomitants of the crash which takes place when the two bodies have come together were entirely ignored. They met, their momentum was cancelled—that was enough for the old hypothesis.

So, when a hammer descends upon an anvil, it was considered enough to believe that the blow was stopped by the anvil; or when a break was applied to a carriage-wheel it was enough to imagine that the momentum of the carriage was stopped by friction. We shall presently allude to the names of those distinguished men who have come prominently forward as the champions of a juster conception of things, but in the meantime let us consider some of those influences which served to prepare men's minds for the reception of a truer hypothesis.

We live in a world of work, of work from which we cannot possibly escape; and those of us who do not require to work in order to eat, must yet in some sense perform work in order to live. Gradually, and by very slow steps, the true nature of work came to be understood. It was seen, for instance, that it involved a much less expenditure of energy for a man to carry a pound weight along a level road than to carry it an equal distance up to the top of a mountain.

It is not improbable that considerations of this kind may have led the way to a numerical estimate of work.

Thus, if we raise a pound weight one foot high against the force of gravity we may call it one unit of work, in which case two pounds raised one foot high or one pound raised two feet high would represent two units, and so on. We have therefore only to multiply the number of pounds by the vertical height in feet to which they are raised, and the product will represent the work done against gravity. The force of gravity being very nearly constant at the earth's surface, and always in action, is a very convenient force for this purpose; but any other force, such as that of a spring, would do equally well to measure work by. Generalising, we may say, *the space moved over against a force multiplied into the intensity of that force will represent the quantity of work done.* So much for the definition of work, and it is necessary to know what *work* is before proceeding to define *Energy*.

Now what does the word Energy really mean? In the first place it does not mean force.

Two substances may have an intense mutual attraction, in virtue of which they form a very intimate union with one another; but when once this union has been consummated, although the force still continues to exist, the combination is singularly deficient in Energy. Nor does Energy mean motion, for although we cannot have motion without Energy, yet we may have Energy without motion.

By the word Energy is meant the power of doing work; and the energy which a labouring man possesses means, in the strictly physical sense, the number of units of work which he is capable of accomplishing.

This is a subject which at this stage we may attempt to illustrate by reference to a very different department of knowledge.*

The analogy which we shall venture to institute is between the social and the physical world, in the hope that those who are more familiar with the former than with the latter may be led to perceive clearly what is meant by the word Energy in a strictly physical sense. Energy in the social world is well understood. When a man pursues his course, undaunted by opposition and unappalled by obstacles, he is said to be a very energetic man.

By his energy is meant the power which he possesses of overcoming obstacles; and the amount of this energy is measured (in the loose way in which we measure such things) by the amount of obstacles which he can overcome—the amount of work which he can do. Such a man may in truth be regarded as a social cannon-ball. By means of his energy of character he will scatter the ranks of his opponents and demolish their ramparts. Nevertheless, a man of this kind will sometimes be defeated by an opponent who does not possess a tithe of his personal energy. Now, why is this? A reply to this question will, if we do not mistake, exhibit in a striking manner the likeness that exists between the social and the physical world. The reason is that, although his opponent may be deficient in personal energy, yet he may possess more than an equivalent in the high position which he occupies, and it is simply this position that enables him to combat successfully with a man of much greater personal energy than himself. If two men throw stones at one another, one of whom stands at the top of a house and the other at the bottom, the man at the top of the house has evidently the advantage.

So, in like manner, if two men of equal personal energy contend together, the one who has the highest social

* The subject has previously been discussed from this point of view by Messrs. Stewart and Lockyer in an article in *Macmillan's Magazine*, August 1868.

position has the best chance of succeeding. For this high position means energy under another form. It means that at some remote period a vast amount of personal energy was expended in raising the family into this high position. The founder of the family had, doubtless, greater energy than most of his fellows, and spent it in raising himself and his family into a position of advantage. The personal element may have long since disappeared from the family, but not before it had been transmuted into something else, in virtue of which the present representative is able to accomplish a great deal, owing solely to the high position which he has acquired through the efforts of another. We thus see that in the social world we have what may justly be termed two kinds of energy, namely :—

1. Actual or personal energy.
2. Energy derived from position.

Let us now again turn to the physical world. In this, as in the social world, it is difficult to ascend. The force of gravity may be compared to that force which keeps a man down in the world. If a stone be shot upwards with great velocity, it may be said to have in it a great deal of actual energy, because it has the power of doing useful work or of overcoming up to a great height the obstacle interposed by gravity to its ascent, just as a man of great energy has the power of overcoming obstacles. But this stone as it continues to mount upwards will do so with a gradually decreasing velocity, until at the summit of its flight all the actual energy with which it started will have been spent in raising it against the force of gravity to this elevated position. It is now moving with no velocity—just, in fact, beginning to turn—and we may suppose it to be caught and lodged upon the top of a house. Here, then, it remains at rest, without the slightest tendency to motion of any kind, and we are led to ask what has become of the energy with which it began its flight? Has this energy disappeared from the universe without leaving behind it any equivalent? Is it lost for ever, and utterly wasted? But the answer to this question must be reserved for another article.

BALFOUR STEWART

LEGISLATION AND NATURE

THE effect of Legislation upon Nature is one of those far-reaching subjects which men are only just beginning to investigate in a practical spirit. It is, of course, only a minor branch of the larger question of man's influence upon all external life and forms, but it has its special attractions, nevertheless, and may be pursued to advantage as an independent study. Incidentally, it illustrates many other problems. The diminutiveness of the Hindu cow, for example, may be due as much to the legislation which has made the domesticated animal sacred as to the nature of the climate of Hindustan. It is quite possible the oxen of this country would not have exhibited such a variety of forms and sizes had we selected one species and made it sacred some two or three thousand years ago. Take, again, the subject of maritime canals, which is now in its infancy. The Suez Canal has not existed long enough to have had any appreciable effect, either in modifying the coast-lines of the Mediterranean, or in creating any interchange of marine species; but it is likely enough to be one of a series, and we cannot predict what may be their effects. The diversion of the Nile may prove a serious matter, and now the Darien scheme has revived, a great impetus has been given to speculation, so that an ingenious projector has actually sketched a canal which should unite the Bristol Channel with the English Channel. Two more illustrations may suffice to make my meaning clear. There seems little apparent connection between woods and national greatness, but, nevertheless, the relation is a real one. When Spain lost the empire of the seas, she lost it from two causes—impoverished finances, due to a speculative trade in precious metals, and want of woods to build her ships. Her people had a foolish prejudice against trees, and an arid climate and reduced shipbuilding were the results. From Danzig to Pillau once stretched a thick pine forest. When King Frederic William I. was in want of money, one Herr Von Korff recommended its destruction. The experiment was a financial success, but the State was injured by it. As Willibald Alexis states, "the sea-winds rushed over the bared hills; the Frische Haff is half choked with sand; the channel between Elbing, the sea, and Königsberg is endangered; and the fisheries in the Haff injured. The operation of Herr Von Korff brought the King 200,000 thalers. The State would now willingly expend millions to restore the forests again."

Neither directly nor indirectly, in fact, can we touch nature by our laws, without beginning a new chain of causes, the end of which we cannot foresee. The consequences of human volition are always a little wonderful. When the treasures of Thorwaldsen were packed up in Rome, it was not dreamed that new plants would be conveyed to Copenhagen in the grasses of the Campagna, any more than Clusius, the first European writer who mentions the potato, could possibly foresee that half the miseries of Ireland would spring from its exclusive cultivation. What we owe to our game-laws, again, is a boundless subject which might be investigated by a naturalist with profit.

My immediate purpose, however, is—strange as it may seem—with Mr. Lowe and his Budget. He deserves to be styled a real friend to the farmer, though apparently he has only given him a restricted use of germinating barley. Readers of Darwin will remember how he traces the connection between the number of cats in a given locality, and the number of humble bees, and the abundance of red clover and heartsease. Well, Mr. Lowe's Budget starts a similar House-that-Jack-built. The freedom of firearms from taxation affects their number in any district, the number of guns determines the number of our small birds, and the number of our small birds affects the immunity of our fields from grasshoppers, cricket-moles, beetles, locusts, slugs, &c. Mr. Lowe was concerned for the security of life, for the prevention of early quasi-poaching habits, but his 1*l.* tax may effect a revolution all the same. It is no longer a secret, that wherever a persistent warfare is carried on against small birds—against martins, blackbirds, sparrows, larks, &c.—vegetable life is sure to suffer. In the Isle of Bourbon, as M. Michelet tells us, the martin was exterminated, and a plague of grasshoppers followed; in Hungary, the sparrow was proscribed, until this valiant militia of the fields had to be recalled; in the neighbourhood of Rouen, the blackbird was shot down without mercy, and many a meadow's turf could be rolled up like a carpet; and in this country we had, until lately, our sparrow clubs, which paid for little victims at so many a dozen, just as two or three hundred years ago some of our pious churchwardens used to purchase hedgehogs of truant schoolboys in the rural districts, a lamentable increase of pestiferous insects being the consequence. The Rev. Charles Kingsley gives us a more recent example. In Trinidad, the free negro has been banging away at the small birds, partly for his own pleasure, and partly to supply the London markets and our ladies' hats. What has been the consequence? "Already the turf of the savannah, or public park, close by, is being destroyed by hordes of mole-crickets, almost exactly like (strange to say) those of our old English meadows; and unless something is done to save the birds, the canes and other crops will surely suffer in their turn. A gun-licence would be, it seems, both unpopular and easily evaded in a wild forest country. A heavy export tax on bird-skins has been preferred" (*Good Words*, April). A single pair of swallows, says M. Michelet, carry every week to the nest 4,300 caterpillars or *coleoptera*. The blackbird is a notorious insect-eater, and consumes hundreds of imperfect insects every day, to say nothing of worms and slugs. The common sparrow is a vivacious feeder, and somewhat dainty withal, but it makes great havoc with young worms and soft insects. All our field birds, in short, troublesome and non-melodious as many of them are, rid us of millions of fast breeding insects which would otherwise do incalculable injury to our vegetation, and could not well be destroyed by artificial means. Indeed, we disturb a natural arrangement when we step in and decimate a predatory class without also destroying their victims, and therefore it is gratifying to find Mr. Lowe putting a check upon amateur sportsmen, who bang away, reckless of consequences either to themselves or others. A little time ago we agreed to protect our sea-birds, because we found they showed us "schooling" fish, and warned our seamen from dangerous rocks in misty weather. This time our legislation is less direct. We have not had a select committee on the sparrow—there are plenty of chatterers in the House of Commons who might be "sat upon" to advantage; we have not even anticipated a Ministry of Agriculture by investigating the sources of injury to growing crops; but we have been moved by social advantages, and the bright-eyed broods of field and wood will profit by our sense of security and our desire to equalise taxation.

A word on another topic. The rating of woods and plantations is threatened. It is part of the very question I have so hastily touched upon. Wherever farms are very bare of trees, insects always abound. The locust and the grasshopper delight in the plain, whilst the smaller insects thrive in the young woods that give shelter to their enemies. If we do anything to diminish the planting of trees, we shall increase our insects and also dry our already impoverished soils. We are protecting salmon—why should we not protect our woods, and with them our birds and our crops? Dean Stanley notes that Jewish tradition ascribes to Joshua certain useful regulations as to woods—the grazing of cattle therein, the cutting of sticks, and the preserving of thinly-planted trees. There was wisdom in them all. Watch a bare and a wooded hill on a cloudy day, or a well-wooded farm in a dry summer, and you will see a difference which need not be described. Disafforesting threatens to become as common in the nineteenth as enclosuring was in the sixteenth century. Are we wise to hasten it?

E. GOADBY.

DR. JELINECK ON METEOROLOGICAL OBSERVATIONS

Anleitung zur Anstellung meteorologischer Beobachtungen und Sammlung von Hilfstafeln. Dr. Carl Jelineck. Royal 8vo. pp. 193, with 17 figures. (Vienna, 1869. London: Williams and Norgate, price 6*s*.)

A COMPARISON between the instructions of M. Carl Kreil, the late director of the Austrian Central Office for Meteorology and Terrestrial Magnetism, and those now issued by his successor, demonstrates steady and sound progress in practical meteorology. M. Kreil had to sow his seed on uncultivated soil, and was only partially supplied with the more modern implements of cultivation; Dr. Jelineck, on the contrary, has had before him the successive results of nearly a quarter of a century, and has profited by the vast experience gained from the correspondence carried on during that time between the central office and the numerous stations, distributed over the wide geographical area of the Austrian empire with its striking physical contrasts. No wonder then, that Dr. Jelineck's work, which the author modestly calls "a guide to meteorological observations, with particular reference to the stations in Austria and Hungary," has developed, under his hands, into an excellent manual of practical meteorology, which will prove, in many respects, most valuable to the observers of every country. In the instructions of his predecessor such important subjects as the employment of the aneroid and marine barometers, and of the maximum and minimum thermometers, are not discussed at all, and little attention is paid to a rigid reduction of the observations.

The introductory part of the present work treats on the following subjects: general organisation of the system of meteorological observations in Austria and Hungary; conditions for establishing new stations; regulations for the official correspondence through the post and telegraph offices; local requirements and instrumental equipment of stations, with a precise statement of the necessary expenditure; a list of the most recent and important works on meteorology published in Germany, England, and France; hours of observation and means for determining the true local mean time.

Then follows a concise and clear description illustrated by excellent figures, of the different kinds of barometers and aneroids, a discussion of their relative advantages and defects, and an exposition of the principal formulæ used in the reductions of the observations, with well-selected examples fully worked out, for those observers whose mathematical knowledge is deficient. It appears that the form of barometer mostly in use at the Austrian stations, is that in which there is no provision for adjusting the zero of the scale to the fluctuating surface of the mercury in the cistern. Hence, only one displacement of the index is made for every observation, viz. that at the upper surface of the mercurial column. This is undoubtedly an advantage, for the lower adjustment requires always great nicety in the observer, and is, in some kinds of light, really difficult; but the advantage is, in our opinion, more than counterbalanced by the complexity of the reductions necessary for the instruments, which obviously require an additional correction for the change of level in the cistern.

The thermometers, maximum and minimum, dry and wet bulb, are described in the same exhaustive manner, and the best methods are discussed for obtaining trustworthy observations on the temperature of air, springs, rivers, and soils; the tension of the vapour of the atmosphere, and hence the relative humidity of the latter. Dr. Jelineck erroneously states on page 41 (foot-note No. 4), that the mean temperatures in England and Scotland are solely derived from the readings of the maximum and minimum thermometers. It is quite possible that in former years such observations, for want of better ones, were made the basis for deducing the mean temperature of some localities; but, as far as we are aware, these are exceptional cases, and the daily and annual mean temperatures are everywhere in this country derived from daily observations at fixed hours.

The remainder of the work comprises chapters on raingauges, the direction and force of wind, anemometers, the amount and form of clouds, the direction of upper currents, thunderstorms, optical phenomena of the atmosphere, ozone observations, and finally, the best methods for deducing from the observations the most probable annual mean results. Although the author shows himself, on the whole, well acquainted with what has been done in this branch of physical science beyond Germany, some of the chapters alluded to appear defective. A great deal of scientific knowledge and mechanical ingenuity have been brought to bear in this country on many of the subjects just mentioned, and our observatories, both public and private, are now supplied with instruments for different purposes, with which those described by Dr. Jelineck will bear no comparison; indeed, his instructions with reference to them, show that very little advance has been made in this respect from an almost primitive state: and if we consider what use is being made in this country of photography for obtaining continuous records of the principal atmospheric phenomena, and how well founded our hopes are thus, at last, to obtain an insight into the great laws which must regulate these phenomena,—we cannot but regret that the wide experience and profound knowledge of continental meteorologists should remain unsupported by the invaluable assistance of our modern appliances in their scientific investigations. The attentive reader will nevertheless find treasures even in those parts which fall short of our expectations, for every page is replete with most valuable hints, instructions, and suggestions, derived from long and extended experience.

The second part consists of very numerous and highly-valuable auxiliary tables, some of which, especially those referring to hypsometrical observations, we do not recollect to have met before in such a compact form.

No allusion whatever is made to solar radiation and atmospheric electricity, two meteorological elements the importance of which is rising more and more in the estimation of all thoughtful meteorologists.

We learn with satisfaction that the metrical system will shortly be introduced in Austria and Hungary, and that in future the Centigrade scale will be made use of in the meteorological observations. B. L.

OUR BOOK-SHELF

The Home Life of Sir David Brewster. By his Daughter, Mrs. Gordon.

WE like this book. It is notoriously difficult for a near relation to write a truthful biography, but Mrs. Gordon has done her work with great ability, taste and judgment. To most readers, the family details at the beginning will be of little interest, but as the life advances the interest grows. The book is essentially what its title imports, it pictures Sir David as a man rather than as a philosopher; yet his daughter tells us much of when and how his literary and scientific work was accomplished, and gives us lively anecdotes both of himself and of many of his contemporaries. In one chapter she analyzes his mental characteristics, and while acknowledging his imperfections, she shows that much which appeared inconsistent in his actions arose from an uusually dual nature, the continuation of a peculiarly impulsive temperament, with a scientific habit of thought. In another, she traces his religious history, and we see his advance from a somewhat cold and rigid orthodoxy to a living and happy faith, when without materially changing his own opinions he was ready to sympathise with good men who differed from him. Those who are well acquainted with the multitudinous optical researches of Brewster, will enjoy a glimpse of him at work among apparatus, often extemporised from corks and bits of metal, and glass, meanwhile indulging in a low purring whistle of satisfaction, and those who remember him only as a Nestor in science with furrowed features and snowy hair, describing his discoveries, or declaring his convictions in clear vehement language, will like to know him also as the head of a family, and the principal of a university, a politician, and a writer of reviews, gaining high distinctions, and promoting valuable institutions. But we can only just indicate these things, and must refer to his daughter's book for details about the dawn full of promise, the brillant noonday, and the beautiful sunset of his life.

J. H. GLADSTONE

On the Rotation of the Embryoes of the Frog within the Egg. By Dr. S. L. Schenk. Pflüger's Archiv. 1870, iii. Jahr., Heft 2 and 3.

IT is well known that the embryo of the frog exhibits remarkable movements of rotation, the direction being in opposition to that of the movements of the hands of a watch, supposing the observer to be looking vertically down upon the instrument, and that the head of the animal is directed away from him. These movements continue without interruption, and may be watched for hours together. They vary considerably in rapidity, but a series of observations made by Dr. Schenk showed that the rotation was effected in from five minutes and thirteen seconds to twelve minutes and two seconds. It has not been accurately ascertained when these movements commence, since in the earliest stages of development the surface of the egg is in close contact with the capsule, and it is only after some water has been imbibed that the two are separated, but Dr. Schenk shows that they result from the presence of ciliated cells on the surface; first, because these can be demonstrated with the microscope; secondly, because they can be accelerated by the application of moderate heat, which is well known to render the movements of cilia more rapid, and thirdly, because they can be arrested almost instantaneously by the action of weak acids, which are known to operate in the same way on ciliary movements.

Des Races Humaines ou Eléments D'Ethnographie. Par J. J. D'Omalius D'Halloy. Pp. 157. 1869. (Williams and Norgate.)

THE author of this treatise divides mankind into five races, distinguished by the colour of the skin—the white, yellow, black, brown, and red races—which he holds to be more reliable than either craniological character or linguistic affinities; adducing against the former, or Retzius' classification, the observation of Brandt that in examining the crania of a large number of beavers he found great variations to exist; whilst in regard to the classification founded on language, admitting that the consideration of language may prove of great service to ethnology, there is yet no identity between the two sciences. He estimates the members belonging to the several great religions of the world as follows: Christianity 380,000,000, Mahommedanism 100,000,000, Buddhism 500,000,000, Brahmanism 100,000,000, other religions 120,000,000, making a total population for the world of 1,200,000,000. M. D'Halloy is unusually orthodox in his opinions, and defends Scriptural authority with more energy than of late years has been customary with anthropological *savants*.

Studien aus dem Institute für experimentelle Pathologie in Wien aus dem Jahre 1869. Herausgegeben von S. Stricker. (Wien: Braunmüller.)

THIS is another of those German local periodical publications which disturb the minds and pockets of English readers. The time is evidently not far distant when a sumptuary law of publications will become a necessity in Germany. This, the first number of an intended series, is devoted to the histology and physiology of inflammation, and contains papers entitled, "Experiments on Corneal Inflammation," "On Cell Division in Inflamed Tissues," "On Endogenous Formation of Pus Corpuscles in the Conjunctiva of the Rabbit," and others, in all nine in number, contributed by Stricker and his pupils, with a prologue "On the Present State of the Inflammation Controversy," and an epilogue "On the Effect on that Controversy of the Preceding Memoirs," both by Stricker. One paper by Oellacher, "On the Cleavage and Stratification of the Hen's Egg," has only a general and indirect reference to inflammation.

Sketches of Life and Sport in South-Eastern Africa. By Charles Hamilton, F.A.S.L. (London: Chapman and Hall. 1870.)

WE do not understand with what object this book has been published. Of sketches of sport there are few, and none that can compare in interest with the many exciting records of South African adventure in earlier books with which we are familiar. The author's ideas on all subjects connected with natural history are of the vaguest, as where he says, "The Struthionidæ may comprise, *for what I know*, other species besides those of the ostrich; a geologist would give the reader information on the possibility of these birds existing in some analogous form centuries before the present formation of the globe!" Of sketches of life there are some, but with not much greater claim to novelty. That Mr. Hamilton succeeded in so far divesting himself of European prejudices as to submit to be carried to his bath by twenty buxom Kaffir girls, and after having been ducked by them in the water (an operation which he found "rather agreeable than otherwise"), to be painted over with red earth, may be interesting to himself and his friends, but hardly to the general public. What becomes of the old crinolines appears from the fact that the ordinary costume of a Kaffir schoolgirl is a necklace and an outrageously large skeleton crinoline without any covering over it. The woodcuts are on a par with the letter-press, and would be a hideous disfigurement to any work of higher literary pretensions.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Analogy of Colour and Music*

I HAVE read with interest the letters in NATURE of 31st March, on the relation between the harmonies of sound and colour, and I wish to point out that the most important principle of harmonising in colour is one which has no parallel or analogue in sound, except only that, like the harmony of sound, it has a mathematical basis. I mean the law that complementary colours harmonise with each other. The definition of complementary colours is, that any two colours which are complementary and of equal intensity, produce white when combined. In sound, on the contrary, there is nothing analogous to white, and consequently no relation analogous to that of complementaries.

All possible colours except white are colours of the spectrum. Black is only the negation of light, and grey is a subdued or lowered white. Brown tints, which to the eye appear unlike any of the colours of the spectrum, are "merely red, orange, or yellow, of feeble intensity, more or less diluted with white." (Clerk Maxwell, *Philosophical Transactions*, 1860.) "One circumstance, however, must not be left unnoticed here: namely, the difficulty of obtaining [that homogeneous red light which forms the transition between the violet and red of the ordinary spectrum, and which can only be produced by the prism under remarkably favourable circumstances (on a bright summer's noon). This outermost colour of the spectrum, which may be equally well regarded as extreme red or extreme violet, I will call purple . . . . In point of fact, the transition from violet to red is just as continuous to the eye as that between any two other colours, though the limit has not yet been fixed by observation at which the same impression of colour is produced by a different duration of vibration." (Prof. Grassmann, *Philosophical Magazine*, April 1864.)

The duration of vibration at the extreme of the violet end of the visible spectrum is about twice what it is at the extreme of the red end. According to Sir John Herschel (*Good Words*, August 1865), the vibrations at the extreme ends of the spectrum, number respectively 399,401,000,000,000 and 831,479,000,000,000 to the second; so that those of the extreme violet are a little more than twice as numerous as those of the extreme red, and the power of vision extends through a little more than a large octave.

With these facts before us it is scarcely possible to doubt that the principle of the octave is as true of light as of sound. Any two notes, whereof the vibrations producing the one are exactly twice as numerous in the same time as those producing the other, are in a manner recognised as the same note, the one being the octave of the other. It is in the highest degree probable that the same is true of light, and that "the limit at which the same impression of colour is produced by a different duration of vibration" is at the point where the vibrations of the one are exactly twice as numerous in the same time as those of the other.

Independently of this speculation (which is not a new one), it is a fact of observation, and is indeed only a statement in other words of the fact quoted above from Prof. Grassmann, that the order of the tints in the spectrum is recurrent. According to Prof. Grassmann, the order of the tints is the following:—

1. Red.
2. Orange.
3. Yellow.
4. Yellowish green.
5. Green.
6. Bluish green.
7. Azure.
8. Indigo.
9. Violet.
10. Purple.

Red again.

And he maintains, reviving Newton's theory, that every colour has its complementary in the spectrum;—the series of complementaries being this:—

1. Red + bluish green = white.
2. Orange + Azure = white.
3. Yellow + indigo = white.
4. Yellowish green + violet = white.
5. Green + purple = white.

*The importance of the accompanying letter from Mr. Murphy induces us to reopen a subject which we had considered closed; we append also two others previously received.—ED.

If the order of the tints is recurrent, it is only using another word for the same fact to say that it is circular; and it is possible so to arrange the colours of the spectrum in a circle that any two tints which are opposite to each other shall be complementaries.

Grassmann's results are purely theoretical, but they coincide in a great degree with the experimental determinations of Helmholtz, and of Clerk Maxwell. In such experiments the method is to mix two or more coloured lights by letting them fall on the same spot of white paper. Mixture of colouring stuffs will not give the same result.

I now come to some remarks of my own on the theory of complementaries.

If colours are so arranged on the circumference of a circle that every tint has its complementary opposite to it, as has been done by Newton and by Grassmann after him, any two tints which are 180° apart are complementaries, and any two tints which are 360° apart coincide. If then the theory of the octave is true, of two tints which are 360° apart, the number of vibrations in a second (or the frequency of vibrations) of one is twice that of the other. It might be expected that the ratio of the frequency of vibrations between any two tints which are 180° apart, would be the square root of this; or, in other words, that when the frequency of the vibrations of any colour is known, that of its complementary might be found by multiplying or dividing, as the case may be, by the square root of two.

To put this in another form: If we so arrange the tints, from red to its octave, where purple turns red again, round the 360° of a circle, that any two tints separated by equal areas shall have their frequencies of vibration in equal ratios; then, as the frequencies of vibration of the two reds which are separated by 360° stand to each other in the ratio of 2 to 1, the frequencies of vibration of any two tints which are separated by 180° will be to each other in the ratio of the square root of 2 to 1. Now if the theory of a chromatic octave be true, the pair of tints which are 360° apart are exactly alike, and we might expect those which are 180° apart to be complementary to each other.

But this is not the case.

The ratios of the wave-lengths and of the frequencies of vibration (which, of course, are in the ratios of the reciprocals of the wave-lengths), corresponding to various tints, have been determined with great accuracy by Prof. Clerk Maxwell (*Philosophical Transactions*, 1860), by means of an interference-spectrum. The numbers in the following table, which are given on his authority, are the numbers of wave-lengths in the retardations; each colour is written in the same line with its complementary. In the case of bluish-green, blue, and indigo, I take the middle one of three places in the same colour.

Red	36·40	Bluish green	48·30
Orange	39·80	Blue	51·80
Yellow	41·40	Indigo	54·70

If the frequency of vibration of the colours in the second column were to that of their complementaries in the first, in the ratio of the square root of 2 to 1, the numbers would be—

Bluish green	51·47
Blue	56·28
Indigo	58·54

Thus the frequencies as observed were considerably less than as calculated from the hypothesis. The differences are all on the one side, and are much too great to be the result of any accidental error. The complementary tints in the foregoing table are not precisely opposite, but approach each other by the green side of the circle; and if from the portions of the circle from red to yellow, and from bluish green to indigo, any two tints are taken which stand exactly opposite, so that their frequencies of vibration are in the ratio of 1 and the square root of 2, their unison will not give pure white, but white with a blue tinge.

But does this disprove the hypothesis that the true complementaries are those tints whereof the frequencies of vibration are in the ratio of 1 and the square root of 2? I think not.

Complementaries are usually understood to be tints, which by combination form a colour sensibly identical with that of sunshine. But is this correct? The solar spectrum is not pure, in consequence of the great number of absorption lines towards the violet end. That of the electric light, on the contrary, is free from absorption lines, and, in consequence of their absence, the electric light is sensibly bluer than that of the sun. If now the colour of the electric light, instead of that of sunshine, were taken as the true white, it appears probable that experiment would show the frequencies of vibration in any colour and its complementary to be in the ratio of 1 and the square root of 2.

There are some remarks on this subject in the 2nd vol. of my work on "Habit and Intelligence," of which book you inserted a notice by Mr. Wallace on 15th Nov. and 2nd Dec., 1869, but it is more thoroughly thought out in this letter.

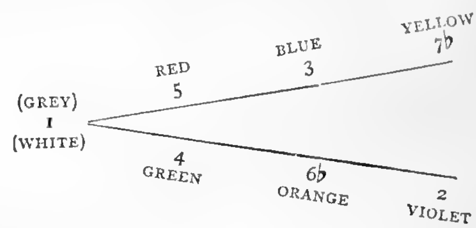
JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, April 16

M. RADAU, in his "Acoustique," says:—"The disdain with which most musicians repel the invasion of their domain by the exact sciences is to a certain extent justified." I venture to think it is very much justified, since little has been accomplished in aid of a technical theory of music by scientific men from Pythagoras down to Helmholtz. The highest service the mathematicians have rendered was to assist in destroying the application of their own theories by establishing the universally received system of "equal temperament." Now that the "effects" of colours are falling under the manipulation of mathematicians, could not the learned who are occupying your columns with the old discussion on "ratios" condescend to receive some warning from the history of "speculative music"?

One of your correspondents asks for a "white sound"! Seeing that a complementary colour completes the numerical value of the white rays more or less as the inversion of any musical interval completes the octave, is it unscientific to assume that the white ray must be the analogue of the monochord? Allow me to assume that it is so, and that white and black are complementaries, as M. Chevreul admits. Let me also assume that they are the two extremes of *light and shade*, including many gradations —*many octaves*—of intermediate shades of grey.

Taking any normal gradation of light and shade, and calling it grey or white, as the generator, the primary colours and their complementaries correspond to the harmonics, thus:—



The following series of figures

1	2	3♭	3	4	4♭	5	6♭	6	7♭	7	1
1	7♭	6	6♭	5	5♭	4	3	3♭	2	2♭	1

represent what musicians call a table of inversions in the octave. It must be understood that in the system of inversions of numbers I employ, what is meant by a number and its inversion are the distinct notes in the scale the two numbers represent. For instance, 1 to 5 is C to G in ascending, and the inversion is 1 to 4, C to F—always in ascending, and counting from the generator No. 1.

Hence the following table of abstract intervals and their inversions, produced in regular order from the generator:—

Unison 1 White or Grey.	5th Red.	Minor 3rd Indigo.	Major 3rd Blue.	Minor 7th Yellow.	Major 7th Lemon.	5th Red+Green (brown). (tritone).
1 White Octave	4th Green.	Major 6th Chrome.	Minor 6th Orange.	Major 2nd Violet.	Minor 2nd Lavender.	Sharp 4th Green+Red (brown

Musically speaking, the generator No. 1, as the root of a natural dissonant chord 1, 5, 3, 7♭, becomes No. 5 of the scale, or dominant of the key, the tonic of which is four degrees higher.

Consequently, if there be any analogy at all between sound and light, or between musical intervals and colours, the key-note of the spectrum would be *green*—the ray of medium refrangibility—and four degrees higher than the dominant or generator *white*. In modern views of harmony, I may remark it is not the concord or triad, but the dissonance, which is the basis of the technical theory.

Collecting, then, the abstract intervals given above, and considering them as representing separate notes, and arranging them in regular order, counting the original generator as No. 5, we get the following scale—major, minor, and chromatic—of F♮, or *green*:—

					(Tonic)						
5	6♭	6	7♭	7	1	2	3♭	3	4	4♯	5
C	D♭	D	E♭	E	F	G	A♭	A	B♭	B	C
Grey.	Laven-der.	Violet.	Indigo.*	Blue.	Green.	Red.	Orange.	Chrome.	Yel-low.	Lemon.	White.

* Indigo is, I think, a misnomer: it should be purple between blue and violet.

On the same system it is easy to construct an enharmonic scale on the principle employed by M. Chevreul. The double flats and sharps sometimes give ternary compounds. For example, 4♯♯ equals green + red + red, and its inversion 5♭♭ would give red + green + green. Some of the neutral greys, olives, slates, browns, &c., which would not appear in a table so constructed and calculated at a normal pitch, are produced by lowering the diapason.

From the above very brief explanation of the system of inversions, the following results may be suggested:—

1. That a table of colours of all gradations, with their complementaries, may be musically expressed in numerical notation with the greatest exactitude.

2. That, contrary to scientific opinion, it does not follow that because the red ray has the lowest degree of refrangibility, &c. &c., or perhaps because it happens to be at the bottom of the series of prismatic colours, it should necessarily be the initial note on the tonic of a scale.

3. Even if the red ray be the tonic, it does not follow that the scale of the spectrum should be *major*, as is too frequently given in elementary works on optics. By the system of inversions of numbers here presented, the scale of the spectrum appears, by disjoining the conjunct tetrachords, to consist of one tetrachord major and one minor, corresponding to the descending minor scale in use, of F♮ minor, supposing C♮ to represent the normal pitch of the dominant No. 5 corresponding to any given intensity of white light. Moreover, one conjunct tetrachord of the spectrum appears in *ascending* and one in *descending*, both tetrachords *converging* on the tonic.

4. If the analogy be true so far, there is only one colorific key. Modulation through a series of colorific keys, as in *modern* music, is impracticable. The reasons I have not space to explain.

J. G.

Mr. Sedley Taylor has, it seems to me, written his criticism on my letter published in Nature, Feb. 10th, far too hastily. I do *not* compare the diameter of the rings with one another, but *their cubes*, otherwise we should be led in establishing the musical analogy to the absurd equation $\frac{1}{\sqrt[3]{2}} = \frac{1}{2}$. It would perhaps have been better to have said, that the ratios of the spheres described on the diameters of the rings, taken successively from red to violet, two and two together, the 1st to the 2nd and the 2nd to the 3rd, &c., give a series of fractions identical with those expressing the relative lengths of the musical chords from D to C, ascending and taken in like manner. As Mr. Taylor doubts Prof. Zannotti's accuracy, I will quote the following passage from Biot's "Precis Elémentaire de Physique," 3rd Ed., Vol. ii. Paris, 1824, p. 400, *et seq.* Speaking of Newton, "Il mesura les diamètres des anneaux simples *de même ordre*, dans la partie intérieure et dans la partie extérieure de leur périmètre, et en les considérant successivement aux limites des diverses couleurs du spectre a commencé par le violet extrême. Suivant sa méthode constante, il prit soin de lier ces resultats par une loi mathématique qui les représentât avec une suffisante exactitude. Il trouva ainsi que les diamêtres, soit intérieurs, soit extérieurs, étaient sensiblement entre eux comme les racines cubiques des nombres $\frac{1}{2}$, $\frac{9}{16}$, $\frac{3}{5}$, $\frac{2}{3}$, $\frac{3}{4}$, $\frac{5}{6}$, $\frac{8}{9}$, 1, lesquels représentent les longueurs que doit avoir une corde de musique pour produire toutes les notes d'une gamme mineure; c'est-à-dire, que si l'on représente par 1 le diamètre intérieur d'un certain anneau, lors qu'il est formé par les rayons rouges qui composent la partie la plus extrême du spectre, $\sqrt[3]{\frac{8}{9}}$ exprimera le diamètre intérieur du même anneau, quand il sera formé par les rayons qui sont la limite du rouge et de l'orange, et ainsi de suite jusqu' à $\sqrt[3]{\frac{1}{2}}$ qui représentera le diamètre intérieur du même anneau quand il sera formé par les derniers rayons violets pris à l'autre extrémité du spectre."

I can only add, that if Mr. Taylor doubts also the accuracy of M. Biot, he can easily refer to Newton's own treatise on colour.

The Barlow Lens

I have found the addition of a double concave lens to my telescope and microscope of so much service that I am anxious to call the attention of your readers to this simple application for increasing and improving the working power both of telescopes and microscopes. The application consists in the introduction of a biconcave lens in the adapter, which holds the eye-piece of the telescope, at a distance of two or three inches from the field-lens; as the focal length of the instrument is thereby increased, it is necessary to adjust the distance of the lens from the eye-piece according to the length of the adapter, so that the latter still admits of being drawn out sufficiently for focussing. A friend procured me several lenses of different powers at the ridiculous price of a shilling a-piece from an optician and spectacle-maker at Brighton, which answer admirably.

The chief advantage obtained by the use of this lens is the great increase of magnifying power without a corresponding loss of light. This is a great desideratum in looking at a planet, but it is equally important in separating double stars. With a low eye-piece of 60, my refractor (one of Cook's with a 3½in. object glass, and the addition of the Barlow lens) shows the Companion of Rigel beautifully.

I first became aware of this useful application many years ago, in reading Admiral W. H. Smyth's "Cycle of Celestial Objects." In page 343, vol. i., he states: "On receiving it, I directed the telescope upon a watch-plate fixed on a distant chimney, which quickly proved the power of the lens in enlargement, with scarcely any obscuration of light. While the image expanded under each progressive eye-piece, I was surprised at the additional advantage of its simultaneously flattening the whole field of view; and though the magnifying power became double on distant objects, the apparent magnitude of the spider-lines diminished in an equal ratio: a property which, with all powers above three hundred, is of considerable benefit to operations upon close double stars, and the finer micrometric desiderata. I afterwards raised the discs of the Satellites of Jupiter, and examined several double stars, with equal facility and advantage, the definition being quite distinct, and the stray light rather subdued than increased. After a little practice, I came to the conclusion that the achromatic concave lens will render the instrument to which it shall be applied equal to two telescopes for particular cases; for if a set of observations be made *with* it and another set *without* it, the errors of vision will be in some degree neutralised, or even done away with."

In spite of this strong recommendation I never gave it a trial until a few weeks ago, when a paper in the Polish language by Prof. Piotrowsky passed through my hands. It remains to this

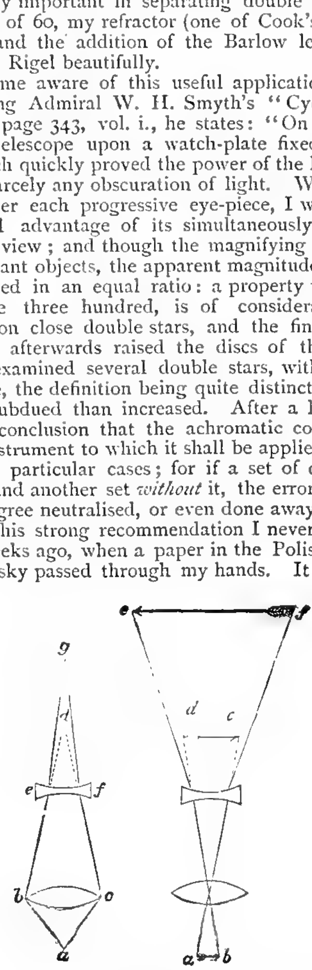

Fig. 1. *b c*, object glass; *ef*, Barlow lens; *d g*, foci of *b c*, with and without Barlow lens.
Fig. 2. *a b*, object; *c d*, image, with convex lens alone: *ef*, image, with Barlow lens.

day a sealed book to me, but the two annexed figures taken from it leave no doubt in my mind that the paper treats on the same subject of which Admiral Smyth speaks so favourably. The result of my own trial made me regret having foregone for many years an advantage which I have every reason to congratulate myself on now possessing; but this circumstance it is also which induced me to ask for a small corner in Nature for these remarks, when other more interesting subjects are less pressing than usual.

Walham Grove F. d'A.

A Word in Defence of Physicists.

Two passages in NATURE of April 14th show that the supposed opposition between geologists and physicists is not forgotten. This feud can only impede the advancement of truth.

Prof. Duncan, in his instructive paper on Dr. Carpenter's Report, writes thus :—" Physicists have propounded theories which have been accepted by some geologists, but they are looked upon as doubtful hypotheses by others. Palæontologists and such theories have been constantly at issue. The theories involving pressure, and the hardness of deep-sea deposits, will suffer from the researches ; but many difficulties in the way of palæontologists will be removed."

I cannot think that either of the "theories," to which allusion appears to be made, can ever have been accepted by any one who understood the nature of fluid pressure. The tissues of a living being inhabiting the depths must necessarily be permeated by liquids at the same pressure as that of the water without. Hence no crushing effect can be produced. So, too, the particles of mud or sand at the bottom of the ocean are buoyed up by water at the same pressure as that by which they are forced down, and they sink only by the difference of weight between themselves and the dense water ; so that the ooze at a profound depth ought actually to lie lighter than beneath shallower water. These considerations have always occurred to me when reading about the misconceptions to which Prof. Duncan alludes. But what I wish to point out is, that it is not the deductions of physicists which are overthrown, but the fancies of those who are not physicists, which were always opposed to physical principles.

Mr. Wilson's letter about "geological time" may possibly elicit a reply from Professor Pritchard. But why is Sir W. Thomson's name introduced into the heading? And does Mr. Wilson intend to tell us that Mr. Darwin considers natural selection incompetent to produce the human eye? For unless Mr. Darwin admits direct *design* in the arrangement of the human eye, it does not appear how Mr. Pritchard's *lapsus* in seeming to include man among the *Articulata*, can vitiate his argument as against Darwin. O. FISHER

Heat Units

IN No. 24 of NATURE (April 14) Mr. Thomas Muir calls atention to the inconvenience arising from the want of some uniform and generally recognised mode of expressing qualities of heat. As there can be no question that the inconvenience is a real one, I venture to suggest as one remedy for it, the employment of the following terms, namely—

grain-degree,
pound-degree,
gramme-degree
kilogramme-degree,

to denote respectively the quantities of heat required to raise the temperature of one grain, pound, gramme, or kilogramme of water from 0° to 1° Centigrade. These expressions are used in the article HEAT, in Watts's "Dictionary of Chemistry"; and having been for several years in the habit of using them in my lectures, I am able to say from experience that the employment of them greatly facilitates statements relating to quantities of heat.

It appears to me to be in favour of these terms, as compared with Mr. Muir's "therm," "kilotherm," &c., that they enable us to do without the formation of any new word, that they are self-interpreting, and that by means of them quantities of heat can be expressed with reference to the British or to the metrical standards of mass, with equal facility.

University College, London, April 25. G. C. FOSTER

The Sun's Chromosphere

Is there any way, by means of an ordinary telescope with coloured glasses, of seeing the red prominences on the sun's edge —that is, without a spectroscope? If so, what coloured glasses ought to be used? In one of the former numbers of NATURE, an observer saw, with only a telescope, what he believed to be these prominences ; the sun was near the horizon, a series of rose-coloured undulations became visible, unconnected, as supposed, with atmospheric disturbance, and which it was suggested might be due to the red flames of the chromosphere.

A.

Lefthandedness

IN a letter on this subject by J. S., in this week's number of NATURE, the hypothesis is mentioned that left-handed persons may owe their peculiarity to a transposition of the viscera, or at least of the great arteries of the upper limbs. This supposition, which has been more than once advanced, is certainly not true. Several cases of transposition of viscera are on record in which the persons affected were right-handed. One was recorded by M. Géry (quoted in Cruveillier's *Anatomie*, tome 1, p. 65, note), another by M. Gachet (*Gazette des Hopitaux*, Aug. 31, 1861), and a third in the *Pathological Transactions*, vol. xix., p. 447.

Your correspondent's opinion seems probable that righthandedness is the result partly of hereditary, partly of individual education, and is intimately associated with the more complex functions of the hand. P. S.

April 18, 1870

THE ABRADING AND TRANSPORTING POWER OF WATER

II.—FRICTION OF WATER

ON a former occasion the abrading and transporting power of water (which is supposed to increase as the velocity increases, but to decrease as the depth increases) was considered from a mechanical point of view, and arguments were brought forward to show that water rolls rather than slides. The question then arises—

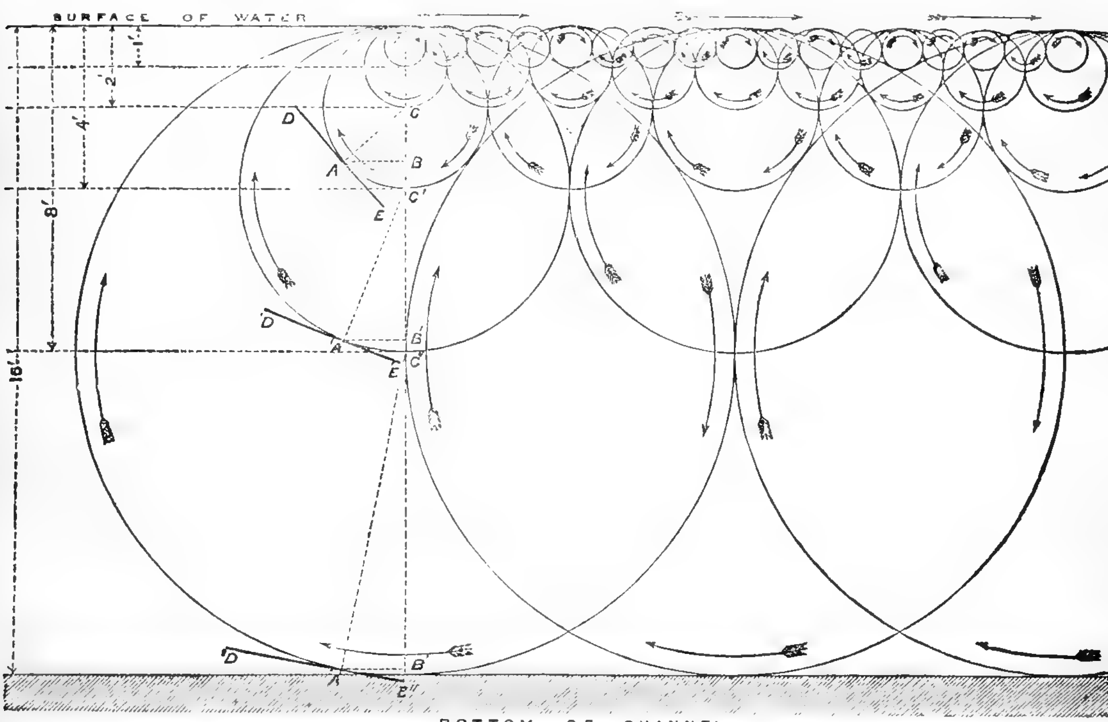
III. How does flowing water obtain this rolling motion? The reply to this is, By *friction*.

Take, for example, the rifling of a gun ; we all know that it is owing to the spiral grooves or prominences in the chamber that the shot gets its spinning motion ; but supposing the shot be a sphere, and fired from a smooth bore, it has not this rotatory motion at right angles to the line of flight, and no great dependence can be placed on its accuracy, but it may rise or fall, pass to the right or left, all depending on which side of the gun's mouth the shot touched when passing out, for so will it revolve. Should it ricochet, it will, when nearly spent, be observed to roll over the ground, and this is all caused by the friction offered by the resistance of the ground with which it came in contact. And what reason can there be assigned against water adopting this most simple of all laws for bodies in motion ; and is it not owing to this that water in a cistern takes a circular motion when escaping through an orifice in its bottom, or presents a cork-screw appearance when poured out of a small vessel? Again, on the large scale, with rapid currents such as in the Pentland Frith, what but this circular motion of the stream can cause that boiling apappearance given to the water, which everyone must have observed who has navigated waters where there is a strong tideway? And cannot this explain why there should be an enormous breaking sea at the point where the heavy swell of the Atlantic meets the ebb tide ; and does not this rolling motion given to the tide, acting in an opposite direction, check the oscillations of the Atlantic swell, causing those huge breakers so well known to the Orcadian boatmen?

Supposing every particle of water to be a sphere in itself that can roll independently, and that a number of them being collected together form a larger sphere, which also rolls, and so on, then the diameter of the spheres increases with the depth, be it ever so great. Consequently, the facility for rolling will also increase, so that the deeper and broader a stream is—that is, the farther the centre of a stream is from the retarding medium (the bed and banks of a river)—the less is this rotatory motion obstructed ; and does not this explain how the velocity increases with the hydraulic mean depth? The air also has a retarding effect even in a perfect calm ; for where the Mississippi was very deep, it has been observed that the greatest velocity was not at the surface, but at some distance below it.

Supposing that water moves in an innumerable number of circles, varying from a single particle in diameter to that of hundreds of feet, and that every obstruction sets these circles revolving at right angles to their surfaces, we can at once begin to understand how, by increasing the areas exposed to friction, an innumerable set of wheels of various sizes are set spinning in all directions, but are retarded in this action by the attraction of the several particles to each other. Thus wheels within wheels will be set in motion, some revolving in opposite directions; and the quicker the revolutions—that is, the smaller the diameter of the wheels, in other words the shallower the stream—the greater will be the power expendend, which power Nature exerts in holding solid matter in suspension; therefore, if the foregoing arguments be correct, it is evident that the transporting and abrading power of water must increase in some ratio inversely as the depth, and that the retarding of a ship's sailing on a flowing river must depend on the increased area of surface exposed, thus explaining why a ship with a foul bottom, a rough, rocky bed to a river, or weeds in a stream, all retard velocity, because they one and all set so many more wheels spinning. This leads us to the important questions where abrasion and the power of flowing water to hold solid matter in suspension have to be investigated, with the view of showing how this rotatory motion acts in nature. To do so the following diagram will perhaps give a slight idea of the complicated nature of this rotation, the circles being supposed to increase in diameter with the depth. This diagram is only intended to show the relative motion of one set of particles with respect to its neighbouring set of particles, each for its own depth of 1, 2, 4, 8, or 16 feet deep. Thus where the depth is 16 feet, there would be a series of circles 16 feet in diameter rolling within each other, where the depth was 8 feet, there would be circles of 8 feet in diameter, and so on. That is, with the same velocity, the rotation would decrease as the diameters became greater.

The various angles with the horizon are represented by the lines D E, D′ E′, and D″ E″, which show the necessary slopes, in order that the centre of gravity of each circle should be equally beyond the point of support A′, and that consequently A B, A′ B′, A″ B″, should be all equal; they indicate that where the slope of the surface of the water remains in each case the same (say, for example, one foot in a mile), the velocity probably increases proportionally to the increased hydraulic mean depth, or that where the velocities are the same, and the depths differ, the slope requires also to vary. Let, for example, the velocity be in each case about 5 miles an hour, or some 7½ ft. a second, while the depths are 5ft., 8ft., 10ft., and 90ft. respectively, the slopes vary from 25 feet in the mile to only some 4 inches, while the load of solid matter held in suspension is about 7 per cent., 5 per cent., 3 per cent., and only $\frac{1}{1100}$ of the weight of water in each of the above cases respectively. With the assistance of the diagram, therefore, it will



at once be seen how the whirling motion given to a stream must increase as the depth decreases, and how, by the increased agitation, the water is able to hold proportionally more solid matter in suspension, while the action on the bed of the channel must at the same time be increased.

To carry this action to extreme cases it appears evident that where the velocities are considerable, and the depths only a foot or two, the slopes must become almost precipitous, while the stream must become semi-fluid mud, or transport a large proportion of boulders, and even rocks; in doing which a certain amount of power must be expended, and in transporting this solid matter this loss of power cannot but retard the flow of the stream. On the other hand, it may be assumed that, even with considerable velocities, which at small depths would tear up and hurl forward rocks, boulders, sand, and mud, with excessive depths the water may flow on in almost a comparatively pure state, and instead of holding in suspension stones and coarse sand, can only transport fine particles of mud.

THE SCIENCE OF EXPLOSIVES AS APPLIED TO WARLIKE PURPOSES

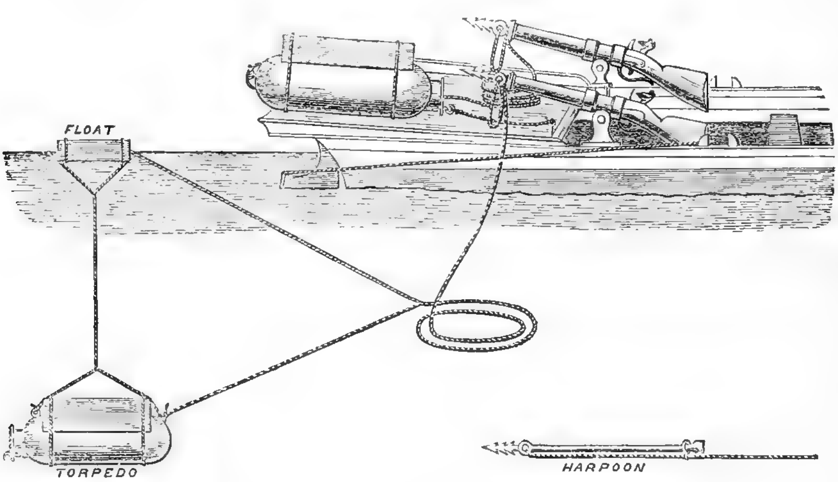
I.—EARLY STUDY AND APPLICATION OF EXPLOSIVES

THE protracted and disastrous war between the Northern and Southern States of America was fruitful in the development of expedients to serve as auxiliaries to the hitherto well-recognised materials of defence and attack. No subject connected with the details of that war has, however, received more general attention on the part of European Powers, great and small, than the extensive and successful applications of a somewhat ancient class of war-engine, the value of which up to that time had received no practical demonstration, but which is now on every hand regarded as destined to play a most important part in future wars.

The idea of employing floating or submerged charges of gunpowder as agents for the destruction of ships and other marine structures, has been occasionally put into practice from a somewhat early date, although with but few instances of success. The earliest form of marine-mine was the so-called *Explosion Ship*, which the Dutch appear to have been the first to employ. When Antwerp was besieged by Alessandro de Farnese, Duke of Parma, in 1585, a boom or boat-bridge was constructed across the Scheldt by the besiegers, and this, an Italian engineer, Jambelli, undertook to destroy for the Dutch. Four large flat-bottomed vessels were each of them loaded with several thousand pounds of powder, over which were placed fireworks and large masses of stone; two of the boats were provided with slow matches, the burning of which had been timed, and the others fitted with clock-work contrivances by whose agency the powder was to be exploded at a pre-determined period. The vessels, thus equipped, together with a number of fire-ships, were allowed to drift towards the boom, and, on its centre being reached, one of them immediately exploded with such violence as to destroy several of the ships composing the structure, and likewise to kill 800 men and wound many more, among whom was the Prince Farnese himself.

Vessels of this kind were repeatedly used by the English in the seventeenth century; thus an attempt was made in 1693 to destroy St. Malo by the explosion of a vessel of 300 tons laden with a large quantity of gunpowder, besides various other combustibles; and similar attacks were likewise directed with little or no success two years later against St. Malo, Dieppe, and Dunkirk. For some time after these operations explosion-vessels seem to have fallen into disuse, there being no instance of their employment on record until 1809, when Lord Cochrane destroyed a boom in the Basque Roads by exploding in contact with it a vessel laden with very closely packed gunpowder. Some unsuccessful attempts at the destruction of English ships by means of explosion-vessels were also made by the Americans during the War of Independence; but this very wasteful and uncertain mode of applying gunpowder in marine operations appears to have been since then altogether abandoned, until the late American War, when Admiral Porter, of the United States Navy, added one more to the list of unsuccessful operations of this kind, by endeavouring to destroy or disable Fort Fisher by the above means.

The earliest form of submerged self-acting mine was the so-called *floating petard* used by the English during the operations in Rochelle, in 1628. These implements of warfare consisted of small cases of sheet-iron filled with powder and fitted with a spring which was released as soon as the drifting machine came into collision with a ship, or other obstruction, and thus determined the explosion of the powder by means of a match-lock. They appear to have been too small to inflict any serious injury upon ordinary vessels, and many of them were captured by the French. Similar contrivances were constructed by an American, Mr. Bushnell, in 1777, who endeavoured to apply them to the destruction of the English fleet anchored near Philadelphia in that year; but the machines were started at too great a distance from the ships, and drifted away in wrong directions, the damage inflicted by them being limited to the destruction of a ship's boat and her crew, who were engaged in capturing one of the dangerous shoal. In 1800 another American, Robert Fulton, submitted to the French Government several projects for the destruction of ships by means of submarine mines, or as they were called at the time, infernal machines. This gentleman appears to have spent three or four years in perfecting his system of warfare, but received such scant assistance and encouragement from his own Government, that in 1805 he determined to offer his invention to the English, who about that time had been creating a considerable panic in the French fleet off Boulogne, by sending among the vessels a number of fire-ships and small drifting mines of a self-acting nature, termed *catamorons*.



THE FIRST SO-CALLED "TORPEDO" PROPOSED BY FULTON IN 1800

The first of Fulton's torpedoes, of which trial was made by the English naval authorities, consisted of a metal vessel holding about 100lb. of gunpowder, and fitted with a clockwork instrument which could be regulated to release a flint-lock at a determined period after it was set in motion. The machine was partly encased in cork, so that when charged with powder it was a little heavier than sea-water, and it was attached by a line to a box float, whereby it could be kept suspended at any particular depth. These torpedoes were carried in harpoon-boats, and connected by long lines with harpoons fired from small guns at the ship to be attacked. If the harpoon was successfully planted in the ship's side, the torpedo was drawn into the water by the line, and this, as it ran out, released a pin from the torpedo, setting the clock-work in motion. The submerged torpedo was then supposed to drift into close proximity with the ship by the time the flint-lock caused ignition. Several French ships were attacked by means of these explosive machines—which, by the way, Fulton was the first to term *torpedoes*—but although they were in some instances successfully exploded, the enemy's vessels sustained no material injury, from the fact that the charges were immersed in too great a depth of water. Fulton's drifting torpedoes were employed in a more simple form in an experiment made in October 1805, in the presence of the principal officers of the fleet commanded by Lord Keith, on which occasion a 200-ton brig, the *Dorothea*, anchored for the experiment off Walmer Castle, was destroyed at one operation. The torpedo employed contained 180lb. of powder, and was suspended at a depth of fifteen feet; it was simply allowed to drift with the tide against the hulk, the clockwork which regulated the explosion being timed to run eighteen minutes before the machine was cast adrift.

The torpedoes made use of by the Russians in the Baltic in 1855, were mechanical self-acting machines, containing charges of from 8lb. to 10lb. of powder; they were constructed with some care and ingenuity, and if they had been but of larger size, their existence would have greatly jeopardised the safety of our ships. The machines were conical in form, and were so arranged as to explode on being struck by a passing vessel, the blow causing the fracture of a glass tube containing sulphuric acid, which, falling upon a tuft of cotton wool saturated with chlorate of potash, sulphur, and sugar, at once ignited the charge.

But it was not, as previously stated, until the subject of torpedoes was seriously taken in hand by the Americans during the recent war, that torpedo-warfare assumed a grave and wide-spread importance. In the hands of the Confederates especially, the applications of submarine mines to warlike purposes were very carefully studied, and with such marked success, that, according even to the official despatches of the Federals themselves, twenty-five ships are admitted to have been destroyed. In the first instance *mechanical* torpedoes only were used, such, viz., as exploded by means of percussion arrangements fitted on the outside, or by a drifting line attached to a trigger, but these were afterwards succeeded to some extent by machines ignited at will from the shore by electricity. The latter were, in the opinion of Admiral Porter, of inferior value, from the fact of their ignition not being effected at the proper time; and the gallant officer reports, that on one occasion he safely ran the gauntlet through a channel bristling with these machines, by simply sending forward as pioneer a sham *Monitor* built of logs, and furnished with an imitation turret, which passed without damage over several torpedoes exploded at her, and was afterwards followed by the fleet unharmed.

Consequent upon the successful employment of torpedoes by the Confederates, the Federals turned their attention more closely to the matter, building a torpedo-boat especially for this kind of warfare, and reconstructing six *Monitors* for the same purpose.

The perfection to which submarine mines have been brought up to the present time, and the various methods adopted for applying electricity to their ignition, will form the subject of the second part of this paper.

THE DEEP-SEA SOUNDINGS AND GEOLOGY

SOME little time ago an eminent geologist, Professor Gümbel of Munich, applied to Sir Roderick Murchison for specimens of the Deep-sea Soundings which have lately been the subject of so much discussion. Sir Roderick mentioned Dr. Gümbel's wish to me, and I immediately sent him a small quantity of North Atlantic mud from 2,350 fathoms, which had been preserved in spirit. The following translation of a letter, dated April 18th, 1870, with which Dr. Gümbel has favoured me, and which embodies the result of his researches hitherto, will, I am sure, be read with the greatest interest by geologists and biologists. I may mention that I long since found coccoliths in the nummulitic limestone of Egypt. T. H. HUXLEY

Many thanks for sending me the specimen of mud obtained by the deep-sea dredge. I have already subjected it to searching investigation, and have obtained results, which have the most important bearing upon my other work. Although my inquiries are, at present, only commenced, it will possibly interest you to receive some information respecting them. I call the new kind of investigations which I have begun to carry out, "Deep-sea investigations on the dry land;" *i.e.*, examinations of the different calcareous rocks, with reference to the share which the smallest organic forms, similar to those at present existing in the deep sea, have had in their formation. When limestone is soft and earthy, traces of the smallest marine animals can be detected by triturating it in water. In chalk, for instance, from Palestine, I have convinced myself, in the most unequivocal manner, of the formation of the calcareous mass, for the greater part from your so-called coccoliths, besides *Foraminifera*, &c., which have long been known. Similar soft calcareous rocks are unfortunately rare in older formations. With these another process must be adopted. I started from the fact that in many of these calcareous rocks, the original calcareous portion of the organic beings is replaced by silica, and that hence in such rocks, by the separation of chert or flint, at least a part of the calcareous portion of the coccoliths and coccospheres might be replaced by silica. It was to be expected that the exterior form might suffer by this replacement, as, in fact, the chalk coccoliths have become materially different in their form from those of the existing deep-sea ooze.

I found, in fact, by treating such a siliceous limestone with very dilute acetic or hydrochloric acid, in the fine mud which is left, an organic residuum corresponding to the coccoliths of the present day. Even in the Trenton limestone, and in a yellow limestone of the Potsdam series, corresponding minute bodies were to be recognised, although sparingly, presenting themselves amongst an incredible multitude of other minute particles of organic origin. The microscope discloses, like the telescope, in the vault of heaven, a new world of the smallest organic beings, respecting which, however, I must say nothing at present, but confine myself to the coccoliths. These casts of coccoliths are found very sparingly. I explain this from the circumstance that the silica is chiefly the result of the decomposition of large masses of organic material, especially of the larger testacea. I obtained, however, important results by subjecting the deep-sea ooze, for which I am indebted to your kindness, to the action of the acids. These with violent development of carbonic acid, dissolve the minute bodies of the coccoliths, of the coccospheres, and perhaps also those of *Bathybius* (although of this I am not quite sure), and there remain only certain peculiarly formed but very much changed portions of the coccoliths as roundish discoidal flakes, the organic portion of the original coccoliths. In single isolated coccoliths this change of form is difficult to follow, but this can easily be done in those which appear to be firmly bound up (enveloped?) with a mass of the granular flakes (*Bathybius*?); and after the operation of the acid, can be again easily recognised in their exact position. Accompanying these coccoliths transformed by the action of acids, are countless little bodies extremely similar to those which can be obtained, in most cases, by dissolving siliceous limestone in acids.

This is the first commencement of researches which I propose following up, with, I hope, important results; since thin sections are of no good in studying these minute forms. I cannot close these notes of the researches with which I am at present engaged, without adding a further contribution, and I hope not an unimportant one, to what is known respecting the nature of the deep-sea mud.

You speak of the chemical behaviour of these masses. The question whether these minute organisms represent animals or plants is still open. I have exposed the ooze to the action successively of a solution of iodine, of iodine and sulphuric acid, and of zinc chloride with potassium iodide, and have each time obtained in a remarkable manner a distinct blue colour, different shades from violet to green, in the substance of the coccoliths. There must therfore exist in the organism of the coccoliths, besides the calcareous skeleton, a kind of cellulose. Their organic nature is thus established beyond all doubt; but the conclusion might after all be drawn that we are dealing with plants, were it not that in the animal kingdom cellulcse has been found in the Ascidians. But it is at all events interesting here on the boundary of organic life, to meet with cellulose. As a confirmatory test, I treated the substance with Millons' test which, as is well known, colours conchiolin red, but leaves the chitin of the *Orthropoda* on the other hand unchanged.

I obtained by this means no red colour in the flakes belonging to the coccoliths after the limestone had been dissolved by the excess of acid. A red colour showed itself, on the other hand, in many other particles, for instance, in the *Polycistinæ* whose siliceous coat was coloured red at the margins; and in irregular patches, which appeared to be derived from broken and crushed mussel-shells. I also noticed much deep brown and yellow colour. Especially by treatment with different chemical reagents, differentiated minute particles make their appearance which can scarcely be recognised by my microscope, and which, before the treatment with the chemical reagents, cannot be by any means detected. I expect that by this method an important extension of our knowledge of the most minute forms of organic life will be effected. I will only mention further that the red of the conchiolin shows itself of a bright red in the smallest particles which are found in such great numbers in the agglomerated flakes (*Bathybius*), and which are smaller than the little elevations on the epidermal structures, which probably belong to *Holothuridæ*, and which frequently occur in the field of the microscope.

I should like to pursue further the chemical side of these investigations; but, unfortunately, the supply sent over to me is almost exhausted. If you consider these researches of sufficient importance to be worth continuing, and could obtain further material for me for this purpose, I should be greatly indebted to you. If you can make any use of this communication, it is at your service.

NOTES

PROBABLY few are aware of the magnitude or special aim of the Cornell University. While our own rulers can scarcely grapple with the Education question because of the unsettled state of Ireland, the Government of the United States laid the foundation, during the height of the most terrible struggle for existence of modern times, of one of the most important educational movements the world has ever seen. On the 2nd of July, 1862, Congress passed an Act granting public lands to the several States and Territories which might provide colleges for the benefit of agriculture and the mechanical arts; the share of the State of New York amounting to 990,000 acres. In 1865, this grant was conferred on a University about to be established, on the condition that the Hon. Ezra Cornell should give to the institution 500,000 dollars, with a few other conditions. This munificient grant was afterwards supplemented by another of 200,000 dollars; and the University was established at the village of Ithaca. It is needless to say that the Act of Inauguration provides that the education shall be given to all comers irrespective of creed, colour, or race; the motto of the founder being, "I would found an institution where any person can find instruction in any study." Besides the original grants, the University has since been enriched by private liberality, with gifts of public buildings, laboratories, libraries, museums, a herbarium, printing-press, &c. A simple, but, as far as it goes, a strict entrance examination in geography, English grammar, and arithmetic and algebra, admits intending pupils as undergraduates, and they can then take their choice of pursuing their studies in either of several departments in which degrees are conferred, in Science, Philosophy, Arts, or in some other special subjects, the full course extending over four years. The special feature of the University, however, is what is called the voluntary labour scheme, by which students are enabled to work out a portion or the whole of the expenses of their education, either by unskilled labour on the farm, or by skilled labour at the printing-press or workshops. The University Register just published states that the scheme has thus far been worked with a degree of success hardly to be expected at so early a stage. We shall look with great interest on the progress of the University.

WE are in a whirl of soirées. Last Saturday the second Royal Society's soirée of the season drew together a brilliant gathering, and we shall next week give an account of the scientific novelties exhibited. On Wednesday the President of the Linnean Society's conversazione came off, and to-morrow Sir R. Murchison, the president of the Geographical Society, receives his friends at Willis's Rooms.

THE question of admitting lady students of medicine to classes in the Edinburgh University on the same footing as other students was discussed at the half-yearly meeting of the University Court on the 19th inst. Professor Masson moved a resolution in favour of so admitting them, and quoted Miss Pechey's case in support of his motion. Mr. Balfour, Professor of Botany, seconded the resolution. Mr. Laycock, Professor of Physic, moved a negative resolution. Professor Christison seconded the amendment, which was carried by 58 votes against 47 in favour of the motion.

A PROPOSITION was some time ago made to telegraphists by Mr. Robert B. Hoover, of Alleghany, Pennsylvania, to present Professor Morse, the "father of the telegraph," with a testimonial upon his eightieth birthday. The response was general, and the nucleus of a fund was immediately raised. It has since been found that this fund will warrant the casting of a bust, or perhaps a full-length figure, of the professor; so the original idea of making Professor Morse a birthday testimonial has been abandoned, and a really national one is to take its place.

THE corner-stone of a new college for Melbourne, which is to be affiliated with the Melbourne University, under the title of Trinity College, was laid on the 10th February, by the Right Rev. the Bishop of Melbourne. The building stands near the south-west corner of the reserve, to the north of the University, and considerable progress in the erection of it has already been made by the builder. Only a small portion of the whole design, namely, the Provost's lodge, &c., has been undertaken, and it is to cost 7,500*l.* The funds in hand amount to 4,000*l.*, and the buildings will be carried out as far as the money will allow.

THE schooner yacht *Norna*, Mr. Marshall Hall, owner and master, is fitting out to dredge off the west coast of Spain and Portugal. Mr. W. S. Kent, of the British Museum, and Mr. Edward Fielding accompany the expedition.

EVENING Technical Schools are to be established in the chief towns of Massachusetts. A museum of mechanical inventions and models of machinery are to be formed in connection with each, and there is to be one instructor for every twenty-five pupils.

WE regret to have to announce the death, in his 82nd year, of Mr. Jonathan Couch, of Polperro, Cornwall, a well-known naturalist. His name is especially associated with ichthyology, the standard works of Bewick and Yarrell owing much to his assistance; his own work on the subject being also a very valuable one. Hs was also a frequent contributor on various branches of Natural History to the scientific journals. A correspondent of the *British Medical Journal* states that he was a good linguist, and devoted a considerable time to antiquities. He was a man in whom simple tastes were combined with persistent industry and very accurate powers of observation, and was one of few in whom these qualities were not spoiled by easy circumstances.

THE photographic journals announce the sudden death, in his 72nd year, of a distinguished photographer, M. Niepce de St. Victor, one of the most skilful and indefatigable of experimentalists, and unquestionably the practical originator of photography on glass plates. His name will, however, be associated chiefly with the process of photo-engraving.

THE conversazione of the Society of Arts is fixed to take place at the South Kensington Museum on Wednesday evening, the 4th of May. Cards of invitation have been issued.

IT will be remembered that on the 13th of July last a deputation from the Council and India Committee of the Society of Arts waited on the Duke of Argyll for the purpose of urging the Government of India to take steps for providing a Department of Agriculture for India. The Council have great pleasure in announcing that a Department of Agriculture and Commerce for India has now been established, and that Mr. Rivett Carnac has been appointed the secretary.

AT the last meeting of the Society of Arts, a valuable paper was read by Mr. Alexander J. Ellis on a practical method of meeting the spelling difficulty in school and in life, which was followed by an interesting discussion.

A SERIES of ladies' classes has been arranged at Blackheath, and a large number will attend lectures by the Rev. Stopford Brooke, and Professors Seeley, Miller, and Duncan.

MR. W. RALSTON will deliver a lecture at St. George's Hall, Langham-place, at 4 p.m. on Wednesday, May 4, on "Russian Folk-lore," which will be illustrated by a number of stories taken from the "Skazki" (or prose tales answering to Dasent's "Tales from the Norse," or Grimm's "Mährchen"), with a few notes on their historical, mythological, and social bearings.

DR. HOOKER'S "Student's Flora of the British Isles" is announced as nearly ready. It will contain fuller descriptions of the orders, genera, and species of British plants than the existing manuals aim at giving, together with the distribution of the species in area and altitude, and their hitherto recognized sub-species and varieties. The method adopted will differ from those of the author's predecessors in many points, and the whole will be contained in a pocket volume suited for the class-room and the field.

A PECULIAR variety of *Chamælio Vulgaris*, found near Bughodeer, on the Grand Trunk Road, was presented by Mr. H. Hexter to the Asiatic Society of Bengal, Calcutta, on January 5. Dr. Stoliczka, the palæontologist of the Indian Survey, said that the specimen was very interesting, and of a kind not often found in India so far north. It was fully 12 inches long, the tail measuring slightly more than half. Dr. Günther remarks in his "Reptiles of India," p. 162, that most of the Indian specimens are of a green colour. The present specimen was a distinct greyish olive, having throughout a slight green tinge, which Mr. Hexter stated appeared to have been more prevalent and variable during the life of the animal; but faded quickly after its death. Each side was marked with eight irregular orange brown cross bands. The head, the greater part of the feet, and part of the tail were bright yellow. The animal is more fully described in the the Society's *Proceedings*, 1870. No. 1.

FROM Thorell's Essays on European Spiders ("Nova Acta regiæ Societatis Scientiarum Upsaliensis," ser. III. vol. vii. fasc. 1, 1869), we extract the following observations, first suggested by M. Westring, a Swedish naturalist, on the best mode of preserving spiders in Natural History collections. The essential feature of the method is that the spider's *abdomen*, and that part only of its body, is *hardened by heat*. The spider is first killed, either by the vapour of ether or by heat, and is impaled by an insect pin, which is passed through the right side of the cephalo-thorax; the abdomen is then cut off close to the cephalo-thorax, and the cut surface dried with blotting-paper. The head of another insect pin is cut off, and the blunt extremity introduced through the incision into the abdomen, up to the spinners. The abdomen thus spitted is inserted into a large test-tube held over the flame of a candle, the preparation being constantly rotated till dry, avoiding the extremes of too much or too little heat—the firmness of the abdomen being tested every now and then with a fine needle, till it is so firm as not to yield to pressure; the front extremity of the pin is now cut off obliquely, and the point thus made inserted into the cephalo-thorax, the two halves of the body being thus again brought into apposition. The animal may then be mounted as usual. This method is stated by Mr. Thorell to preserve the appearance of the animals almost entirely unchanged.

AN attempt is being made to cultivate the Japanese tea-plant in California. 27,000 trees have been imported.

THE third course of Cantor Lectures of the Society of Arts for the present session is being given by Professor A. W. Williamson, The course consists of four lectures, "On Fermentation," on Monday evenings, the 25th of April, and the 2nd, 9th, and 16th of May, at 8 o'clock, and will include an account of important investigations of M. Pasteur. The subjects treated of will be as follows:—Chief varieties of fermentation; chemical processes which take place in the best known processes of fermentation; other chemical processes analogous to them; how these cyclical processes are distinguished from ordinary processes of chemical action; cyclical action analysed; 1. in known cases; 2. in less known cases; theory of "contagiousness" of chemical action; composition of yeast, and changes which it undergoes; assimilation of food by yeast plants during life; decomposition of yeast plants during life; propagation of ferments; prevention of fermentation; germs in air: how removed: how destroyed; processes for arresting fermentation; wine-making and wine-keeping; chemical changes which improve the quality of wine; chemical changes which deteriorate the quality of wine.—These lectures are open to members, each of whom has the privilege of introducing two friends to each lecture.

A TELEGRAPHIC despatch from Marseilles announces the discovery there, by M. Borelly, of a new planet. Its position on the 19th at 10h. 33m., 13s. was—Right ascension, 13h. 2m. 39s. North declination, 6° 50′ 39″.

THE Italian Parliament is engaged in discussing a vast financial plan of the new Ministry, one feature of which is the suppression of a number of the smaller Italian universities. Irrespective of considerations of economy, it is thought that the cause of education will gain by the concentration of the teaching power of the nation in a few towns where a great educational movement exists. A portion of the scheme which meets with less favour is the suppression of the Superior Institute of Florence, an establishment which, the capital having no University, somewhat supplies the place of a national college and musuem, and which numbers among its staff the distinguished names of Donati in Astronomy, Maurice Schiff in Physiology, Ugo Schiff in Chemistry, Targioni-Tozzetti in Zoology, and Parlatore in Botany.

THE South Kensington authorities have printed syllabuses of the courses of lectures already delivered at the Museum, under the title of "Instruction in Science and Art for Women." We have before us "Notes of fifteen lectures on Physics, by Professor Guthrie," and "Notes of ten lectures on Botany, by Professor Oliver." We commend both these programmes to lecturers on natural science, as models of what scientific lectures ought to be—thorough, exact, and yet popularly intelligible.

WE have received a German edition, by Dr. Oppenheim, of Wurtz's History of Chemical Theory, from the time of Lavoisier to our own day.

THE *Paisley and Renfrewshire Standard* prints an unpublished letter of Wilson the ornithologist. It is dated Nashville, Tennessee, May 1st, 1810, and deals more with the manners and customs of the people than with his favourite science of Ornithology.

MR. KEITH JOHNSTON, jun., publishes a map of the Lake Region of Eastern Africa, showing the sources of the Nile, recently discovered by Dr. Livingstone. To it is appended an interesting account of the progress of discovery in the Lake Region, with notes on its physical features, climate, and population.

DR. J. LEON SOUBEIRAN has reprinted from the Annals of the Linnean Society of Maine-et-Loire an article on the herring fishery, which gives an account of the fishery from the earliest times in the different countries of Europe, and of the various modes of curing the fish.

THE *Architect*, for April 9, describes the projected new buildings for Owens College, Manchester. The designs for the first portion being now complete, the works will shortly be commenced on a site about a mile to the south of the centre of Manchester, on the west side of Oxford Road. The style of the building is Gothic, of a collegiate and early type.

C. G. EHRENBERG'S "Gedächtnissrede auf Alexander von Humboldt," presented to the Academy of Sciences at Berlin, is a graceful centenary tribute to the memory of the great *savant.*

THE Commissioners for the Annual International Exhibitions of selected works of fine and industrial art and scientific inventions have issued a code of rules for educational works and appliances produced in the United Kingdom, or produced abroad, but submitted to the British judges. We suspect that exhibitors will find it somewhat difficult to determine under which of the denominations named in the commissioners' list they should range themselves; thus we find "philosophical instrument makers," and "optical instrument makers," with separate headings for "microscope makers," "telescope makers," "stereoscope makers," &c. We should hardly have thought that it would have been necessary to make arrangements for the special exhibition of objects under the heads of "coloured saucer makers," "pink saucer makers," "preparers of botanical specimens," "Ward's case makers," &c. Everything intended for exhibition must be sent in by Wednesday, the 8th of February, 1871.

M. CLOEZ has detected in the leaves of *Eucalyptus globulus*, a tree which has been recently largely introduced into France for purposes of ornamentation, a substance extremely analogous to camphor. Ten kilogrammes of fresh leaves give 275 grammes of this new substance, the formula for which is $C_{24}H_{20}O_2$, and its boiling point 175° C.

A MONTHLY journal has been started in Jena devoted to the interest of Sericiculture. We have before us the first number of the *Seiden-bau-Zeitung für Nord-deutschland;* bearing the names of Dr. E. Hallier, H. Maurer, and J. Zorn, as Editors.

MADREPORARIA OF THE RED SEA

THE following table is required to complete Prof. Duncan's account in NATURE, No. 24, p. 612, of the Madreporaria dredged up in the *Porcupine* Expedition. The specific names given in the table are those finally adopted by Prof. Duncan:—

Name.	No.	Latitude.	Longitude.	Depth.	Temp.	Remarks.
1. Caryophyllia borealis, *Fleming*	2	51° 57 N.	10° 23 W.	fathoms. 30-40	52°·00	Specimens very numerous.
Syn. C. clavus	...	....	....	......	....	The species is found in the coralliferous British seas and Mediterranean. Fossils in Miocene and Pliocene of Sicily. At great depths in Mediterranean (recent).
C. Smithii	88	59 26 N.	8 23 W.	705	42·65	
C. cyathus and many varieties.						
2. Ceratocyathus ornatus, *Seguenza*	88	....	....	705	42.65	One specimen. Not known elsewhere; the genus is, with this exception, extinct. The species is fossil in the Sicilian Miocene.
3. Flabellum laciniatum, *Ed. & H.*	3	51 51 N.	11 50 W.	370	....	Specimens numerous.
Syn. Ulocyathus arcticus, *Sars*	25	56 41 N.	13 39 W.	164	46·5	This is a well-known Norwegian recent form.
4. Lophohelia prolifera, *Pallas*, sp.	5	52 4 N.	12 8 W.	364	48·8	Specimens numerous.
Syn. All the species hitherto published, viz:—						The variability of this species at different depths is so great that all the known species must in consequence be considered varieties of one form. Recent in Norwegian seas, Mediterranean, and off the Shetlands. Fossil in Miocene and Pliocene deposits of Sicily. A variety is found off the American coast. A considerable number of specimens was found in the "cold area" at depths from 500-600 fathoms.
L. anthophyllites, *Ed. & H.*	13	53 42 N.	13 55 W.	208	49·6	
L. subcostata, *Ed. & H.*	14	53 49 N.	13 15 W.	173	49·6	
L. affinis, *Pourtales*	15	54 5 N.	12 7 W.	422	47·0	
L. Defrancei, *Defrance.*	25	56 41 N.	13 39 W.	164	46·5	
L. gracilis, *Seguenza*	54	59 56 N.	6 27 W.	363	31·5	
and several varieties.						
5. Amphihelia profunda, *Pourtales*, sp.	54	59 56 N.	6 27 W.	363	31·5	Many specimens.
6. —— oculata *Linnæus*, sp.	54	....	....	......	....	The necessity for absorbing *Diplohelia* is stated in the following pages.
7. —— miocenica, *Seguenza*	54	....	....	......	....	The species of *Amphihelia* range from the Miocene to the present day; but only *A. oculata* has hitherto been found in recent fauna.
8. —— atlantica, *nobis*	54					
9. —— ornata, *nobis*	54					
10. Allopora oculina, *Ehrenberg*	54	....	....	......	....	A few specimens.
		59 40 N.	7 10 W.	530	47·0	Dredged in *Lightning* Expedition. A recent form.
11. Balanophyllia (Thecopsammia) socialis, *Pourtales*, sp.	54	59 56 N.	6 27 W.	363	31·5	These are West Indian forms, and are included in *Thecopsammia*, a subgenus, by Pourtales.
var costata						
britannica						
Jeffreysia	65	61 10 N.	2 21 W.	345	29.9	
12. Pliobothrus symmetricus, *Pourtales*	...	....	....	500-600	Cold area.	It is a West Indian form.

Total species, 12; species absorbed, 9. Good varieties numerous. Greatest depth from which species were dredged, 705 fathoms.
Lowes temperature of sea at bottom whence corals were dredged, 29°·9.

ON THE CHARACTER AND INFLUENCE OF THE ANGLO-SAXON CONQUEST OF ENGLAND, AS ILLUSTRATED BY ARCHÆOLOGICAL RESEARCH*

THERE are numerous points of general and living interest relating to the Anglo-Saxon conquest of this country which are very largely dependent upon archæological research for their elucidation. Amongst these may be mentioned the question of the extent to which the Romano-British population previously in occupation was extirpated; the question of the relative position, in the scale of civilization, held by victors and vanquished; and the question of the extent of our indebtedness as to language and laws to one or other of the two nationalities. Light is thrown even upon points apparently of the most purely archæological character from such literary sources as histories of the nomenclature of localities; as the records of monasteries; as illustrations in manuscripts; and as laws. But the graves of the Anglo-Saxons and their contents have been for the present investigator the primary; and such literary works as those alluded to, and such as many of those published under the direction of the Master of the Rolls and by the Early English Society, have been only a secondary source of information. They have however, been by no means neglected by him.

It may be well to begin by stating how an Anglo-Saxon is to be distinguished from a Romano British interment. Anglo Saxons, during the period of their heathendom, which may be spoken of roughly as corresponding in England to a period of some 200 or 230 years onwards from their first invasion of the country in force, were interred in the way of cremation, and in urns of the pattern so common in the parts of North Germany and of Denmark whence they are supposed on all hands to have come. A reference to any manual of archæology, or an inspection of any such series as that figured by Mr. Kemble in the *Horæ Ferales* from the Museum in Hanover, will show the unmistakable identity of the pattern, fashion, and moulding of such urns as these, and these which I have had figured after digging them up in Berkshire. The Romans and Romano-Britons had given up the practice of burning the dead long before the time of Hengist and Horsa. When they practised it in England, their urns were of a very different kind, being well burnt and lathe-turned. All the Romano-Britons I have exhumed in the particular cemetery which has furnished me with the tolerably wide basis of something approaching to 200 interments of all kinds, were interred much as we inter our dead now. They were oriented, though by the aid of the sun and not by that of a compass; and, dying in greater numbers in the winter quarters of the years, had the bearings of their graves, as has been observed by the Abbé Cochet, pointing a little south of east. Now a Romano-British interment in this way of burial has to be distinguished from an Anglo-Saxon one in the same way of non-cremation; and this may be done thus. The Romano-Britons never buried arms nor any other implements which could be of use in this, and might be supposed to be of similar use in the next world, together with a corpse. Funeral ware, such as lacrymatories, I have not found in company with coins of the Christian Emperors; but such articles stand in relation to quite a different idea from that which caused the Teuton to inter the dead with spear, shield, and knife; to say nothing of the less common *situla* and sword.

The Anglo-Saxons are supposed by Kemble to have relinquished cremation only when they assumed Christianity; it is a little difficult to be quite sure of this; at any rate, when we find, as we often do, an Anglo-Saxon in a very shallow grave, which may point to any one point of the compass, and in the arms or other insignia which it contains, gives us such clear proof that its tenant thought that whatever he may *not* have brought with him into the world, at all events he could take *something* out, we are tempted to differ even from such authority as Mr. Kemble's. But I am inclined to think that in some cases it is possible to identify the tenant of a properly oriented grave as having been an Anglo-Saxon. In many such graves Anglo-Saxons are to be recognised by virtue of their insignia; and mixed up with their bones may be found the bones of the Romano-Briton who occupied the grave before them. But farther, in some such cases it is possible to be nearly sure that we have to deal with an Anglo-Saxon, even though there be no arms or insignia in the grave. These cases are those in which we have evidence from the presence of stones under the skull that no coffin was employed in the burial; and in which stones are set alongside of the grave as if vicariously. In many such cases the craniological character of the occupant of such a grave lends some colour to this supposition. But upon such identifications as had been come to in the absence of arms and insignia I have based no statistics. The results of the statistics of the cemetery which I have explored, as stated above, when brought to bear upon the large questions alluded to at the beginning of the paper, would lead us to think that the Anglo-Saxons were in a considerably lower grade of civilisation than the people they conquered, firstly and most forcibly on account of the shorter lives they led. An old Anglo-Saxon male skeleton was a rarity, an old Romano-British one a very common "find" in my excavations. Nothing however in this life is from the natural history point of view more characteristic of real civilisation or real savagery than this matter of the duration of life. The Merovingian Franks had, like the followers of Cerdic, been observed to have led short lives, merry, as the Capitularies of Charlemagne teach us of their kinsmen, with those kinds of mirth the end of which is heaviness. The next question which suggests itself upon the mastery of these facts and figures is, were not these men merely soldiers encamped? are not these statistics just such as a cemetery similarly explored now-a-days, say at Peshawur or Samarcand, would yield? Not altogether such; for, however improbable it may seem, it is nevertheless true that the Anglo-Saxons, at all events in Berkshire, appear to have brought their own wives with them, and not to have provided themselves with wives from the families of the conquered previous inhabitants. The figures of the crania of females interred with Anglo-Saxon insignia, when compared with figures of the crania of Romano-British women, show a very great difference, to the disadvantage of the former of the two sets of females. The soldiers of Cerdic, who conquered this part of Berkshire about half-a-century or so after the time of the first invasion, resembled the soldiers of Gustavus Adolphus in very little else, but they appear to have resembled them in being accompanied by their wives. Whether this was the case elsewhere in England, I do not know; I am inclined to think that savagery was no great recommendation, nor heathendom either, to a Christianised female population in those days; and that the reluctance which would on these grounds interpose itself to prevent inter-marriage between Romano-Britons and Saxons, sets up as great an *a priori* improbability against the theory which assumes that such inter-marriages did take place, as the difficulty of bringing wives over in the ships in those days sets up in its favour.

Indeed, on the hypothesis of much inter-marriage the actuality of our Anglo-Saxon language is a very great difficulty. We do speak a language which, though containing much Celtic and a good deal of Norman-French, is nevertheless "English." Now we know, from finding cremation urns of the Anglo-Saxon type all over England nearly, that the whole of the country was overrun by a heathen population; to thus overrun it, this population must have been (relatively at least) numerous: add to the two conditions of heathendom and multitude which may be considered as proved, the third condition of isolation which may be considered as matter for dispute; and then the fourth of this heathendom and isolation lasting from the time of Hengist to that of Augustine; and the present fact of our language being what it is is explained.

For proving anything as to the period of which I have been speaking, a period which is rendered Pre-historic, not so much by conditions of time as by conditions of space, the absence of contemporary historians having been entailed by geographical and political isolation, arguments of two kinds, literary arguments and natural history arguments, must be employed. Neither the one kind nor the other is sufficient by itself. The empires of the natural sciences and of literature touch at many isolated points, and here and there they lie alongside of each other along lengthy boundary lines. But empires need not be hostile though they be conterminous; and that the empires of which we have just spoken may be united happily and in a most efficient alliance for work in common, may be seen from the title-page of that most excellent German periodical, the 'Archiv für Anthropologie,' where we have the name of the Physiologist Ecker coupled in editorship with that of the Antiquarian Lindenschmit. The necessity for a combination of the two lines of evidence and argument is as obvious when we have to controvert, as when we have to establish a conclusion. If you have to attack or resist a force comprising both cavalry and infantry, you must have both

* A paper read at the Royal Institution on Friday evening, March 25, 1870.

cavalry and infantry of your own; otherwise, some day or other, either in a country intersected with woods, or in some open plain furrowed into deep undulations, one of the two arms in which you are deficient will take you in one or both flanks, and you will be surprised, broken, and routed.

GEORGE ROLLESTON

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, April 21.—Prof. Williamson, F.R.S., president, in the chair. T. Patchett was elected a Fellow. Prof. Roscoe, F.R.S., delivered a lecture on "Vanadium." This metal was discovered in 1830 by Sefström, who also ascertained some of the most peculiar characters of the substance, and prepared some of its compounds in the pure state. Sefström not having leisure to prosecute the full examination of the new metal, handed over his preparations to Berzelius; and it is to the investigations of the great Swede that we owe almost all our acquaintance with the chemistry of vanadium. He found the atomic weight of the metal = 68·5, and wrote its oxides:—VO, VO_2, VO_3, and its chloride VCl_3. Some years afterwards Rammelsberg observed that the mineral vanadinite, a double salt of lead vanadate and lead chloride, is isomorphous, with apatite and with mimetesite, the former containing phosphoric, the latter arsenic acid. This crystallographic analogy would have led to the conclusion that the oxide of vanadium in the vanadinite has the formula V_2O_5, agreeing with the corresponding oxides of phosphorus and arsenic, P_2O_5, and As_2O_5. But the unyielding facts Berzelius had obtained in his analysis, and according to which the oxide in question was represented by the formula VO_3, compelled to regard vanadinite as an exception to the law of isomorphism. Prof. Roscoe, having come into the possession of a plentiful source of vanadium, determined to ascertain whether there really was such an exception, or whether Berzelius's formula may not perhaps be erroneous. He soon found the latter to be the case. He proved that the substance supposed by Berzelius to be vanadium, is not the metal, but an oxide, and that the true atomic weight of the metal is 51·3. Thus the VO_3 of Berzelius becomes V_2O_5, corresponding to P_2O_5 and As_2O_5. The lecturer went on to demonstrate that the characters of the vanadates bear out the analogy of V_2O_5, with P_2O_5 and As_2O_5, and vanadium, hitherto standing in no definite relation to other elements, must therefore be regarded as a member of the well-known Triad class of elementary substances, comprising nitrogen, phosphorus, boron, arsenic, antimony, and bismuth. The above-mentioned source of vanadium is a by-product obtained in the preparation of cobalt from the copper-bearing beds of the lower Keuper sandstone of the Trias at Alderley Edge, in Cheshire.

The President, in proposing a vote of thanks to the lecturer, called attention to the great service Prof. Roscoe had rendered chemical science by his successful investigation of vanadium. The President's remarks were fully endorsed by Profs. Frankland and Odling, and the meeting expressed its appreciation of Prof. Roscoe's lecture by prolonged applause. Prof. Hofmann, from Berlin, who was present at the meeting, favoured the Society with some observations on a compound ($C\ H_2\ N_2$), which he had obtained when treating sulpho-urea with silver oxide. The body is distinguished by its great tendency to polimerise. Dr. Hofmann further communicated that a compound isomeric with chloral (the new anæsthetic) had recently been discovered by two Berlin chemists. It differs from the ordinary chloral by possessing a much higher boiling point.

Geological Society, April 13.—Sir P. de Malpas Grey Egerton, Bart., M.P., F.R.S., vice-president, in the chair. Mr. S. W. North, of Castlegate, York, was elected a Fellow of the Society. The following communications were read:—

1. A letter from Dr. Gerard Krefft, dated Sydney, 29th January, 1869, accompanying a model of the left lower incisor of *Thylacoleo carnifex*, Owen, and the original fragment from which the model was made. Dr. Krefft also referred to the fossil remains of herbivorous marsupials in the museum at Sydney, which included, according to him, besides a great number of Wombats (*Phascolomys*), many wombat-like Kangaroos or Wallabies (*Halmaturus*). He proposed to divide the Kangaroos into the following groups:—

1. *Macropus*, dentition as in *Macropus major.*
2. *Halmaturus*, with the premolar permanent, divided into two sub-groups:—
   a. True Wallabies, with the premolars long, narrow, and compressed, and the rami of the lower jaw but slightly anchylosed.
   b. Wombat-like Wallabies, with the premolars compact, rounded, and molar-like, and the rami of the lower jaw firmly anchylosed.

Illustrative sketches and photographs accompanied this paper. Prof. Owen remarked upon the importance of the researches made by Dr. Krefft and Prof. Thompson. No traces of man had been found. The numerous remains of mammals, especially the herbivorous species, had doubtless been carried into the caves by *Thylacoleo.* Prof. Busk inquired on what evidence Prof. Owen decided that the tooth of *Thylacoleo* was that of a Carnivore. Prof. Owen indicated the remarkable compression of the tooth and the absence of the spatulate form proper to the Kangaroos as characteristic of *Thylacoleo* and indicative of carnivorous habits. Mr. W. Boyd Dawkins stated that *Thylacoleo* was most closely allied to *Plagiaulax*, which was probably a true Herbivore. He indicated the importance of the question, as if *Thylacoleo* were a Carnivore, *Plagiaulax* would be one also. Prof. Owen remarked that *Plagiaulax* was also a Carnivore. The premolars resembled the small tubercular molars of the Hyenas, Felidæ, &c. The anterior tooth, associated with the small tubercular tooth, was compressed and sharp pointed. The low condyle forming part of the angle of the jaw, was such as occurs in *Thylacinus.* Dr. Duncan remarked that it was by no means necessary that all carnivorous mammals should be formed upon the same type, and that he did not see why there should not be a carnivorous form of the kangaroo type. The chairman said that the settlement of these questions must now be postponed until we obtain further materials. He mentioned the discovery by Dr. Krefft, in the interior of Australia, of a species of fish resembling *Lepidosiren*, and possessing singular affinities to some of the Devonian fishes.

2. "On the Fossil Remains of Mammals found in China." By Prof. Owen, LL.D., F.R.S., F.G.S. The specimens of teeth described by the author were obtained by Robert Swinhoe, Esq., late H. M. Consul at Formosa, chiefly by purchase in the apothecaries' shops at Shanghai. They included two new species of Stegodon (named *S. sinensis* and *S. orientalis*), a new Hyena (*H. sinensis*), a new Tapir (*Tapirus sinensis*), a new Rhinoceros (*R. sinensis*), and a species of Kaup's genus Chalicotherium (*C. sinense*). The author remarked that the whole of these teeth presented an agreement in colour, chemical condition, and matrix, which led to the conclusion that all belonged to the same period. But for the presence of the Chalicotherium, they would have been referred either to the Upper Pliocene or the Post Pliocene period. The author did not consider that the occurrence of the Anoplotherioid species need affect the determination of the age of the fossils, especially as Chalicotherium departs in some respects from the type genus Anopoltherium, and is not known from deposits older than the Miocene. The Chairman called attention to the remarkable association of forms among the fossils described by Prof. Owen. Prof. Busk remarked that the materials at command seemed to him insufficient for the establishment of new species. He observed that the distinctive characters of *Stegodon sinensis* appeared to be very slight, and that the Hyena was probably *H. spelæa.* The tooth of Rhinoceros might be a milk-molar of *R. sumatranus.* Mr. W. Boyd Dawkins suggested that, as the specimens were obtained from apothecaries, there was no evidence of the contemporaneity of the fossils. Mr. H. Woodward stated that Mr. Swinhoe had himself obtained a series of these fossils from a cave many miles inland, he believed on the course of the Yang-tse-kiang. Mr. Woodward also called attention to Mr. Hanbury's paper on Chinese Materia Medica, in which many fossil teeth of mammalia are noticed. Prof. Owen, in reply, stated that great quantities of the fossils had passed through his hands, and that he had selected for description those which, from their minute agreement in chemical and other characters, might justly be inferred to be derived from caves of the same age.

3. "Further discovery of the Fossil Elephants of Malta." By Dr. A. A. Caruana. Communicated by Dr. A. Leith Adams, F.G.S. The author described a new locality in Malta in which the remains of elephants had been found recently—the Is-Shantin fissure at the entrance of Micabbiba. It was filled with a compact deposit of red earth containing fragments of limestone, many teeth and fragments of bones of elephants, associated with bones of large birds. The author found three small

shark's teeth, and a small tooth which he regarded as belonging to a Hippopotamus. He indicated the nature of the teeth and bones of elephants found by him in the newly-discovered fissure. The whole of the five localities in which ossiferous fissures have been discovered are in the same part of the island; and the author concluded with some remarks upon the geological conditions under which the remains of mammalia must have been accumulated, and upon the probability that a connection then existed between Malta and Africa. In a note appended to the paper, Dr. A. Leith Adams stated that the supposed tooth of Hippopotamus was a germ true molar of one of the pigmy elephants, and that the shark's teeth had probably been derived from the Miocene deposits. Prof. Busk remarked that there was no doubt that three species of elephants had lived in Malta. Capt. Spratt said that it appeared to him that the chief interest of the communication lay in the greater comparative abundance of the larger species of elephant in the new locality.

Royal Geographical Society, April 11.—Sir R. I. Murchison, President, in the Chair. The first paper was on a Pundit's explorations in Western and Central Thibet in 1868, by Major T. G. Montgomerie, R.E. The previous exploration having furnished some information as to the districts between Rudok and the Thok Jalung gold-field, it was decided to send the third Pundit to Rudok, and through Rawung and Tingche, north of the Aling Gangri Peaks. A reported trade route from Thok Jalung to Tengri-noor lake, and thence to Lhasaon, was to be attempted; failing this, the route by Majin and Shellifuk to Tadum Monastery. The result has been to give definite information as to the character of the great elevated plain of Thibet, 15 to 16,000ft. above sea level, extending probably to Sew Choo, nearly to the great wall of China. The Pundit, as one of a party of Bisahiris, went from Spiti to Demchok, on the upper Indus; the river was 270ft. broad, and 5ft. deep in July—velocity of stream $2\frac{3}{10}$ miles per hour; Rudok had not been visited; officers had penetrated to within 12 miles of the Fort, where the Jong-pon or Governor resides. The Pundit determined the position; the Fort is on a hill of 250ft., with 4 monasteries and 150 houses round it. July 22nd.—The party proceeded eastward through Rawung and Tingche to Dak-korkor, a standing camp and annual fair. Large and small salt lakes were passed, and three days' march of a waterless country, the soil of a dazzling white. Five days north he heard of a district called Tung Phaiyu-Pooyu, of the same character, very lofty, named from high snowy-peaks, probably E. Kiun-kuenlun. A large river is said to flow N. and E. to China; the population is numerous, consists of Dokpas under Lhasa: The snow-white plains have been noticed east of Changchenmo Pass; no high peaks were seen to north and east. All accounts and observations confirm the existence of great plains from the Chang Thang of Rudok to China; the Pundit identified "Jiling," with Sining, N. lat. 37, E. long. 102. The party reached Dak-korkor, 20 miles N. of Aling Gangri, during the annual fair. Robbers attacked the camp. The Jong-pon levied a black mail from the traders to avoid pillage, probably sharing the plunder. The Pundit proceeded eastward by the Aling Chu river, which falls into lake Hagongcho. He passed lake Chakchaka, whence Nepal, &c., is supplied with salt. These lakes are nearly connected. A salt field of 20 miles by 10 is nearly on a level with the lakes. The Pundit heard of seven gold-fields besides those visited, Thok Sailung and Thok Jalung, and those of the northern district. South of Thok Jalung the gold bearing rocks were left. The supply in the gold districts is inexhaustible.

From Thok Jalung they passed through Majin—the country drained eastwards, partly undulating and partly level; all about 16,000ft. above the sea. They reached Kinglo on the large river Chu Sangpo, unfordable in summer, flowing east into a large lake Cho Sildu, which receives three large streams but has no exit. Shellifuk Monastery lies south of this lake from Kinglo. They were obliged to turn off the Tengri-noor route, and go south-west to Lake Mansarowae. Crossing the Nagchail and Riego ranges, offshoots of Kailas Peak, numerous borax fields were passed, furnishing a sufficient supply for the potteries of Europe. A tax of 10 annas or 1s. for above 240 lb. only is imposed. Large herds of black wild yaks, wild asses, numbers of Hodgsonian antelope, wild goats and sheep, including Ovis Ammon wolves, reddish hares, marmots, and a kind of fox were observed. The lakes were tenanted by quantities of geese, ducks, and storks; eagles and vultures were seen everywhere. Robbers abounded, but went off at the sight of guns. The Pundit surveyed the Mansarowae Lake; the water was sweet; no exit. He failed to join the Ladak caravan to Lhasa, but proceeded to Shigatse, where he was stopped, and obliged to return. His servant reached the Tadum Monastery, but was sent back. He crossed into Nepal by the Muktinath, pass of only 13,000 feet.

Mr. Shaw described the white plains which he had traversed for 10 or 12 miles as resembling ice covered with snow, one being soda; under it lay crystallised salt. The thieves were encouraged by the authorities, but were so afraid of guns, that a quantity of stolen sheep were voluntarily restored on the approach of European shooting party. Sir Henry Rawlinson considered there were no mountains north of Rudok, but that the plain descended by a gentle slope, affording facilities for a great road to be connected with the road from India. He referred to a Persian work, Tarik-i-Ras-chidi, written by a cousin and general of the great Baber, giving full topography of Thibet and Kashmir. Mr. Saunders exhibited a map of Thibet, he believed Central Asia proper was encircled by mountains with an escarpment descending rapidly on the north as well as the south, and argued against the hypothesis of a gentle slope. He pointed out the remarkable depth of the Himalayan gorges. The Pundit's servant who had penetrated behind Mr. Everest, found the base of the peaks to be only on a level of 6,000ft., the gorges 20,000ft. deep. Dr. Campbell stated that a Chinese army had invaded Nepaul by the Muktinath Pass.

The President remarked that our knowledge of the country had till now been derived from the Jesuits and Thibetan survey. The discussion made him realise our ignorance of it.

A second paper was read by Captain I. Gregory on an attempt made to communicate from Assam with Catholic missionaries now residing at Sakka and on the Mekong and Salween rivers. The envoy was turned back. A letter received from the missionaries was read, mentioning that Europeans were casting cannon for the Mahommedan king. They expressed their desire to aid English travellers, and mentioned that last year they had received "a nice young gentleman from Bathang named Cooper." The bishop is at Ta-Tsien. Col. Yule mentioned that 10 years ago a letter from the Vicar Apostolic at Bonga to Bishop Des Mesures at Rangoon first disclosed the presence of Catholic missionaries in Thibet. Information was sent by them concerning the rivers flowing from the plateau of Thibet, between the Bramapootra and the Upper Yang-tze-kiang. The upper waters of these and the Mekong Salween and Irrawaddy, issue from a higher latitude than supposed and can be traced to 35°. The determination of the disputed questions connected with these rivers is proposed as an object of future exploration. A paper on the Upper Irrawaddy is shortly to be read before the Society.

Royal Astronomical Society, April 8.—William Lassell, F.R.S., president, in the chair. The minutes of the last meeting were read and confirmed, and 37 presents announced. A paper by Mr. Plummer on the Orbit of the Comet of 1683 was read. From the observations of Flamsteed, a parabolic orbit was decided by Halley, but recently Clausen of Dorpat has computed an elliptical orbit. The author, at Mr. Hind's suggestion, re-examined the matter, making all possible corrections, and using the latest star places, and finds as the result that the orbit is parabolic, so that the return of the comet in a few years hence is not to be expected.—Mr. Tebbutt, junr., sent some observations from Australia, of the Lunar Eclipse on January 17, 1870. During the totality, the details of the surface of the moon were distinctly seen through the copper-coloured tint pervading the disc, which was given at the edges. A number of telescopic stars became visible in the path of the moon, and several occultations of these during the eclipse were noted. The times of contact were likewise given. Mr. Bird read a paper on "The Floor of Plato." There are now 35 spots known on this space, 8 of them having been discovered since November 1869. The result of 771 observations was given in a tabular form, showing the degree of visibility in the first 6 lunations of a year, in the last 6 lunations, the increase and decrease of visibility, and the amount of the variation. The observations were made with telescopes of 6 to 9 inches aperture, the greater number coming from Mr. Crossby's Reporter of the latter size. The President announced that there was a possibility of the Government providing the means of transit to and from Mediterranean ports, for observers of the eclipse in December next, and he invited the Fellows willing to take part in an organised scheme to send in their names, as nothing could be done until the probable number was known. The Astronomer Royal opened a discussion on the subject by tracing the course of the eclipse from Portugal to the Black

Sea, and stated that the only points which were especially available would be Xeres near Cadiz, or Gibraltar; Oran in Algeria, and a station in Sicily, near Syracuse or Catania. [This subject has already been fully discussed in our columns.] The remainder of the evening was occupied by Mr. Watson, who brought forward his hypothesis, the result of ten years' study of the moon, that both water and air exist on the side invisible to us. His argument was, that from his telescopic views of the moon he was convinced water and volcanoes had left traces of their action; that chemically and geologically air and water were necessary for such action; that the air and water could not get away from the moon, and that as they were not present on the side visible—which he admitted to the fullest extent—they must be existing on the other side—although he could give no other proof in support of his assertion. Mr. Watson's views were severely criticised in a jocular tone by Capt. Noble, and more seriously by Col. Strange, who said that Mr. Watson having wished to extract an opinion whether he was right from the society, could not have it, as that body as such never gave an opinion on any communication, and that if distinguished astronomers did not rise to confute him he must not take silence for consent. Even assuming all that Mr. Watson said to be correct, which Col. Strange by no means admitted, there was even another explanation than that offered, viz., that the water had been absorbed into the interior of the moon. Mr. Watson's remarks were a striking example of the danger of bringing forward opinions formed without a foundation of facts.—After electing seven new Fellows, the long and interesting meeting came to an end.

Anthropological Society of London, April 19.—Dr. Berthold Seemann, V. P., in the chair. Mr. John Colam, 105, Jermyn Street, St. James's; and Mr. David Mitchell Henderson, 1, Carden Place, Aberdeen, and Old Calabar, West Africa, were elected Fellows. Dr. D. Lubach, of Kampen, Holland, was elected a corresponding Member.

A paper, by Mr. Alfred Sanders, was read "On Mr. Darwin's Hypothesis of Pangenesis as applied to the Faculty of Memory." The first question to be asked was—"Is thought a function of the brain?" The author answered it in the affirmative, and cited facts and appearances in physiology, anatomy, pathology, and physics in support of his opinion. Thought could not be considered as a product of the brain-cells any more than light could be produced by the cells of the retina, yet the brain-cells were necessary for the communication between the mind and the external and internal world, and were exhausted in the process of thinking and willing, in the same manner as the cells of the retina were exhausted and required renewal in the process of seeing. Passing to the consideration of the faculty of memory, the author combated the theory of Mr. John Stuart Mill, that the mind is a series of feelings and nothing more, and that memory is an ultimate fact incapable of explanation. The remainder of the paper was devoted to the application of Mr. Darwin's hypothesis of Pangenesis, which the author maintained was capable of explaining the difficulty raised by Mr. Mill; it being granted that the mental faculties depend upon the brain, and that the brain-cells give off self-propagating gemmules indefinitely, everything becomes plain. After describing in detail the action of external impressions on the brain at different times in the life of an individual, some of the many conditions favourable or the reverse to the retention of such impressions, and the dormant and active states of the brain-cells, the author entered into a consideration of the growth of the supposed gemmules, their action at maturity, and their power of self-propagation. Mr. W. B. Kesteven supplemented the paper by a speech of some length in general support of Mr. Darwin's hypothesis, but not of its treatment by Mr. Sanders, and by the exhibition of a series of microscopic anathomical preparations in illustration of his remarks. The discussion was further sustained by Dr. Langdon Down, Rev. Dunbar Heath, Mr. Dendy, Dr. Ellis, M. Robert Des Ruffières, Mr. George St. Clair, the Chairman, and others.

Mr. George C. Thompson contributed a note on "Consanguineous Marriages," urging upon the Society an investigation into the following questions:—1. When the defects commonly attributed to relationship of the parents are exhibited, are the germs of these defects traceable in the parents or their families? 2. When the medical pedigree of the parents is faultless are the children sound and healthy? 3. When any particular excellence occurs in the parents' family, is it transmitted to the children in increased force? Dr. Langdon Down said that after an examination of some five thousand cases of interbreeding he had arrived at the conclusion that the practice was not only not necessarily injurious, but that a methodical and judicious selection in the marriage of close relations would be of enormous value to the community in the improved race of men that would by that means be obtained. Captain Blair cited in support of that view the case of a people on the Ganges, while other speakers adduced conflicting evidence.

London Mathematical Society, April 14.—Prof. H. J. S. Smith, V.P., in the chair. The Chairman made some remarks on a problem in kinematics; Mr. Cotterill communicated some propositions bearing on residuals and former papers of his own read before the society; Mr. Crofton drew attention to a locus in Cartesian ovals; Mr. Jenkins gave a geometrical construction for showing the spherical excess of a triangle; and the chairman mentioned some focal properties of skew surfaces to which he had been led.

Palæontographical Society, April 8.—Annual general meeting; Dr. J. S. Bowerbank, F.R.S., in the chair.—The Council reported that the Society was in a most prosperous condition; that the volume for the present year was in progress, and would be published in the autumn; that new monographs by Mr. Carruthers, on the Fossil Cycades, by Dr. Lycett on the Fossil Tregoniæ, and by Prof. Owen on the Purbeck Mammalia, were in preparation. It was added that Mr. H. Woodward would continue the Monograph on the Trilobites, left unfinished through the death of Mr. Salter, and that Mr. Wood would issue a supplement to the Crag Mollusca. The ballot for the council and officers was taken, and the following gentlemen were elected. President, Dr. S. J. Bowerbank. Vice-Presidents: Prof. Bell, C. Darwin, T. Davidson, and Prof. Owen. Council: Prof. Ansted, Dr. J. J. Bigsby, W. Boyd Dawkins, Prof. Duncan, Sir P. Egerton, Bart., J. W. Flower, R. Hudson, J. W. Ilott, J. Gwyn Jeffreys, H. Lee, Sir C. Lyell, Bart., J. Pickering, J. Prestwich (Pres. Geol. Soc.), Prof. Tennant, C. Tyler, H. Woodward. Treasurer, Searles Wood; Honorary Secretary, Rev. T. Wiltshire.

EDINBURGH

Royal Society, April 18.—"On Change of Apparent Colour by Obliquity of Vision." By Robert H. Bow, C.E., Edinburgh. Mr. Bow observed the peculiarity of chromatic vision in the month of January, when experimenting upon the perfection of definition at different parts of the retina. Coloured objects seen obliquely undergo two changes: first, they become less obviously coloured,—this is particularly the case with greens, yellows, and oranges; and secondly, the colour becomes altered in character, most strikingly so in the cases of pinks, purples, and scarlets; pinks and purples become blue, and a brilliant scarlet (such as given by biniodide of mercury fixed with gum arabic) becomes successively orange and yellow, according to the degree of obliquity. The phenomena are most satisfactorily produced when the coloured objects are held on the nasal side of the observing eye. The author speculates on the influence this discovery may have upon the theories of colour sensation, and upon our knowledge of the nature of colour-blindness and the anatomy of the retina.

PARIS

Academy of Sciences, April 18.—A memoir by M. Moutard, entitled "Researches upon the Equations with partial derivatives of the second order, with two independent variables," was communicated by M. Bertrand.—M. Boileau presented a memoir on the determination of the latent work in systems, with uniform or uniformly periodical movements.—M. G. A. Hirn communicated a second note on the specific heat of water towards its maximum of density.—A note by M. Croullebois on the variations of the index of refraction of water with temperature, was presented by M. Balard. Upon this subject the author had come to a conclusion directly opposite to those of Arago and M. Jamin, and maintained that the index of refraction attains its maximum at the maximum density of water (4° C = 39° 1 F.) and decreases both above and below that temperature. He described the apparatus employed by him.—M. L. Sonrel communicated a note on the Aurora Borealis of the 5th April, of which he described the appearance and the various phenomena accompanying it. The Aurora only became visible in the evening, but it was then decreasing in intensity; it was visible over the greater part of Europe, and everywhere presented the same characters. It was accompanied by a strong and disagreeable odour, which was noticed both in France and Germany. Magnetic perturbations were observed both on the 4th and 5th of April.—M.

Delaunay presented some remarks upon M. Flammarion's note on the law of the rotatory movement of the planets, by M. G. Quesneville. The author maintained that M. Flammarion's numbers were incorrect.—A note on the spectrum-analysis of a solar spot, by M. G. Rayet, was also communicated by M. Delaunay. The author stated that while observing the spectrum of an immense spot in the south-west region of the solar disc, he saw the line C become luminous in the portion answering to the nucleus.—The greater number of the papers presented to the meeting were on chemical subjects. M. Descloiseaux presented a note on the clinorhombic form of the red oxide of mercury.—M. H. Sainte-Claire Deville indicated some experiments which he is now completing, upon the decomposition of aqueous vapour by iron. The phenomena, according to him, resemble in some important points, the mechanical phenomena of vaporisation and condensation; that is to say, they favour hygrometric laws.—M. J. P. Prat presented some experimental researches upon gold and its compounds. The author described the formation of a spongy gold by the addition of bicarbonate of potash to a solution of sesquichloride or gold, adding oxalic acid to the filtrate, and boiling it for two minutes. The spongy gold, heated with a combination of sulphuric and iodic acids, is entirely oxydised; the product dissolves in forming nitric acid. The solution, when diluted and heated, gives a precipitate of protosulphate of gold. The author noticed further the chlorides, iodides, and oxides of gold, two of the latter being new compounds ($Au^2\ O^2$ and $Au\ O^2$). A current of chlorine passed over a heated chloride of gold may produce a volatile chlorine superior to the sesquichloride.—M. H. Debray communicated a note on the assay of silver containing mercury. After noticing and explaining the process of Levol for effecting this assay in the humid way, the author described the method adopted by him, which consisted in heating a small portion of the silver, known to contain mercury, in a small crucible of gas charcoal for about a quarter of an hour, when the mercury is driven off and the silver remains as a button.—M. Balard presented a note by M. E. Reboul, on the hydriodates and hydrochlorates of monobrominated æthylene and propylene. —In a note on black phosphorus, M. Blondlot stated that after many unsuccessful trials by Thenard's method, he had prepared this substance by distilling phosphorus, or heating it to 212° F. under water in contact with mercury. Its colour is due to a multitude of black points, which disappear when the substance is fused and reappear on its cooling. At first the black phosphorus thus prepared, contained a trace of mercury, but after several distillations this disappeared, although the coloration was retained. The black material is more volatile than ordinary phosphorus, of which the author believed it to be an allotropic form.—M. Boussingault communicated a note by M. Musculus, on a dextrine insoluble in cold water, prepared by treating starch with crystallisable acetic acid. The author considered their insolubility of this dextrine to be due to its retaining the organisation of the starch grains. He described its characters and behaviour under various circumstances.—M. L. Henry presented two important memoirs, one on the chloronitric and bromonitric æthers of glycerine; the other, on the direct combination of allylic compounds with chloride of iodine and hypochlorous acid. In the former paper he described the action of nitric acid upon the halogenated æthers of glycerine, and especially the compounds *dichloromononitrine* (C^3H^5), Cl^2 (NO^3), and *monochlorodinitrine* (C^3H^5), Cl $(NO^3)^2$,.—M. A. Béchamp communicated a note on the formation of urea by the action of hypermanganate of potash upon albuminous matters, in which he maintained the correctness of his assertion that this reaction takes place, and described his mode of expeiimentation and the results of the analysis of his products.—M. P. Guyot communicated the results of his investigations into the toxical properties of some products of the phenic group—azuline and lydine.—M. J. Cloquet presented a note by M. L. Van Backer, containing a list of earthquake shocks and volcanic eruptions recorded as having taken place in the Dutch East Indies since the commencement of the sixteenth century. This list is derived from Junghuhn's "History of volcanoes."—M. H. Baillon made some observations on the crests of ice which have been noticed on the stems of plants, and stated that this phenomenon was a purely physical one, and had nothing to do with the life of the plant.—According to M. Guérin-Méneville, the parasitic insect, called *uji* or *oudji*, which attacks the silkworms in Japan, is a Dipterous fly, like the Chinese one noticed by M. Castellani, and the French fly which has transferred its attentions to the *Cynthia*-silkworm. M. Guérin names the parasite *Tachina oudji*.—M. N. Joly, in a letter to M. Dumas, noticed the occurrence of a distinct rotation of the embryos in the eggs of the axolot.—Dr. Pettigrew, presented some observations on the flight of Insects, with reference to M. Marey's communications on this subject. Dr. Pettigrew claims the priority in determining that the wings of insects in movement describe a figure of 8.—M. Andral, presented a note on the temperature of new-born infants; M. Moyret proposed the employment of perchloride of iron for the purification of the air evacuated from hospitals; and M. Namias forwarded some remarks upon the employment of bromide of potassium as a medicine, in reply to which M. Balard, made some observations, reccommending the use of bromide of sodium. Of the following communications the titles only are given:—A note on cholera by M. Levery; a note on the movement of liquids by M. d'Estoquois; and a note on vapour in a state of saturation, by M. Leloup.

VIENNA

Imperial Academy of Sciences, March 17.—A memoir was communicated by Professor V. Graber "On the resemblance of the structure of the female external sexual organs in the Locustidæ and Acrydii from the point of view of their developmental history." The author stated that in these two families of saltatorial orthopterous insects the external sexual organs of the females are exactly similar in number, form, and position in their original condition when the young animals leave the egg, and that it is only by changes taking place during development that the great differences observable in the mature insects are brought about. These developmental changes were described by the author in detail.

March 24.—Professor J. Stefan presented a preliminary communication "On a new experimental method of analysing the movement of sounding columns of air," by Professors A. Toepler and L. Boltzmann; and also a paper by himself "On the excitation of longitudinal vibrations by transverse ones."—Dr. S. Stern communicated a memoir "On the resonance of air in free space, as a contribution to the theory of sound."—Dr. A. Boué spoke upon the accumulation of erratic blocks in the sedimentary rocks, and in tertiary sandstones or conglomerates. He discussed the various hypotheses which have been put forward to account for these phenomena, which occur in various formations from the older carboniferous sandstones to the most recent beds. For the Eocene and Miocene rocks the author adopted the theory of their having been floated by ice; he also opposed the notions of those geologists who ascribe the excavation of lake-basins to the action of glaciers and assume the existence of glaciers at all geological periods.—A memoir was communicated by Professor Brücke "On the physiological significance of the partial decomposition of fat in the small intestine."

PHILADELPHIA

American Philosophical Society, March 4.—"On the Periods of Certain Meteoric Rings." By Daniel Kirkwood.

I. The Meteors of April 20. In the *Astronomische Nachrichten*, No. 1632, Dr. Weiss called attention to the fact that the orbit of the first comet of 1861 very nearly intersects that of the earth, in longitude 210°; the point passed by the latter at the epoch of the April meteoric shower. A relation between the meteors and the comet, similar to that recently detected between the November meteors and the comet of 1866, was thus suggested as probable. Is this hypothesis in harmony with facts? and if not, are our present data sufficient for determining with any reasonable probability the true period of the April meteors?

Dates of the April Shower.—Prof. Newton selects the following from Quetelet's catalogue as belonging to this period:*

1.	B. C. 687,	4.	A. D.	1093,	'4 '5, and '6
2.	,, 15,	5.	,,	1122,	'3
3.	A. D. 582,	6.	,,	1803,	

Period of the first Comet of 1861.—The elements of this body were computed by Oppolzer, who assigned it a period of 415 y. 4. Now, while it is true that the interval from B. C. 687 to A. D. 1803, is very nearly equal to six periods of 415 years, the slightest examination will show that this period does not harmonise with *any of the intermediate dates*. This fact, then, without further discussion, seems fatal to the hypothesis that the period of the meteors is nearly equal to that of the comet.

* Silliman's Journal for July, 1863.

What is the probable period of the ring?—The showers of 1093-6 and 1122-3 at once suggest a period of from 26 to 30 years. The nodal passage of the densest portion of the ring at the former epoch may be placed anywhere between 1093 and 1096, and that of the latter, in either 1122 or 1123. The entire interval from B. C. 687 to A. D. 1803 is 2490 years, or 88 periods of 28 y. 295 each; and the known dates are all satisfied by the following scheme:—

B.C. 687 to B.C. 15	672.000 yrs.	=24	periods of	28.000	each.
15 to A.D. 582	597.000 ,,	=21	,,	28.429	,,
A.D 582 to 1093.714	511.714 ,,	=18	,,	28.429	,,
1093.714 to 1122.143	28.429 ,,	= 1	,,	28.429	,,
1122.143 to 1803	680.857 ,,	=24	,,	28.369	,,

These coincidences indicate a period of about $28\frac{1}{3}$* years, corresponding to an ellipse whose major axis is 18.59. Hence the distance of the aphelion is very nearly equal to the mean distance of Uranus. It will also be observed that the time of revolution, which seems to have been somewhat lengthened about the Christian era, was previously one-third of the period of Uranus.

II. The Meteors of December 11-13.

In the catalogue of Quetelet we find the four following extraordinary displays which belong undoubtedly to this period. Observations made in England, 1862, indicate also a more than ordinary number of meteors at the December epoch in that year.

1. A.D. 901. "The whole hemisphere was filled with those meteors called falling stars, the ninth of Dhu'lhajja (288th year of the Hegira) from midnight till morning, to the great surprise of the beholders, in Egypt."—*Modern part of the Universal History*, 8vo. vol. 2, p. 81. Lond. 1780. The date of this phenomenon corresponds to the December epoch, A.D. 901.

2. 930. "Averse remarquable d'ètoiles filantes en Chine."

3. 1571. "On vit à Zurich 'du feu tomber du ciel.'"

4. 1830, 1833, and 1836. The maximum seems to have occurred in 1833, when as many as ten meteors were seen simultaneously. "Dans la nuit du 14 au 12 décembre, on vit, à Parme une grande quantité d'étoiles filantes de différentes grandeurs, qui se dirigeaient presque toutes avec une grande vitesse vers le SSE. A 10 heures et ¼, entre les seules constellations du Bélier et du Taureau, on en compta environ une dizaine."

5. (Doubtful.) 1861, 1862, and 1863. Maximum probably in 1862. The meteors at this return were far from being comparable in numbers with the ancient displays. The shower, however, was distinctly observed. R. P. Grey, Esq., of Manchester, England, says the period for December 10-12 was, in 1862, "exceedingly well defined."†

These dates indicate a period of about $29\frac{1}{8}$ years. Thus:—

901 to 930	1	period of 29.000 years.
930 to 1571	22	periods of 29.136 years.
1571 to 1833	9	periods of 29.111 years.
1833 to 1862	1	period of 29.000 years.

III. The Meteors of October 15-21.

The showers of the following years (see Quetelet's Catalogue) belong to this epoch:—

1. 288. "Apparition en Chine."

2. 1436 and 1439. In each year a remarkable apparition was observed in China.

3. 1743. (Quoted from Herrick, in Silliman's Journal for April 1841.) "A clear night, great shooting of stars between 9 and 10 o'clock, all shot from S.W. to N.E. [*Qu.* N.E. to S.W. ?] One like a comet in the meridian very large, and like fire, with a long broad train after it, which lasted several minutes; after that was a train like a row of thick small stars for twenty minutes together, which dipt N."

4. 1798. "Brandès marque, à Goettingue, un grand nombre d'étoiles filantes dans les observations simultanèes qu' il fait avec Benzenberg."

These dates indicate a period of about $27\frac{1}{2}$ years:—

288 to 1439	42 periods of	27.405 years each.
1439 to 1743	11 ,,	27.636 ,,
1743 to 1798	2 ,,	27.500 ,,

If these periods are correct, it is a remarkable coincidence that the aphelion distances of the meteoric rings of April 18th—20th, October 15th—21st, November 14th, and December 11th—13th, as well as those of the comets 1866 I, and 1867 I, are all nearly equal to the mean distance of Uranus.

* Herrick assigned a value of 27 years. See Silliman's Journal for April 1841, p. 365.

† Silliman's Journal for May, 1863, p. 461.

DIARY

THURSDAY, April 28.

Royal Society, at 8.30.—On the organs of Vision in the Common Mole: Dr. R. J. Lee.—On an Aplanatic Searcher applied to Microscopes: Dr. Royston Pigott.—On a cause of error in Electroscopic Experiments: Sir Chas. Wheatstone.

Zoological Society, at 8.30.—Notes on a North-American Batrachian (*Spelerpes rubra*): Mr. St. George Mivart.—Notes on some points in the anatomy of certain Kingfishers: Dr. Cunningham.—On a new gigantic Amphibian, allied to *Lepidosiren* from Queensland:—Mr. G. Krefft.

Royal Institution, at 3.—Electricity: Prof. Tyndall.

FRIDAY, April 29.

Royal Institution, at 8.—Popular Myths: Prof. Blackie.

Zoological Society, at 1.—Anniversary Meeting.

SATURDAY, April 30.

Royal Institution, at 3.—Comets: Prof. Grant.

MONDAY May 2.

Entomological Society, at 7.

Society of Arts, at 8.—Cantor Lecture on Fermentation: Prof. A. W. Williamson.

Royal Asiatic, at 3.

Royal Institution, at 2.—Annual Meeting.

TUESDAY, May 3.

Anthropological Society, at 8.—The Aboriginal Tribes of the Nilgiri Hills: Major Ross-King.—The Armenians of Southern India: Dr. John Shortt.—The Kajahs of Southern India: Dr. John Shortt.

Royal Institution, at 3.—Moral Philosophy:—Prof. Blackie.

THURSDAY, May 5.

Royal Society, at 8.30.

Society of Antiquaries, at 8.30.

Chemical Society, at 8.—Vapour Densities: J. T. Brown.—New Cornish Minerals, No. 7: Prof. Church.

Royal Institution, at 3.—Electricity: Prof. Tyndall.

Linnean Society, at 8.

BOOKS RECEIVED.

English.—On Natural Selection: A. R. Wallace (Macmillan and Co.).—Sketches of Creation, illustrated by Prof. Winchell: (S. Low, Son, and Co.)—The Population of an Old Pear Tree, translated from the French of E. Van Bruyssel (Macmillan and Co.).—Records of the Geological Survey of India. Vol. I., parts 1, 2, 3; vol. II., part 1.—Contributions to Botany: J. Miers; vol. 2 (Williams and Norgate).—Symons's Monthly Meteorological Magazine; vol. for 1869.—Trees and Shrubs for English Plantations: A. Mongredien (Murray).

Foreign (through Williams and Norgate).—Die Schule der Chimie: Dr. J. A. Stöckardt.—Der Elektromagnetische Telegraph: Dr. H. Schellen.—Le Darwinisme et les générations spontanées: D. C. Rossi.—Catalogus Musei Botanici Lugduno-Batavi: Prof. Miguel.—Verzeichniss von 4793 teleskopischen Sternen: Dr. J. V. Lamont.—Annalen der königlichen Sternwarte; vol. 17.—Der rationelle Wiesenbau: L. Vincent.—Die fünf Sinne des Menschen: W. Preyer.—Zeitschrift für die gesammten Naturwissenchaften; vols. 33, 34: Drs. Giebert und Siewert.—Handbuch der Mathematik: Physik, Geodäsie und Astronomie: Dr. A. Wolf.—Die Erfindung des Fernrohrs und ihre Folgen für die Astronomie.—De la Reforme de l'enseignement supérieur et des libertés Universitaires: C. Schützenberger.—Mémoires de la société royale des Sciences de Liége; vols. 1, 2.

CONTENTS

Errata.—In No. 24, page 630, second column, line 10: for "Acalephic" read "Acalephæ."—Page 635, column 1, line 5 from bottom, for "Von Martins," read "Von Martius; and column 2, line 4: for "Martins," read "Martius."

Printed by R. CLAY, SONS, & TAYLOR, at 7 and 8, Bread Street Hill, in the City of London, and published by MACMILLAN & Co. at the Office, 63, Bleecker Street, New York.—THURSDAY, April 28, 1870
